IMPLICATIONS FOR NURSING: Nurses should consider using cognitive-behavioral interventions with breathing exercises for those who are depressed to improve their mood and reduce their depressive symptoms.

Wellness Challenges

Depression robs the individual of energy to carry out simple activities. Previous wellness activities from physical activities, nutrition, and stress management often disappear during depression. The side effects of the antidepressants may actually interfere with normal wellness activities. The nurse should work with the individual to re-establish these activities. The individual may not feel like doing anything, but through the nurse–patient relationship, the nurse should seek commitment to gradually incorporate wellness activities. See [Chapter 1](#) and [Box 25.4](#).

Medication Interventions

Antidepressant medications have proved effective in all forms of major depression. To date, controlled trials have shown no single antidepressant drug to have greater efficacy in the treatment of major depressive disorder. See 12 for a list of antidepressant medications, usual dosage range, half-life, and therapeutic blood levels.

An antidepressant is selected based primarily on an individual patient's target symptoms; genetic factors; responses related to cultural, racial, and ethnic influences; and a pharmacologic agent's side-effect profile. Other factors that may influence choice include prior medication response, drug interactions and contraindications, concurrent medical and psychiatric disorders, patient age, and cost of medication. Selecting medications on the basis of pharmacogenetic properties improves symptom remission (Bousman et al., 2019).

BOX 25.4

Wellness Challenges

- Coping effectively with lack of energy and sadness
 - Strategies: Start with the easiest—take a walk after dinner; talk to a friend.
- Stress management.
 - Strategies: Say “no” to being a perfectionist; consider a massage; meditation.
- Decreasing feelings of worthlessness.
 - Strategies: Keep a list of accomplishments, help others; keep busy.
- Understanding the stigma of depression.
 - Strategies: Educate yourself and others about depression; join a support group.
- Recognizing the need for physical activity, healthy foods, and sleep.
 - Strategies: Track physical activity, diet, and sleep in a journal.
- Developing a sense of connection, belonging, and a support system.
 - Strategies: Contact at least one friend, attend religious service.
- Expanding a sense of purpose and meaning in life
 - Strategies: Pray, meditate, help others, volunteer.

The newer antidepressants, selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and the norepinephrine dopamine reuptake inhibitor (NDRI) are used most often because these drugs selectively target the neurotransmitters and receptors thought to be associated with depression and minimize side effects. See [Box 25.5](#). Individualizing dosages is usually done by fine-tuning medication dosage based on patient

feedback. The tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) are being used less often than the other agents. See [Box 25.6](#).> Given their dietary restrictions, MAOIs usually are reserved for patients whose depression fails to respond to other antidepressants or patients who cannot tolerate typical antidepressants.

NCLEXNOTE Patients may be reluctant to take prescribed antidepressant medications or may self-treat depression based on their cultural beliefs and values (Jung et al., 2020). A culturally competent nursing care and teaching plan needs to address the importance for adherence to a medication regimen and emphasize any potential drug–drug interactions.

Administering Medications

Antidepressants are available in oral form and should be taken as prescribed (see [Box 25.7](#)). Even after the first episode of major depression, medication should be continued for at least 6 months to 1 year after the patient achieves complete remission of symptoms. If the patient experiences a recurrence after tapering the first course of treatment, the regimen should be reinstituted for at least another year, and if the illness reoccurs, medication should be continued indefinitely (Schatzberg & DeBattista, 2019).

Monitoring Medications

Patients should be carefully observed for therapeutic and side effects of the antidepressants. In the depths of depression, saving medication for a later suicide attempt is quite common. During antidepressant treatment, the nurse should monitor and document vital signs, plasma drug levels (as appropriate), liver and thyroid function tests, complete blood counts, and blood chemistry to make sure that patients are receiving a therapeutic dosage and are adherent to the prescribed regimen. Results of these tests also help evaluate for toxicity (see [Chapter 11](#) for therapeutic blood levels).

Baseline orthostatic vital signs should be obtained before initiation of any medication, and in the case of medications known to have an impact on vital signs, such as TCAs, MAOIs, or SNRIs, they should be monitored on a regular

basis. If these medications are administered to children or older adults, the dosage should be lowered to accommodate the physiologic state of the individual.

BOX 25.5

Drug Profile: Escitalopram Oxalate (LEXAPRO)

DRUG CLASS: Antidepressant

RECEPTOR AFFINITY: A highly SSRI with low affinity for 5-HT 1–7 or α - and β -adrenergic, dopamine D_{1–5}, histamine H_{1–3}, muscarinic M_{1–5}, and benzodiazepine receptors or for Na⁺, K⁺, Cl⁻, and Ca⁺⁺ ion channels that have been associated with various anticholinergic, sedative, and cardiovascular side effects.

INDICATIONS: Treatment of major depressive disorder, generalized anxiety disorder

ROUTES AND DOSAGES: Available as 5-, 10-, and 20-mg oral tablets

Adults: Initially 10 mg once a day. May increase to 20 mg after a minimum of 1 week. Trials have not shown greater benefit at the 20-mg dose.

Geriatric: 10-mg dose is recommended. Adjust dosage related to the drug's longer half-life and the slower liver metabolism of older adult patients.

Renal Impairment: No dosage adjustment is necessary for mild-to-moderate renal impairment.

Children: Safety and efficacy have not been established in this population.

HALF LIFE (PEAK EFFECT): 27 to 32 hours (4–7 hours)

SELECTED ADVERSE REACTIONS: Most common adverse events include insomnia, ejaculation disorder, diarrhea, nausea, fatigue, increased sweating, dry mouth, somnolence, dizziness, and constipation. Most serious adverse events include ejaculation disorder in men; fetal abnormalities and decreased fetal weight in pregnant patients; and serotonin syndrome if coadministered with MAOIs, St. John wort, or SSRIs, including citalopram (Celexa), of which escitalopram (Lexapro) is the active isomer.

BOXED WARNING: Suicidality in children, adolescents, and young adults

WARNING: There is potential for interaction with MAOIs. Lexapro should not be used in combination with an MAOI or within 14 days of discontinuing an MAOI.

Specific Patient and Family Education

- Do not take in combination with citalopram (Celexa) or other SSRIs or MAOIs. A 2-week washout period between escitalopram and SSRIs or MAOIs is recommended to avoid serotonin syndrome.
- Families and caregivers should be advised of the need for close observation and communication with

the prescriber.

- Notify your prescriber if pregnancy is possible or being planned. Do not breast-feed while taking this medication.
- Use caution driving or operating machinery until you are certain that escitalopram does not alter your physical abilities or mental alertness.
- Notify your prescriber of any OTC medications, herbal supplements, and home remedies being used in combination with escitalopram.
- Ingestion of alcohol in combination with escitalopram is not recommended, although escitalopram does not seem to potentiate mental and motor impairments associated with alcohol.
- MAOI, monoamine oxidase inhibitor; OTC, over-the-counter; SSRI, selective serotonin reuptake inhibitor.
- http://www.accessdata.fda.gov/drugsatfda_docs/label/2014/021323s044,021365s032lbl.pdf

Managing Side Effects

Many people stop taking the prescribed antidepressants because of the side effects. (See [Box 25.8](#).) Ideally, side effects are minimal and can be alleviated by nonpharmacologic interventions. For example, if patient is having difficulty going to sleep, avoiding caffeinated products may help ([Table 25.1](#)). SSRIs tend to be safer and have fewer side effects than the older medications. The most common reason individuals stop taking their SSRIs are gastrointestinal side effects, including diarrhea, cramping, and heartburn. The most common side effects associated with TCAs are the antihistaminic side effects (e.g., sedation weight gain) and anticholinergic side effects (potentiation of CNS drugs, blurred vision, dry mouth, constipation, urinary retention, sinus tachycardia, and decreased memory).

For the MAOIs, the most common side effects are headache, drowsiness, dry mouth and throat, constipation, blurred vision, and orthostatic hypotension. Additional selected adverse effects of MAOIs include insomnia, nausea, agitation, dizziness, asthenia, weight loss, and postural hypotension. Although priapism was not reported during clinical trials, the MAOIs are structurally similar to trazodone, which has been associated with priapism (prolonged painful erection). For those taking MAOIs, close attention to dietary restrictions should be given. See [Chapter 12](#) for tyramine-restricted diets.

EMERGENCY CARE ALERT ! If coadministered with food or other substances containing tyramine (e.g., aged cheese, beer, red wine), MAOIs can trigger a hypertensive crisis that may be life threatening. Symptoms include a sudden, severe pounding, or explosive headache in the back of the head or

temples, racing pulse, flushing, stiff neck, chest pain, nausea and vomiting, and profuse sweating.

BOX 25.6

Drug Profile: Mirtazapine (Remeron)

DRUG CLASS: Antidepressant

RECEPTOR AFFINITY: Believed to enhance central noradrenergic and serotonergic activity antagonizing central presynaptic α_2 -adrenergic receptors. Mechanism of action is unknown.

INDICATIONS: Treatment of depression

ROUTES AND DOSAGE: Available as 15- and 30-mg tablets

Adults: Initially, 15 mg/day as a single dose preferably in the evening before sleeping. Maximum dosage is 45 mg/day.

Geriatric: Use with caution; reduced dosage may be needed.

Children: Safety and efficacy have not been established.

HALF-LIFE (PEAK EFFECT): 20 to 40 hours (2 hours)

SELECTED ADVERSE REACTIONS: Somnolence, increased appetite, dizziness, weight gain, elevated cholesterol or triglyceride and transaminase levels, malaise, abdominal pain, hypertension, vasodilation, vomiting, anorexia, thirst, myasthenia, arthralgia, hypoesthesia, apathy, depression, vertigo, twitching, agitation, anxiety, amnesia, increased cough, sinusitis, pruritus, rash, urinary tract infection, mania (rare), agranulocytosis (rare)

BOXED WARNING: Suicidality in children, adolescents, and young adults

WARNING: Contraindicated in patients with known hypersensitivity. Use with caution in older adults, patients who are breast-feeding, and patients with impaired hepatic function. Avoid concomitant use with alcohol or diazepam, which can cause additive impairment of cognitive and motor skills.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Take the dose once a day in the evening before sleep.
- Families and caregivers should be advised of the need for dose observation and communication with the prescriber.
- Avoid driving and performing other tasks requiring alertness.
- Notify your prescriber before taking any OTC or other prescription drugs.
- Avoid alcohol and other CNS depressants.
- Notify your prescriber if pregnancy is possible or planned.
- Monitor temperature and report any fever, lethargy, weakness, sore throat, malaise, or other “flu-like” symptoms.

- Maintain medical follow-up, including any appointments for blood counts and liver studies.

CNS, central nervous system; OTC, over-the-counter.

BOX 25.7

Guidelines for Administering and Monitoring Antidepressant Medications

Nurses should do the following in administering and monitoring antidepressant medications:

- Observe the patient for cheeking or saving medications for a later suicide attempt.
- Monitor vital signs (such as orthostatic vital signs and temperature): obtain baseline data before the initiation of medications.
- Monitor periodically results of liver and thyroid function tests, blood chemistry, and complete blood count as appropriate and compare with baseline values.
- Monitor the patient symptoms for therapeutic response and report inadequate response to prescriber.
- Monitor the patient for side effects and report to the prescriber serious side effects or those that are chronic and problematic for the patient. (Table 25.1 indicates pharmacologic and nonpharmacologic interventions for common side effects.)
- Monitor drug levels as appropriate. (Therapeutic drug levels for antidepressants are listed in Chapter 12.)
- Monitor dietary intake as appropriate, especially with regard to MAOI antidepressants.
- Inquire about patient use of other medications, alcohol, “street” drugs, OTC medications, and herbal supplements that might alter the desired effects of prescribed antidepressants.

MAOI, monoamine oxidase inhibitor; OTC, over-the-counter.

MANAGEMENT OF COMPLICATIONS

Suicidality

Suicidality is mentioned in a “black box” warning on all antidepressants, indicating an increased risk of suicide exists in children, adolescents, and young adults with major depressive or other psychiatric disorders. After the age of 24 years, the suicidality risk does not increase and after 65, the risk of suicide actually decreases when taking an antidepressant. The SSRIs are the least lethal of the antidepressants, but fatalities have been reported (Schatzberg & DeBattista, 2019).

EMERGENCY CARE ALERT ! If possible, TCAs should not be prescribed for patients at risk for suicide. Lethal doses of TCAs are only three to five times the therapeutic dose, and more than 1 g of a TCA is often toxic and may be fatal.

Death may result from cardiac arrhythmia, hypotension, or uncontrollable seizures.

Serum TCA levels should be evaluated when overdose is suspected. In acute overdose, almost all symptoms develop within 12 hours. Anticholinergic effects are prominent and include dry mucous membranes, warm and dry skin, blurred vision, decreased bowel motility, and urinary retention. CNS suppression (ranging from drowsiness to coma) or an agitated delirium may occur. Basic overdose treatment includes induction of emesis, gastric lavage, and cardiorespiratory supportive care.

BOX 25.8

Antidepressants and Common Side Effects in Treating Depression

Medications

Common Side Effects

Selective Serotonin Reuptake Inhibitors (SSRIs)

Fluoxetine (Prozac)	Gastrointestinal distress
Sertraline (Zoloft)	Sedation
Paroxetine (Paxil)	Anticholinergic effects
Fluvoxamine (Luvox)	Weight gain or loss in some people
Citalopram (Celexa)	Sexual dysfunction
Escitalopram (Lexapro)	Dizziness
	Diaphoresis

Serotonin Norepinephrine Reuptake Inhibitors (SNRIs)

Desvenlafaxine (Pristiq extended release)	Gastrointestinal distress
Duloxetine (Cymbalta)	Anticholinergic effects
Levomilnacipran (Fetzima)	Insomnia or sedation
Venlafaxine (Effexor XR)	Decreased appetite
	Sexual dysfunction
	Abnormal dreams
	Dizziness
	Jitteriness
	Hypertension
	Irritability
	Photosensitivity

Norepinephrine Dopamine Reuptake Inhibitor (NDRI)

Bupropion (Wellbutrin)	Anticholinergic effects
	Headache
	Agitation
	Gastrointestinal distress
	Insomnia
	Anorexia
	Anxiety
	Weight loss
	Diarrhea and flatulence

Alpha 2 Antagonist

Mirtazapine (Remeron)

Sedation
Anticholinergic effects
Appetite increase
Weight gain
Hypercholesterolemia
Weakness and lack of energy
Dizziness
Hypertriglyceridemia

Other Antidepressants

Trazadone (Oleptro)

Sedation
Anticholinergic effects
Headache
Dizziness
Nausea/vomiting

Vilazodone (Viibryd)

Diarrhea
Nausea
Dizziness
Dry mouth
Insomnia
Abnormal dreams

Vortioxetine (Brintellix)

Nausea
Diarrhea
Dizziness
Dry mouth
Constipation
Vomiting

Tricyclic Antidepressants

Amitriptyline

Amoxapine

Clomipramine (Anafranil)

Imipramine (Torfanil)

Desipramine (Norpramin)

Doxepin

Nortriptyline (Aventyl, Pamelor)

Protriptyline (Vivactil)

Drowsiness
Anticholinergic effects
Orthostatic hypotension
Palpitations
Tachycardia
Impaired coordination
Increased appetite
Diaphoresis
Weakness
Disorientation
Sexual side effects (impotence, changes in libido)

Tetracyclic Antidepressants

Maprotiline

Blurred vision
Dizziness
Lightheadedness
Sedation
Dry mouth
Libido changes
Impotence
Weight changes

Monoamine Oxidase Inhibitors

Isocarboxazid (Marplan)

Dizziness
Headache
Nausea

Phenelzine (Nardil)	Dry mouth
	Constipation
	Drowsiness
	Sleep disturbance
	Orthostatic hypotension
	Orthostatic hypotension
	Edema
	Dizziness
	Headache
	Drowsiness
Tranlycypromine (Parnate)	Sleep disturbance
	Orthostatic hypotension
	Dizziness
	Headache
	Drowsiness
	Sleep disturbance
	Restlessness
Selegiline (Emsam)	Central nervous system stimulation
	Application site reaction
	Headache
	Insomnia
	Diarrhea
	Dry mouth
	Orthostatic hypotension
	Dyspepsia

MAOIs are more lethal in overdose than are the newer antidepressants and thus should be prescribed with caution if the patient's suicide potential is elevated (see [Chapter 12](#)). An MAOI generally is given in divided doses to minimize side effects.

Serotonin Syndrome

Serotonin syndrome is a potentially serious side effect caused by drug-induced excess of intrasynaptic serotonin, 5-hydroxytryptamine (5-HT) (see [Box 25.9](#)). First reported in the 1950s, it was relatively rare until the introduction of the SSRIs. Serotonin syndrome is most often reported in patients taking two or more medications that increase CNS serotonin levels by different mechanisms (Duignan et al., 2020). The most common drug combinations associated with serotonin syndrome involve the MAOIs, the SSRIs, and the TCAs.

Although serotonin syndrome can cause death, it is mild in most patients, who usually recover with supportive care alone. Unlike neuroleptic malignant

syndrome, which develops within 3 to 9 days after the introduction of neuroleptic medications (see [Chapter 24](#)), serotonin syndrome tends to develop within hours or days after starting or increasing the dose of serotonergic medication. Symptoms include altered mental status, autonomic dysfunction, and neuromuscular abnormalities. At least three of the following findings must be present for a diagnosis: mental status changes, agitation, myoclonus, hyperreflexia, fever, shivering, diaphoresis, ataxia, and diarrhea. In patients who also have peripheral vascular disease or atherosclerosis, severe vasospasm and hypertension may occur in the presence of elevated serotonin levels. In addition, in a patient who is a slow metabolizer of SSRIs, higher-than-normal levels of these antidepressants may circulate in the blood. Medications that are not usually considered serotonergic, such as dextromethorphan and meperidine have been associated with the syndrome (Dy et al., 2017).

BOX 25.9

Serotonin Syndrome

CAUSE: Excessive intrasynaptic serotonin

HOW IT HAPPENS: Combining medications that increase CNS serotonin levels, such as SSRIs + MAOIs; SSRIs + St. John wort; or SSRIs + diet pills; dextromethorphan or alcohol, especially red wine; or SSRI + street drugs, such as LSD, MDMA, or ecstasy

SYMPTOMS: Mental status changes, agitation, ataxia, myoclonus, hyperreflexia, fever, shivering, diaphoresis, diarrhea

TREATMENT

- Assess all medications, supplements, foods, and recreational drugs ingested to determine the offending substances.
- Discontinue any substances that may be causative factors. If symptoms are mild, treat supportively on an outpatient basis with propranolol and lorazepam and follow-up with the prescriber.
- If symptoms are moderate to severe, hospitalization may be needed with monitoring of vital signs and treatment with intravenous fluids, antipyretics, and cooling blankets.

FURTHER USE: Assess on a case-by-case basis and minimize risk factors for further medication therapy.

- CNS, central nervous system; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; MDMA, 3-methoxy-4,5-methylenedioxymphetamine; SSRI, selective serotonin reuptake inhibitor.

Emergency Care Alert ! The most important emergency interventions are

stopping use of the offending drug, notifying the prescriber, and providing necessary supportive care (e.g., intravenous fluids, antipyretics, cooling blanket). Severe symptoms have been successfully treated with antiserotonergic agents, such as cyproheptadine (Frye et al., 2020).

Monitoring for Drug Interactions

Several potential drug interactions are associated with antidepressants. Alcohol consumption should be avoided when taking any antidepressant because SSRIs are metabolized in the liver; other medications that are also metabolized by the same enzyme can cause an increase in drug levels leading to toxicity and serotonin syndrome. For example, if migraine medications known as “triptans” are given with the SSRIs, serotonin syndrome can occur. Bupropion cannot be given at the same time as an MAOI. Grapefruit should not be consumed while taking trazodone. It is beyond the scope of this text to review drug–drug interactions in detail. Nurses should check with pharmacy resources for any drug–drug interactions when administering medications.

Teaching Points

If depression goes untreated or is inadequately treated, episodes can become more frequent, more severe, longer in duration, and can lead to suicide. Patient education involves explaining this pattern and the importance of continuing medication use after the acute phase of treatment to decrease the risk for future episodes. Patient concerns regarding long-term antidepressant therapy need to be assessed and addressed. All teaching points need to be developed and delivered using a culturally competent approach to enhance patient adherence.

Patients should also be advised not to take herbal substances such as St. John wort or SAMe if they are also taking prescribed antidepressants. St. John wort should also not be taken if the patient is taking nasal decongestants, hay fever, and asthma medications containing monoamines, amino acid supplements containing phenylalanine, or tyrosine. The combination may cause hypertension.

Other Somatic Therapies

Electroconvulsive Therapy

Although its therapeutic mechanism of action is unknown, ECT is an effective treatment for patients with severe depression. It is generally reserved for patients whose disorder is refractory or intolerant to initial drug treatments and who are so severely ill that rapid treatment is required (e.g., patients with malnutrition, catatonia, or suicidality).

ECT is contraindicated for patients with increased intracranial pressure. Other high-risk patients include those with recent myocardial infarction, recent cerebrovascular accident, retinal detachment, or pheochromocytoma (a tumor in the cells of the adrenal gland) and those at risk for complications of anesthesia. Older age has been associated with a favorable response to ECT, but the effectiveness and safety in this group have not been shown. Because depression can increase the mortality risk for older adults, in particular, and some older adults do not respond well to medication, effective treatment is especially important for this age group (Hermida et al., 2020).

The role of the nurse in the care of the patient undergoing ECT is to provide educational and emotional support for the patient and family, assess baseline or pretreatment levels of function, prepare the patient for the ECT process, monitor and evaluate the patient's response to ECT, provide assessment data with the ECT team, and modify treatment as needed (see [Chapter 12](#) for more information). The actual procedure, possible therapeutic mechanisms of action, potential adverse effects, contraindications, and nursing interventions are described in detail in [Chapter 12](#).

Light Therapy (Phototherapy)

Light therapy is described in [Chapter 12](#). Given current research, light therapy is an option for well-documented mild-to-moderate seasonal, nonpsychotic, winter depressive episodes in patients with recurrent major depressive disorders, including children and adolescents. Evidence also indicates that light therapy can be as effective as antidepressants (Geoffroy et al., 2019).

Repetitive Transcranial Magnetic Stimulation

In 2008, the U.S. Food and Drug Administration approved rTMS for the treatment of patients with mild treatment-resistant depression. In rTMS, a magnetic coil placed on the scalp at the site of the left motor cortex releases small electrical pulses that stimulate the site of the left dorsolateral prefrontal cortex in the superficial cortex. This rapidly changing magnetic field stimulates the brain sufficiently to depolarize neurons and exert effects across synapses. These pulses (similar in type and strength as a magnetic resonance imaging machine) easily pass through the hair, skin, and skull, requiring much less electricity than ECT. The patient is awake, reclining in an rTMS chair during the procedure, and can resume normal activities immediately after the procedure. Because anesthesia is not required, no risks are associated with sedation. Treatment of depression typically consists of 20 to 30 sessions, lasting 37 minutes each over 4 to 6 weeks. Depending on the level of practice and training, the nurse's role in the use of the rTMS varies from patient education, pre- and postprocedure care to performing the procedure (Sehatzadeh et al., 2019).

Psychosocial Interventions

Therapeutic Interactions

Individuals experiencing depression have often withdrawn from daily activities, such as engaging in family activities, attending work, and participating in community functions. During hospitalization, patients often withdraw to their rooms and refuse to participate in unit activity. Nurses help the patient balance the need for privacy with the need to return to normal social functioning. Even though depressed patients should not be approached in an overly enthusiastic manner, they should be encouraged to set realistic goals to reconnect with their families and communities. Explain to patients that attending social activities, even though they do not feel like it, will promote the recovery process and help them achieve their goals.

Enhancing Cognitive Functioning

Cognitive interventions such as thought stopping and positive self-talk can dispel irrational beliefs and distorted attitudes and, in turn, reduce depressive symptoms during the acute phase of major depression (see [Chapter 13](#)). Nurses should consider using cognitive approaches when caring for persons who are depressed. The use of cognitive interventions in the acute phase of treatment combined with medication is now considered first-line treatment for mildly to moderately depressed outpatients.

NCLEXNOTE A cognitive therapy approach is recommended for helping persons restructure the negative thinking processes related to a person's concept of self, others, and the future. This approach should be included in most nursing care plans for patients with depression.

Using Behavioral Interventions

Behavioral interventions are effective in the acute treatment of patients with mildly to moderately severe depression, especially when combined with pharmacotherapy. Therapeutic techniques include activity scheduling, social skills training, and problem solving. Behavioral therapy techniques are described in [Chapter 7](#).

Psychoeducation

Teaching about Symptoms

Patients with depression and their significant others often incorrectly believe that their illness is their own fault and that they should be able to “pull themselves up by their bootstraps and snap out of it.” Persons from some cultural groups believe that the symptoms of depression may be a result of someone placing a hex on the affected person because the person has done something evil. It is vital to be culturally competent to be effective in teaching patients and their families about the treatment modalities for depression.

Patients need to know the full range of suitable treatment options before consenting to participate in treatment. Information empowers patients to ask questions, weigh risks and benefits, and make the best treatment choices. The nurse can provide opportunities for patients to question, discuss, and explore their feelings about past, current, and planned use of medications and other treatments. Developing strategies to enhance adherence and to raise awareness of early signs of relapse can be important aids to increasing treatment efficacy and promoting recovery ([Box 25.10](#)).

Wellness Strategies

Teaching persons how to develop wellness goals and strategies is an evidence-based approach that psychiatric nurses can implement to build patients' recovery process (Anthony, 1993; Jacob, 2015). This teaching combines approaches that strengthen a person's clinical and emotional (i.e., biopsychosocial) functioning (Ohrnberger et al., 2017). The client and the psychiatric nurse set mutual goals that may focus on healthy eating, exercise, and cognitive-behavioral change (Roosenschoon et al., 2019). The psychiatric nurse can engage patients in role-playing in order to learn and practice social skills that can be used in their everyday interactions with other individuals.

BOX 25.10

Psychoeducation Checklist: Major Depressive Disorder

When caring for the patient with a major depressive disorder, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents, including drug action, dosing frequency, and possible side effects
- Risk factors for recurrence; signs of recurrence
- Adherence to therapy and treatment program
- Recovery strategies
- Nutrition
- Sleep measures
- Self-care management
- Goal setting and problem solving

- Social interaction skills
- Follow-up appointments
- Community support services

Providing Family Education

The family needs education and support during and after the treatment of family members. Because major depressive disorder is a recurring disorder, the family needs information about specific antecedents to a family member's depression and what therapeutic steps to take. For example, one patient may routinely become depressed during the fall of each year, with one of the first symptoms being excessive sleepiness. For another patient, a major loss, such as a child going to college or the death of a pet, may precipitate a depressive episode. Families of older adults need to be aware of the possibility of depression and related symptoms, which protect from self-harm (see [Chapter 22](#)). During the depths of depression, patients may not have the energy to complete a suicide. As patients begin to feel better and have increased energy, they therefore may be at a greater risk for suicide. If a previously depressed patient appears to have become energized overnight, they may have decided to commit suicide and thus may be relieved that the decision is finally made. The nurse may misinterpret the mood improvement as a positive move toward recovery; however, this patient may be very intent on suicide. These individuals should be carefully monitored to maintain their safety.

Convening Support Groups

Individuals who are depressed can receive emotional support in groups and learn how others deal with similar problems and issues. As group members serve as role models for new group members, they also benefit as their self-esteem increases, which strengthens their ability to address their issues (see [Chapter 14](#)). Group interventions are often used to help an individual cope with depression associated with bereavement or chronic medical illness. Group interventions are also commonly used to educate patients and families about their disorder and medications.

Nurses are exceptionally well positioned to engage patients and their families

in the active process of improving daily functioning, increasing knowledge and skill acquisition, and increasing independent living. Consumer-oriented support groups can help to enhance the self-esteem and the support network of participating patients and their families. Advice, encouragement, and the sense of group camaraderie may make an important contribution to recovery (APA, 2013). Organizations providing support and information include the Depression and Bipolar Support Network (DBSA), National Alliance on Mental Illness (NAMI), and the Mental Health Association and Recovery, Inc. (a self-help group).

Implementing Milieu Therapy

While hospitalized, milieu therapy (see [Chapter 11](#)) helps depressed patients maintain socialization skills and continue to interact with others. When depressed, people are often unaware of the environment and withdraw into themselves. On a psychiatric unit, depressed patients should be encouraged to attend and participate in unit activities. These individuals have decreased energy levels and thus may be moving more slowly than others; however, their efforts should be praised.

Family Interventions

Patients who perceive high family stress are at risk for greater future severity of illness, higher use of health services, and higher health care expense. Marital and family problems are common among patients with mood disorders; comprehensive treatment requires that these problems be assessed and addressed. They may be a consequence of the major depression but may also predispose persons to develop depressive symptoms or inhibit recovery and resilience processes. Marital and family therapy may reduce depressive symptoms and the risk for relapse in patients with marital and family problems. The depressed spouse's depression has marked impact on the marital adjustment of the nondepressed spouse. Treatment approaches should be designed to help couples be supportive of each other, to adapt, and to cope with the depressive symptoms within the framework of their ongoing marital relations. Many family

nursing interventions may be used by the psychiatric nurse in providing targeted family-centered care. These include the following:

- Monitoring patient and family for indicators of stress
- Teaching stress management techniques
- Counseling family members on coping skills for their own use
- Providing necessary knowledge of options and support services
- Facilitating family routines and rituals
- Assisting the family to resolve feelings of guilt
- Assisting the family with conflict resolution
- Identifying family strengths and resources with family members
- Facilitating communication among family members

Developing Recovery-Oriented Rehabilitation Strategies

William Anthony (1993) developed a model on recovery from mental illness. The model resonates with patients, families, friends, and psychiatric nurses. The evidenced-based practice model stresses the concept of hope that persons with mental illness develop and enact in their everyday lives (Anthony, 1993). Recovery is not just the emphasis on clinical symptoms. Persons develop new techniques that enhance their strengths in the areas of knowledge regarding their personalities and abilities to develop social support systems (Ohrnberger et al., 2017). In addition, persons learn other evidence-based approaches that help them to increase and maintain their physical and emotional health (Jacob, 2015; Khoury, 2019). Community organizations such as WRAP (Wellness Recovery Action Planning), NAMI, and Mental health boards have recovery evidence-based programs for persons, their families, and mental health providers (Jacob, 2015). Recovery represents a community extended and focused patient-driven approach that puts them in charge: some define it as person-centered but persons who incur mental illness define it as their evidence-based approach to life.

Evaluation and Treatment Outcomes

The major goals of treatment are to help the patient to be as independent as

possible and to achieve stability, remission, and recovery from major depression. It is often a lifelong struggle for the individual. Ongoing evaluation of the patient's symptoms, functioning, and quality of life should be carefully documented in the patient's record in order to monitor outcomes of treatment.

Continuum of Care

Mild-to-moderate depression is often first recognized in primary care settings. Primary care nurses should be able to recognize depression in these patients and make appropriate interventions or referrals

Emergency Care

Those with more severe depressive symptoms may be directly admitted to inpatient and outpatient mental health settings or emergency departments

Inpatient-focused Care

Although most patients with major depression are treated in outpatient settings, brief hospitalization may be required if the patient is suicidal or psychotic (Mitchell et al., 2017). Nurses working on inpatient units provide a wide range of direct services, including administering and monitoring medications and target symptoms; conducting psychoeducational groups; and more generally, structuring and maintaining a therapeutic environment.

Community Care

The continuum of care beyond these settings may include partial hospitalization or day treatment programs; individual, family, or group psychotherapy; and home visits. Nurses providing home care have an excellent opportunity to detect undiagnosed depressive disorders and make appropriate referrals.

Virtual Mental Health Care

Commonly known as Telehealth, virtual mental health care emerged in response to client and psychiatric-mental health educator and practitioner needs (Tyson et al., 2019). *Telehealth* is defined as the use of electronic approaches and communications that support clinical and professional health care that facilitate biobehavioral health needs (Tyson et al., 2019). Telehealth extends psychiatric nurses ability to assess, diagnose, and treat clients, as well as collaborate with other health care providers. Video and phone conferencing technologies facilitate the process. The use of virtual mental health helps psychiatric nurses to assess quality education and provide evidenced-based psychiatric care to persons from underserved populations and those living in rural areas (Tyson et al., 2019).

Integration with Primary Care

Depression is often treated in the primary care setting with readily available antidepressants. Unfortunately, the primary treatment for depression in this setting is medication. Many individuals need more than medication but do not access mental health services for a variety of reasons such as stigma, fear of being labeled as mentally ill, and lack of resources. There are also several medical problems associated with depression, such as hypothyroidism (Uhlenbusch et al., 2019). Pain is a common problem for individuals who are depressed (Zis et al., 2017). It is important to communicate with the primary care provider to coordinate care.

The medical home delivery model is becoming widely accepted in the United States. If a patient is cared within a medical home model, all of their health and mental health needs are coordinated by one health provider. Meaningful long-term relationships can be developed. The advantage of a medical home is a recognition and coordination of all health care needs. This model is helpful when many of the health disorders, associated with depression, occur. For example, substance abuse, obesity, and cardiovascular disorders are associated with depression and mood disorders (Berg et al., 2018).

OTHER DEPRESSIVE DISORDERS

Other depressive disorders with similar symptoms are treated similarly to the major depressive disorders. Nursing care should be individualized and based on their patients' mental health needs and strengths. A diagnosis of persistent depressive disorder (*dysthymia*) is made if major depressive disorder symptoms last for 2 years for an adult and 1 year for children and adolescents. These individuals are depressed for most of each day (APA, 2013). A major depressive disorder may precede the persistent depressive disorder or co-occur with it.

Premenstrual dysphoric disorder is characterized by recurring mood swings, feelings of sadness, or sensitivity to rejection in the final week before the onset of menses. The mood begins to improve a few days after menses begins. Stress, history of interpersonal trauma, seasonal changes are associated with this disorder (APA, 2013).

Disruptive mood dysregulation disorder is characterized by severe irritability and outbursts of temper. The onset of disruptive mood dysregulation disorder begins before the age of 10 when children have verbal rages and/or are physically aggressive toward others or property. These outbursts are outside of the normal temper tantrums children display. They are more severe than what would be expected developmentally and occur frequently (i.e., two or three times a week). The behavior disrupts family functioning as well as the child's ability to succeed in school and social activities. This disorder can co-occur with attention-deficit/hyperactivity disorder. See Chapter 37.

Disruptive mood dysregulation disorder is similar to pediatric bipolar disorder, but the *DSM-5* differentiates it from bipolar disorder. Children with this disorder have similar deficits in recognition of emotion through facial expression, decision-making, and control as those with bipolar disorder. More research is needed in understanding this disorder.

SUMMARY OF KEY POINTS

- Moods influence perception of life events and functioning. Depressive disorders are characterized by persistent or recurring disturbances in mood that cause significant psychological distress and functional impairment

(typified by feelings of sadness, hopelessness, loss of interest, and fatigue).

- Depressive disorders include major depressive disorder, persistent depressive disorder (dysthymia), premenstrual dysphoric disorder, disruptive mood dysregulation disorder, and others related to medical conditions, medications, or substance use.
- Risk factors include a family history of depressive disorders, prior depressive episodes; lack of social support; stressful life events; substance use; and medical problems, particularly chronic or terminal illnesses.
- Treatment of major depressive disorder primarily includes antidepressant medication, psychotherapy, or a combination of both. ECT, light therapy, and rTMS are also used.
- Nurses must be knowledgeable regarding culturally competent strategies related to the use of antidepressant medications, pharmacologic therapeutic effects and associated side effects, toxicity, dosage ranges, and contraindications. Nurses must also be familiar with ECT protocols and associated interventions. Patient education and the provision of emotional support during the course of treatment are also nursing responsibilities.
- Many symptoms of depression (e.g., weight and appetite changes, sleep disturbance, decreased energy, fatigue) are similar to those of medical illnesses. Assessment includes a thorough medical history and physical examination to detect or rule out medical or psychiatric comorbidity.
- Mental health nursing assessment includes assessing mood; speech patterns; thought processes and content; suicidal or homicidal thoughts; cognition and memory; and social factors, such as patterns of relationships, quality of support systems, and changes in occupational functioning. Several self-report scales are helpful in evaluating depressive symptoms.
- Establishing and maintaining a therapeutic culturally competent nurse–patient relationship is key to successful outcomes. Nursing interventions that foster the therapeutic relationship include being available in times of crisis, providing understanding and education to patients and their families regarding

goals of treatment, providing encouragement and feedback concerning the patient's progress, providing guidance in the patient's interpersonal interactions with others and work environment, and helping to set and monitor realistic goals.

- Psychosocial interventions for depressive disorders include self-care management, cognitive therapy, behavior therapy, interpersonal therapy, patient and family education regarding the nature of the disorder and treatment goals, marital and family interventions, and group interventions that include medication maintenance support groups and other consumer-oriented support groups.

CRITICAL THINKING CHALLENGES

1. Describe how you would do a suicide assessment on the patients who come into a primary care office and are distraught and expressing concerns about their ability to cope with their current situation.
2. Describe how you would approach the patient who does not want to talk with you.
3. Describe how you would approach the patients who are expressing concern that the diagnosis of depressive disorder will negatively affect their social and work relationships.
4. Your depressed patients do not seem inclined to talk about their depression. Describe the measures you would take to initiate a therapeutic relationship with them.
5. Compare the side effects of the SSRIs, TCAs, and MAOIs.
6. Think about all the above situations and relate them to persons from culturally and ethnically diverse populations (e.g., African, Latinx, or Asian descent; Jewish or Jehovah Witness religions; across the life span) talk about their depression. Describe the measures you would take to initiate a therapeutic relationship with them.
7. Compare the side effects of the SSRIs, TCAs, and MAOIs.
8. Think about all the above situations and relate them to persons from culturally and ethnically diverse populations (e.g., African, Latinx, or Asian descent; Jewish or Jehovah Witness religions; across the life span of individuals from children to older adult populations).

Unfolding Patient Stories: Li Na Chen

Part 2

Recall from [Chapter 3](#) Li Na Chen with major depressive disorder who was hospitalized

following her third suicide attempt with an overdose. She is transitioning to a partial hospitalization program before formal transition to home. Her husband is concerned about their two children, ages 12 and 14, and his ability to handle her once she is home. What questions can the nurse ask to clarify the husband's concerns? How can Li Na's depression and attempted suicide affect her husband and children? What psychosocial interventions can the nurse consider to support Li Na and her family once she is home?

Movie Viewing Guides

About *Schmidt*: (2002). This movie is about a 67-year-old man, Warren Schmidt, played by Jack Nicholson, who retires from his job as an insurance company executive. He experiences work withdrawal and a lack of direction for his retirement. His wife, Helen, irritates him, and he has no idea what to do to fill his days. While watching television one day, he is moved to sponsor a child in Africa with whom he begins a long, one-sided correspondence. When his wife dies unexpectedly, he is initially numb, then sad, and finally angry when he discovers that she had an affair with his best friend many years ago. He is estranged from his only daughter, Jeanie, whose wedding to Randall, a man he thinks is beneath her, is imminent. The movie follows Warren as he searches for connection and meaning in his life.

SIGNIFICANCE: Warren Schmidt demonstrates a common phenomenon among older adults when they retire. He also shows the impact of grief superimposed on initial dysthymia or depression.

VIEWING POINTS: Look for the changes in Schmidt's manifestations of depression in different situations. Note how he experiences the various stages of grieving. What do you think about Schmidt's search for significance and meaning in his life?

***Dead Poet's Society*:** (1989). This film portrays John Keating, played by Robin Williams, as a charismatic English teacher in a conservative New England prep school for boys in 1959. John brings his love of poetry to the students and encourages them to follow their dreams and talents and make the most of every day. His efforts put him at odds with the administration of the school, particularly the headmaster, played by Norman Lloyd, as well as Tom Perry, the father of one of his students, played by Kurtwood Smith. Tom's son, Neil, played by Robert Sean Leonard, chooses to act in a school play despite the objection of his father to any extracurricular activities. When Neil cannot reconcile his love

of theater and his father's expectations that he pursues a career in medicine, he kills himself. John Keating blames himself for the death, as does the school administration. He is fired by the administration but has a moment of pride when his students demonstrate their ability to think and act for themselves.

SIGNIFICANCE: This film accurately portrays the sensitivity of adolescents and their longing for worthwhile role models. It also shows adolescent growth and development in a realistic manner. It demonstrates the combination of factors that accompany a decision to commit suicide. We can see how Neil feels caught between his desires and the demands of his father. In the cultural context of the late 1950s, few children or adolescents dared to challenge or defy their parents, especially such a domineering man as Tom Perry.

VIEWING POINTS: Look for the differences in Neil's behavior with his peers and his father or other adults besides Mr. Keating. What, if any, clues do you get that Neil might attempt suicide? What actions by any of the main characters might have prevented his suicide?

Bipolar Disorders

Nursing Care of Persons with Mood Lability

Mary Ann Boyd

KEYCONCEPTS

- mania
- mood lability

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of mania and mood lability in mental disorders.
2. Delineate the clinical symptoms and course of bipolar disorder.
3. Analyze the theories of bipolar disorder and their relationship to mood lability.
4. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with bipolar disorder.
5. Apply a person-centered, recovery-oriented nursing process for persons with bipolar disorder.
6. Identify medications used to treat people with bipolar disorder and evaluate their effectiveness.
7. Develop wellness strategies for persons with bipolar disorder.
8. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
9. Discuss the importance of integrated health care for persons with bipolar disorder.
10. Describe other other bipolar and related disorders.

KEY TERMS

- Bipolar I disorder
- Bipolar II disorder
- Cyclothymic disorder
- Elation
- Elevated mood
- Euphoria
- Expansive mood
- Grandiosity
- Hypomania
- Mania

- Mood lability
 - Rapid cycling
 - Social rhythms
-

Case Study

Christine is a 34-year-old female who has a history of bipolar I disorder. She is brought to the emergency room by the police from the airport, where she was demanding a plane ticket to Hawaii. She became very belligerent when she did not get her ticket. She is wearing an evening dress with several pieces of expensive jewelry. How would you document Christine's behavior and appearance? Was her belligerent behavior at the airport excessive considering the circumstances? How would you support her?

INTRODUCTION

Everyone has ups and downs. Mood changes are a part of everyday life; expression of feeling is integral to communication. But when moods are so pervasive that they cloud reasoning and judgment, they become problematic and interfere with interpersonal relationships. In some instances, extreme moods such as mania are symptoms of mental disorders. This chapter discusses bipolar disorders that are characterized by severe mood changes, with bipolar I disorder highlighted.

MANIA

Mania is one of the primary symptoms of bipolar disorders. It is recognized by an elevated, expansive, or irritable mood. Mania is easily recognized by the cognitive changes that occur. Elevated self-esteem is expressed as **grandiosity** (exaggerating personal importance) and may range from unusual self-confidence to grandiose delusions. Speech is pressured (push of speech); the person is more talkative than usual and at times is difficult to interrupt. There is often a flight of ideas (illogical connections between thoughts) or racing thoughts. Distractibility increases.

KEYCONCEPT **Mania** is primarily characterized by an abnormally and persistently elevated, expansive, or irritable mood.

In mania, the need for sleep is decreased and energy is increased. The individual often remains awake for long periods or wakes up several times at night full of energy. Initially, there is an increase in goal-directed activity that is purposeful (e.g., cleaning the house), but it deteriorates into hyperactivity, agitation, and disorganized behavior. Social activities, occupational functioning, and interpersonal relationships are eventually impaired. There can be excessive involvement in pleasurable activities with little regard for painful consequences (e.g., excessive spending, risky sexual behavior, drug or alcohol abuse) ([Box 26.1](#)). Persons with mania are often hospitalized to prevent self-harm.

Even though mania is primarily associated with bipolar disorders, other psychiatric disorders, including schizophrenia, schizoaffective disorder, anxiety disorders, some personality disorders (borderline personality disorder and histrionic personality disorder), substance abuse involving stimulants, and adolescent conduct disorders, may have symptoms that mimic a manic episode. Mania can also be caused by medical disorders or their treatments, certain metabolic abnormalities, neurologic disorders, central nervous system (CNS) tumors, and medications.

BOX 26.1 CLINICAL VIGNETTE

The Patient With Mania

George was a day trader on the stock market. Initially, he was quite successful and, as a result, upgraded his lifestyle with a more expensive car; a larger, more luxurious house; and a boat. When the stock market declined dramatically, George continued to trade, saying that if he could just find the “right” stock he could earn back all of the money he had lost. He spent his days and nights in front of his computer screen, taking little or no time to eat or sleep. He defaulted on his mortgage and car and boat payments and was talking nonstop to his wife. She brought him to the hospital for evaluation.

What Do You Think?

- What behavioral symptoms of mania does George exhibit?
- What cognitive symptoms of mania does George exhibit?

Mood lability is the term used for the rapid shifts in moods that often occur in bipolar disorder. One month a person is happy, and the next month they are in the depths of depression. These mood shifts leave everyone around the person confused and interfere with social interaction.

KEYCONCEPT **Mood lability** is alterations in moods with little or no change in external events.

Rapid cycling is an extreme form of mood lability that can occur in bipolar disorders. In its most severe form, rapid cycling includes continuous cycling between subthreshold mania and depression or **hypomania** and depression.

BIPOLAR DISORDERS OVERVIEW

Bipolar and related disorders are characterized by periods of mania or hypomania that alternate with depression. These disorders are further classified as bipolar I, bipolar II, and cyclothymic disorders, depending on the severity of the manic and depressive symptoms. Bipolar disorder may also be related to substance abuse, prescription use, or a medical condition.

BIPOLAR I DISORDER

Bipolar I disorder is the classic manic-depressive disorder with mood swings alternating from depressed to manic. Although the depression component is

similar to that experienced in a major depressive disorder, in this disorder there is also a distinct period (of at least 1 week or less if hospitalized) of abnormally and persistently elevated, expansive, or irritable mood with abnormally increased goal-directed behavior or energy (American Psychiatric Association [APA], 2013). An **elevated mood** can be expressed as **euphoria** (exaggerated feelings of well-being) or **elation** (feeling “high,” “ecstatic,” “on top of the world,” or “up in the clouds”). An **expansive mood** is characterized by lack of restraint in expressing feelings; an overvalued sense of self-importance; and a constant and indiscriminate enthusiasm for interpersonal, sexual, or occupational interactions.

For some people, an irritable mood instead of an elevated mood is pervasive during mania. Such individuals are easily annoyed and provoked to anger, particularly when their wishes are challenged or thwarted. Maintaining social relationships during these episodes is difficult.

Consider Christine

When Christine is brought to the hospital, she is experiencing grandiose delusions. She believes that she is starting a business. She has spent a large amount of money over a short period of time on clothes and jewelry. Her neighbors reported that she was selling household goods in her yard. Her mood is labile. She is loud and condescending toward staff members. She has push of speech and flight of ideas. What behaviors are characteristic of bipolar disorder?

Clinical Course

Bipolar I disorder is a chronic multisystemic cyclic disorder. Those with an earlier onset have more frequent episodes than persons who develop the illness later in life. Bipolar disorder is a progressive condition with prodromal, symptomatic, and residual states. The progressive nature of this disorder can be arrested with an early diagnosis, proper treatment, and individually tailored management (Muneer & Mazommil, 2018). An early onset and a family history of illness are associated with multiple episodes or continuous symptoms. Symptoms of the illness can be unpredictable and variable. Bipolar I disorder can lead to severe functional impairment, such as alienation from family, friends, and coworkers; indebtedness; job loss; divorce; and other problems of living (Dell'Osso et al., 2020).

Diagnostic Criteria

To be diagnosed with bipolar I disorder, at least one manic episode or mixed episode and a depressive episode have to occur. See Key Diagnostic Characteristics 26.1. The term *mixed episode* is used when mania and depression occur at the same time, which leads to extreme anxiety, agitation, and irritability. These individuals are clearly miserable and are at high risk for suicide.

Bipolar I Disorder Across the Life Span

Children and Adolescents

Only recently has bipolar disorder been recognized in children. Although it has not been well studied, depression usually appears first. Somewhat different than in adults, the hallmark of childhood bipolar disorder is intense rage. Children may display seemingly unprovoked rage episodes for as long as 2 to 3 hours. The symptoms of bipolar disorder reflect the developmental level of the child. Children younger than 9 years exhibit more irritability and emotional lability; older children exhibit more classic symptoms, such as euphoria and grandiosity. The first contact with the mental health system often occurs when the behavior becomes disruptive, possibly 5 to 10 years after its onset. These children often

have other psychiatric disorders, such as attention-deficit hyperactivity disorder or conduct disorder (Arnold et al., 2020). See [Chapter 36](#).

Older Adults

The onset of bipolar disorder can also occur in older adults. Symptoms are similar to the earlier onset bipolar disorder, but the incidence of mania decreases with age. Older adults with bipolar disorder have more neurologic abnormalities and cognitive disturbances (confusion and disorientation) than younger patients (Dols & Beekman, 2020). See [Chapter 39](#).

Epidemiology and Risk Factors

Risk factors for bipolar disorders include a family history of mood disorders, prior mood episodes, lack of social support, stressful life events, substance use, and medical problems, particularly chronic or terminal illnesses (Faedda et al., 2019).

Age of Onset

Bipolar disorders have an estimated prevalence of 1% to 4% (Loftus, et al., 2020). The onset of the majority of cases occurs in early life, from the ages of 14 to 21 years, with fewer cases occurring after 40 years of age (Bolton et al., 2020).

Gender

Although no significant gender differences have been found in the incidence of bipolar I and bipolar II disorder diagnoses, gender differences have been reported in phenomenology, course, and treatment response. In addition, some data show that female patients with bipolar disorder are at greater risk for depression and mixed episodes than are male patients, but male patients may be at greater risk for manic episodes (Fellinger et al., 2019).

296.XX

296.4X—BIPOLAR I, CURRENT OR MOST RECENT EPISODE MANIC

296.4X—BIPOLAR I, CURRENT OR MOST RECENT EPISODE HYPOMANIC

296.4X—BIPOLAR I, CURRENT OR MOST RECENT EPISODE DEPRESSED

Diagnostic Criteria

The essential feature of a manic episode is a distinct period during which there is an abnormally, persistently elevated, expansive, or irritable mood and persistently increased activity or energy that is present for most of the day, nearly every day, for a period of at least 1 week (or any duration if hospitalization is necessary), accompanied by at least three additional symptoms from Criterion B. If the mood is irritable rather than elevated or expansive, at least four Criterion B symptoms must be present.

Manic Episode

- A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).
- B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
 - 1. Inflated self-esteem or grandiosity
 - 2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
 - 3. More talkative than usual or pressure to keep talking
 - 4. Flight of ideas or subjective experience that thoughts are racing
 - 5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed
 - 6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity)
 - 7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

Ethnicity and Culture

Although there is a general belief that no significant racial and ethnic differences related to bipolar disorder exist, most of the research is based on White individuals who have not experienced a disparity in access to health care. A lack of representation from ethnic/racial groups makes it difficult to determine the impact of race and ethnicity on the morbidity of people with bipolar disorder. Also, African American individuals with bipolar disorder are more likely to be misdiagnosed as having schizophrenia, schizoaffective, or major depressive disorders, and older African American individuals are more likely to use general medical services for treatment than mental health services (Akinhanmi et al., 2018, 2020).

Comorbidity

The two most common comorbid mental health conditions are anxiety disorders (panic disorder and social phobia are the most prevalent) and substance use (most commonly alcohol and marijuana). Individuals with a comorbid anxiety disorder are more likely to experience a more severe course. A history of substance use further complicates the course of illness and results in less chance for remission and poorer treatment compliance (Loftus et al., 2020; Spoorthy et al., 2019). Bipolar disorder is associated with several medical conditions, such as irritable bowel syndrome, asthma, migraine, multiple sclerosis, and cerebellar diseases (Flowers et al., 2020; Sinha, et al., 2018).

Etiology

The etiology of mood disorders is unknown, but the current thinking is that bipolar disorder results when an interaction exists between the genetic predisposition and psychosocial stress, such as abuse or trauma (Carvalho et al., 2020).

Biologic Theories

Chronobiologic Theories

Sleep disturbance is common in individuals with bipolar disorder, especially mania. Sleep patterns appear to be regulated by an internal biologic clock center in the hypothalamus. Artificially induced sleep deprivation is known to precipitate mania in some patients with bipolar disorder. It is possible that circadian dysregulation underlies the sleep–wake disturbances of bipolar disorder. Seasonal changes in light exposure also trigger affective episodes in some patients, typically depression in winter and hypomania in the summer in the northern hemisphere (Rosenthal et al., 2020).

Genetic Factors

Results from family, adoption, and twin studies indicate that bipolar disorder is highly heritable. Studies of monozygotic twins show risks from 40% to 70% of acquiring the illness if their identical twin has the disorder (Johansson et al., 2019). No one gene or sequence of genes is responsible for the pathology of bipolar disorder. Evidence suggests that the genetic etiologies of schizophrenia and bipolar disorders overlap (Smeland et al., 2020).

Chronic Stress, Inflammation, and Kindling

The role of an allostatic load or wear and tear on the body (see [Chapter 19](#)) is thought to contribute to cognitive impairment, comorbidity, and eventual mortality of those with bipolar disorder. As the allostatic load increases, the number of mood episodes increases, which, in turn, increases physical and mental health problems. An interaction between stress and brain development is viewed as dynamic; individuals have different kinds of stress adaptation depending on their neurobiologic responses (Dargél et al., 2020).

The characteristic mood dysregulation of bipolar I disorder is associated with a decrease in serum brain-derived neurotrophic factor, oxidative stress resulting in DNA damage, and inflammation. Pro-inflammatory cytokines bind to neuronal death receptors, leading to cell death. In some patients with repeated episodes, there is a decrease in hippocampal volume and reduction in prefrontal grey matter (Muneer, 2020).

A closely related concept is the kindling theory that posits that as genetically predisposed individuals experience repetitive subthreshold stressors at vulnerable times, mood symptoms of increasing intensity and duration occur. Eventually, a full-blown depressive or manic episode erupts. Each episode leaves

a trace and increases the person's vulnerability or sensitizes the person to have another episode with less stimulation. In later episodes, there may be little or no stress occurring before the depression or mania. The disorder takes on a life of its own, and over time, the time between episodes decreases (Carvalho et al., 2020).

Psychosocial Theories

Psychosocial theories are useful in planning recovery-oriented interventions that focus on reducing environmental stress and trauma in genetically vulnerable individuals. It is now generally accepted that psychosocial and environmental events contribute to the severity of the disorder and the frequency of the mood episodes. Two promising theories are currently receiving research support.

The *behavioral approach system dysregulation* theory proposes that individuals with bipolar disorder are overly sensitive and overreact to relevant cues when approaching a reward. That is, the intensity of the goal-motivated behavior leads to manic symptoms such as euphoria, decreased need for sleep, and excessive self-confidence. Conversely, the system is deactivated and leads to depressive symptoms such as decreased energy, hopelessness, and sadness (Arfaie et al., 2018).

The *social rhythm disruption theory* is consistent with the research on circadian rhythm dysregulation previously discussed. According to this theory, there are environmental factors that set the circadian clock, such as the rising and setting of the sun. There are also social cues or **social rhythms** that can set the circadian clock, such as the time we get out of bed, our first contact in the morning (person), when we start our day, have dinner, and go to bed. These are patterned social events. Individuals with bipolar disorder have fewer regular social rhythms than those without bipolar disorder. This theory suggests that when patterned social events are disrupted, mood swings are more likely to appear (Crowe & Inder, 2018).

Family Response to Disorder

Bipolar disorder can devastate families, who often feel that they are on an emotional merry-go-round, particularly if they have difficulty understanding the mood shifts. A major problem for family members is dealing with the

consequences of impulsive behavior during manic episodes, such as taking on excessive debt, assault charges, and sexual infidelities.

Remember Christine?

She has been married for 2 years to Karl, who was unaware of her bipolar disorder. He believed that she used to take antidepressants but that she no longer needed them. Her episode at the airport occurred when he was out of town. He is concerned about her health and their new financial obligations. How do you explain that Karl was unaware of Christine's illness? How would you explain Christine's illness to her husband?

RECOVERY-ORIENTED CARE FOR PERSONS WITH BIPOLAR DISORDER

Teamwork and Collaboration: Working Toward Recovery

An important recovery goal is to minimize or prevent both manic and depressive episodes, which tend to accelerate over time. The fewer the episodes, the more likely the person can live a fully productive life. Three interconnected pathways can lead to relapse: stressful life events, medication nonadherence, and disruption in social rhythms (Crowe et al., 2016). Patients with bipolar disorder have a complex set of issues and have the best chance of recovery by working with an interdisciplinary team. Nurses, physicians, social workers, psychologists,

and activity therapists all have valuable expertise. For children with bipolar disorder, schoolteachers and counselors are included in the team. For older adult patients, the primary care physician becomes part of the team. Helping the patient and family learn about the disorder and manage it throughout a lifetime is critical for recovery.

The primary treatment modalities are medications, psychotherapy, education, and support. Mood stabilizers and antipsychotics are the mainstay medications in the treatment of bipolar disorders. Mood stabilizers are discussed later in this chapter. Antipsychotics are discussed in [Chapter 24](#). Long-term psychotherapy may help prevent symptoms by reducing the stresses that trigger episodes and increasing the patient's acceptance of the need for medication. Patients should be encouraged to keep their appointments with the therapist, be honest and open, do the assigned homework, and give the therapist feedback on whether the treatment is effective.

Safety Issues

Risk of suicide is always present for those having a depressive or manic episode (Ballard et al., 2020). During a depressive episode, the patient may believe that life is not worth living. During a manic episode, the patient may believe that they have supernatural powers, such as the ability to fly.

During a manic episode, poor judgment and impulsivity lead to risk-taking behaviors that can have dire consequences for the patient and family. For example, when one patient gambled all of his family's money away, he blamed his partner for letting him have access to the money. A physical confrontation with the partner resulted.

As patients recover from a manic episode, they may be so devastated by the consequences of their impulsive behavior and poor judgment that suicide seems like the only option.

Consider This:

Consider Christine's history of poor judgment during a manic episode. She left her first husband and their two children during her third manic episode. At that time, Christine went to Hawaii and stayed there for several months without informing her family of her whereabouts. She was homeless most of the time. Once Christine is stable, what interventions will support long-term remission of bipolar disorder?

EVIDENCE-BASED Nursing CARE OF PERSONS WITH BIPOLAR DISORDER

The nursing care of patients with a bipolar disorder is one of the most interesting yet greatest challenges in psychiatric nursing. In general, the behavior of patients with bipolar disorder is normal between mood episodes. The nurse's first contact with the patient is usually during a manic or depressive episode. See Nursing Care Plan 26.1.

Mental Health Nursing Assessment

Recovery-oriented nursing care begins with the initial assessment through engaging the patient in a partnership and empowering the person to make decisions in setting overall goals of care ([Box 26.2](#)). During acute episodes, the patient's judgment may be impaired, but as the manic or depressive symptoms subside, the person will be able to participate in care decisions.

Physical Health

The physical health assessment should follow the process explained in [Chapter 11](#). Target assessment symptoms include the changes and severity of activity, eating, and sleep patterns. The patient may not sleep, resulting in irritability and physical exhaustion. Diet and body weight usually change during a manic or depressive episode. Laboratory studies, such as thyroid function and electrolytes, should be completed to detect evidence of malnutrition and fluid imbalance.

Abnormal thyroid functioning can be responsible for the mood and behavioral disturbances. In mania, patients often become hypersexual and engage in risky sexual practices. Changes in sexual practices should be included in the assessment.

A careful assessment of current medications is important in determining physical status. Many times, manic or depressive episodes occur after patients stop taking their medication. Exploring reasons for discontinuing the medication will help in planning adherence strategies in the future. Some stop taking their medications because of side effects; others do not believe they have a mental disorder. The use of alcohol and other substances should be carefully assessed. Usually, a drug screen is ordered. In some instances, patients have been taking an antidepressant as prescribed for depression without realizing that a bipolar disorder existed.

NURSING CARE PLAN 26.1

The Patient with Bipolar I Disorder

Christine, a 34-year-old woman, is admitted involuntarily to the inpatient unit, following an altercation at the airport when she became loud and belligerent and caused a ruckus. She believes that she has special powers over others and has a direct connection to God. She stated she needed to leave town because of the “three men” in her house, who are chasing her. She is accompanied by her mother and husband, Karl. She believes that she is being taken to a safe place, which can protect her from the men who were chasing

her.

Her mother stated that Christine was first diagnosed with bipolar disorder at age 22 after her first child was born. She received treatment for 2 years. After her second pregnancy, she refused to take her medication. During her third manic episode, she left her husband and children. She was reunited with her parents 4 years later and reinitiated treatment. After her marriage to Karl, she stopped her medication. Karl believed that Christine had a history of depression but did not realize that she has bipolar disorder. He wants to be supportive and help her.

Setting: Intensive Care Psychiatric Unit in a General Hospital

Baseline Assessment: A 34-year-old woman who is flamboyantly dressed in a cocktail dress with several pieces of expensive jewelry. She is oriented to time, place, and person, but she believes she has special powers. She states that she is “not suicidal—I have a mission.” She is displaying push of speech and flight of ideas. She is hyperverbal and hyperactive. It is difficult to interrupt her thoughts. She states she has not slept for several days and does not need to sleep because she is gifted. She is not taking any medications and denies substance use except for an occasional marijuana joint. She admits to taking mood stabilizers in the past but states that they made her gain weight. She does not want to take that medication again. BP 130/70, P 70, R 18, Ht. 5'5", Wt 125 (BMI 20.8).

Associated Psychiatric Diagnosis	Medications
Bipolar I disorder	Ziprasidone (Geodon) 40 mg PO BID (Give with a full meal) Lorazepam 1 mg PO q4h as needed for anxiety or agitation

Priority of Care: Lack of Problem-Solving Ability

Important Characteristics

Denial of problems obvious to others
Projection of blame or responsibility for problems

Associated Considerations

Biochemical/neurophysiologic imbalance

Outcomes

Initial

1. Increase problem-solving ability
2. Identify factors that led to current manic episode
3. Accept treatment of bipolar disorder

Discharge

4. Agree to continue medication and follow-up
5. Attend support group

Interventions

Interventions

Initiate a nurse–patient relationship by demonstrating an acceptance of Christine as a worthwhile human being through the use of nonjudgmental statements and behavior Administer ziprasidone 40 mg BID per health care provider order

(Christine refused mood stabilizers because of side effects.)
Teach Christine the therapeutic and side effects of medication
Instruct her to take medication with a full meal

Rationale

The positive therapeutic relationship can maintain the patient's dignity and open communication

Most new antipsychotics are indicated for mood disorders. Best absorption of ziprasidone

Ongoing Assessment

Assess the stages of the relationship, and determine whether a therapeutic relationship is actually being formed. Identify indicators of trust

Determine effectiveness of medication. Observe for side effects

occurs when
taken with a
full meal

Evaluation

Outcomes

Increased ability to
problemsolve
Is dressing appropriately
for situation
Taking medication as
prescribedafter
discharge
Considering attending
support groups

Revised Outcomes

Take
medication
as prescribed

Interventions

Continue to encourage
Christine to attend support
groups

Priority of Care: Unable to Cope with Life Stressors

Important Characteristics

Asking for help
Reported difficulty
with life stressors
Inability to problem
solve
Insufficient access to
social support
Destructive behavior
toward self
Frequent illnesses
Substance abuse

Associated Considerations

Altered mood (mania) caused by changes secondary
to body chemistry (bipolar disorder)
Sensory overload secondary to excessive activity

Outcomes

Initial

1. Accept support through the nurse–patient relationship
2. Identify areas of ineffective coping
3. Examine the current efforts at coping
4. Identify areas of strength
5. Learn new coping skills

Discharge

6. Practice new coping skills
7. Focus on strengths

Interventions**Interventions****Rationale****Ongoing Assessment**

Identify the current stresses in Christine's life, including bipolar disorder

When areas of concern are verbalized by the patient, she will be able to focus on one issue at a time. If she identifies the mental disorder as a stressor, she will more likely be able to develop strategies to deal with it

Determine whether Christine is able to identify problem areas realistically. Continue to assess for suicidality

Identify Christine's strengths in dealing with past stressors

By focusing on past successes, she can identify strengths and build on them in the future

Assess whether Christine can identify any previous successes in her life

Assist Christine in discussing, selecting, and practicing positive coping skills (e.g., jogging, yoga, thought stopping)

New coping skills take a conscious effort to learn and will at first seem strange and unnatural. Practicing these skills will help the patient incorporate them into her coping strategy repertoire

Assess whether Christine follows through on learning new skills

Assist patient in coping with bipolar disorder, beginning with education about it	A mood disorder is a major stressor in a patient's life. To manage the stress, the patient needs a knowledge base	Determine Christine's knowledge about bipolar disorder
Administer lorazepam as needed for anxiety or agitation	Benzodiazepine helps decrease anxiety and calm the patient	Assess for target action, side effects, and toxicity

Evaluation

Outcomes	Revised Outcomes	Interventions
Christine is easily engaged in a therapeutic relationship. She examined the areas in her life where she coped ineffectively	Establish a therapeutic relationship with a therapist at the mental health clinic	Refer to mental health clinic Seek advice immediately if there are any problems with medications
She identified her strengths and how she coped with stressors and especially her illness in the past. She is willing to try medications again, in hopes of not gaining weight	Continue to view illness as a potential stressor that can disrupt life	Discuss with therapist the outcomes of using new coping skills. Attend bipolar support group
She learned new problem-solving skills and reported that she learned a lot about her medication. She is committed to complying with her medication regimen. She identified	Continue to practice new coping skills as stressful	

new coping skills that she could realistically do. She will focus on strengths

situations arise

BOX 26.2

Research for Evidence-Based Practice: Promoting Personal Recovery

Crowe, M & Inder, M. (2018). *Staying well with bipolar disorder: A qualitative analysis of five-year follow-up interviews with young people*. *Journal of Psychiatric and Mental Health Nursing*, 25(4), 236–244. <https://doi.org/10.1111/jpm.12455>

THE QUESTION: How do participants in psychotherapy for young people with bipolar disorder describe their experiences of the intervention and its impact on living with the disorder?

METHODS: A qualitative study was conducted 5 years after participants had completed a psychotherapy intervention in a randomized controlled trial for young people with bipolar disorder. Thirty people were recruited and interviewed regarding their experiences.

FINDINGS: Three themes were identified: self-awareness in the context of bipolar disorder, understanding bipolar disorder, and learning to stay well with bipolar disorder.

IMPLICATIONS FOR NURSING: Nurses can promote factors recognized by their patients as being helpful in learning to stay well, including self-awareness, understanding the unique characteristics of their disorder, learning to take care of the self, and stabilization of social rhythms.

Psychosocial Assessment

The psychosocial assessment should follow the process explained in [Chapter 11](#). Individuals with bipolar disorder can usually participate fully in this part of the assessment.

Mental Status and Appearance

Mood

By definition, bipolar disorder is a disturbance of mood. If the patient is depressed, using an assessment tool for depression may help determine the severity of depression. If mania predominates, evaluating the quality of the mood (e.g., elated, grandiose, irritated, or agitated) becomes important. Usually,

mania is diagnosed by clinical observation.

Cognition

In a depressive episode, an individual may not be able to concentrate enough to complete cognitive tasks, such as those called for in a mental status assessment. During the acute phase of a manic or depressive episode, mental status may be abnormal, and in a manic phase, judgment is impaired by extremely rapid, disjointed, and distorted thinking. Moreover, feelings such as grandiosity can interfere with executive functioning. See [Box 26.3](#).

BOX 26.3 CLINICAL VIGNETTE

The Personal Experience of Mania

Sam is a 35-year-old man who was diagnosed with bipolar disorder 10 years ago. He is now being successfully treated and has insight into his disorder. In a recent discussion with his close friend, he describes his personal experience of mania.

At first, I started having more energy and felt happy most of the time. I decided to date a couple of women because I thought my girlfriend Jill was rather boring. Within a couple of weeks, I started sleeping less, but I thought that meant I could do more things. I decided to go back to school to be a scientist—thought I could save the world. I started to apply to graduate school and became very upset when I was told that I did not have the prerequisites for biochemistry. I was so mad that I started threatening the admissions counselor, who, in turn, called the police. My family was called. They convinced the police that I would not bother the school again. After that, I started drinking and smoking pot. I had periods of confusion, and my family said I became disoriented. There is a lot I don't remember. Eventually, I was hospitalized and started on medication.

What Do You Think?

- At what point could have an early intervention prevented Sam from progressing to a major manic episode?
- Why does Sam not remember the complete manic episode?

Thought Disturbances

Psychosis commonly occurs in patients with bipolar disorder, especially during

acute episodes of mania. Auditory hallucinations and delusional thinking are part of the clinical picture. In children and adolescents, however, psychosis is not so easily disclosed.

Behavioral Responses

Behavior varies according to mood. In periods of mania and poor judgment, there may be episodes of uncharacteristic behaviors such as excessive spending, impulsive gambling, or sexual activities. Behaviors during a manic episode can lead to life-long relationships or legal problems. During periods of depression, remorse for the consequences of poor judgment and behavior contributes to the negative mood state. See [Chapter 25](#).

Self-Concept

The self-concept of an individual with bipolar disorder is generally consistent with others who have stigmatized mental disorders. Even though bipolar disorder is less stigmatized than schizophrenia, the behaviors that are characteristic of persons with these disorders are often not recognized as symptoms of a disorder, but as a character flaw. Consequently, even in periods of mania, self-esteem is severely impaired.

Stress and Coping Patterns

Stress and coping are critical assessment areas for a person with bipolar disorder. A stressful event often triggers a manic or depressive episode. In some instances, no particular stressors preceded the episode, although it is important to discuss the possibility. Determining the patient's usual coping skills for stresses lays the groundwork for developing interventional strategies. Negative coping skills, such as substance use or aggression, should be identified because these skills should be replaced with positive coping skills.

Social Network

Cultural views of mental illness influence the patient's acceptance of the

disorder. During illness episodes, patients often behave in ways that jeopardize their social relationships. Losing a job and going through a divorce are common events. When performing an assessment of social function, the nurse should identify changes resulting from a manic or depressive episode.

Functional Status

Symptoms of bipolar disorder can interfere with daily functioning. Sleep, nutrition, and hygiene often suffer during manic or depressive episodes. The individuals are often unable to maintain normal functioning and activities of daily living.

Support Systems

The nurse should assess the available support systems. Individuals who have had been symptomatic may have destroyed their support networks as a result of the depressive or manic behavior. The nurse should determine if there are any positive support systems that can help the person toward recovery.

Risk Assessment

Persons with bipolar disorder are at high risk for injury to themselves and others, with 23% to 26% attempting suicide. People with bipolar disorder account for 3.4% to 14% of all suicide deaths, with self-poisoning and hanging being the most common methods (Schaffer et al., 2015). Child abuse, spouse abuse, or other violent behaviors may occur during severe manic or depressive episodes; thus, patients should be assessed for suicidal or homicidal risk. In addition, they are at high risk for comorbid mental disorders, such as substance abuse and anxiety disorders. Significant risks for cardiovascular and metabolic diseases are found in this group (Grover et al. 2020). Smoking is also a major health hazard (Smith et al., 2020).

Several risk factors associated with bipolar disorders make patients more vulnerable to relapses and resistant to recovery. Among these are high rates of nonadherence to medication therapy, obesity, marital conflict, separation, divorce, unemployment, and underemployment. Even those who take their medication regularly are likely to experience recurrences and may have

difficulty keeping jobs and maintaining significant relationships

Social and Occupational Functioning

One of the tragedies of bipolar disorder is its effect on social and occupational functioning. Individuals with this disorder are often employed, but when unrecognized symptoms erupt, their job is often jeopardized. Manifestations of their symptoms often result in being excluded from social and occupational groups.

Quality of Life

The quality of life for someone with bipolar disorder depends upon their ability to manage their symptoms, maintain meaningful employment, and engage in relationships. Some individuals are able to manage their symptoms, adhere to a treatment plan, and live productive lives. Others struggle with symptoms that interfere with their ability to work and maintain meaningful, supportive relationships.

Strength Assessment

The nurse should always be listening for thoughts, feelings, or behaviors that could be identified as strengths. For example, one patient recognized an increase in drinking alcohol as a sign that he was beginning a manic episode and made an appointment with a health care provider. The following questions may be used to determine a person's strength.

- What healthy behaviors do you routinely practice?
- Are there any cues that a manic or depressive episode will occur?
- Who provides emotional support to you?
- What do you do to relax? Manage stress?
- What makes you feel good when you are on medication?
- How do you remember to take your medications?

CLINICAL JUDGMENT

The priority of nursing care is always patient safety. Is the patient likely to self-injure or hurt another person? See [Chapter 20](#). After the patient's safety is established, the nurse analyzes the assessment data for other priorities. For example, sleep deprivation, inadequate nutrition, and dehydration may be imminent needs. The person may be depressed or manic and unable to function socially. The person's coping skills may not be effective, and the person's job may be in jeopardy.

THERAPEUTIC RELATIONSHIP

Interacting with a person with mania is interesting and, at times, exhausting. The individual often quickly jumps from subject to subject and is usually unable to sit still. When in a manic state, the individual can be very engaging and intense. Their stories may be very grandiose. The nurse should acknowledge the verbal content but recognize that many of the thoughts, feelings, and behaviors are symptomatic of mania and then try to re-focus the patient. If a person is in a depressive state, the nurse should use the same approach as when caring for a person with a depressed disorder as discussed in [Chapter 25](#).

People with mania are typically impatient with others and may express irritability at someone's perceived incompetence and lack of understanding of their special powers. When interacting with a person with bipolar disorder, the nurse should remain calm and avoid any arguments. This is not the time to confront the person about their unrealistic perceptions of their status. For example, one agitated person was convinced that he owned a hotel. The nurse acknowledged how difficult it must be to have such responsibilities. He agreed with her and subsequently became less agitated. See [Box 26.4](#).

BOX 26.4

Interacting with a Person with Mania

- Use a calm, nonthreatening approach.
- Be direct and use simple commands (e.g., time for lunch, let's go to group).

- Avoid open-ended sentences; redirect conversation if flight of ideas occurs; avoid confrontation and arguments.
- Limit interaction time and recognize the patient's need for space and movement.
- Do not place demands on patients that may be interpreted as excessive.

In some instances, a person who has mania cannot sit still long enough to have a meaningful interaction. The nurse can initiate a conversation while walking with the patient, but there will be times when the nurse needs to give the patient space to avoid increasing agitation.

A therapeutic relationship can actually be instrumental in preventing a relapse. When a person is in the depths of a depression or the height of mania, therapeutic interaction is critical in helping the person take steps in recovery from either the depression or mania. However, often long periods of time pass when the affected person is living comfortably with bipolar disorder and attending to other issues.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

The person with a bipolar disorder has emotional ups and downs with periods of poor judgment and erratic behavior. However, there are many periods (months to years) where there are few symptoms. The periods of stable mental health are perfect times to focus on stress reduction, illness management, and relapse prevention. During these relatively quiet periods, it is possible to establish recovery and wellness goals. Goals focus on managing the long-term illness and supporting well-being. Recovery and wellness goals are interrelated. For example, preventing relapse includes managing stress (wellness dimension) that can trigger erratic behavior (mental health goals).

Physical Care

In a state of mania, the patient's physical needs are rest, adequate hydration and nutrition, and reestablishment of physical well-being. Self-care has usually deteriorated. For a patient unable to sit long enough to eat, snacks and high-energy foods that can be eaten while moving should be provided. Consumption

of alcohol should be avoided. Sleep hygiene is a priority but may not be realistic until medications have taken effect. Limiting stimuli can be helpful in decreasing agitation and promoting sleep.

NCLEXNOTE Protection of patients with mania is always a priority. Ongoing assessment should focus on irritability, fatigue, and the potential for harming self or others.

After the patient's mood stabilizes, the nurse should focus on monitoring changes in physical functioning in sleep or eating behavior and teaching patients to identify antecedents to mood episodes such as a family argument or a financial problem. Strategies for dealing with future events can then be identified. The patient can begin to problem solve the best approach for future episodes.

A regular sleep routine should be maintained if possible. High-risk times for manic episodes, such as changes in work schedule (day to night), should be avoided if possible. Patients should be encouraged to monitor the amount of their sleep each night and report decreases in sleep of longer than 1 hour per night because this may be a precursor to a manic episode.

Highlighting the recovery concept of hope will support the person who has had multiple episodes and is frustrated with the impact of several episodes ([Box 26.5](#)). In educating persons with bipolar disorder, the nonlongitudinal nature of the disorder should be emphasized.

Wellness Challenges

Many self-care interventions that prevent or delay symptoms are also wellness strategies. For example, individuals with bipolar disorder who relapse often describe a stressful life event that led to the manic episode. These individuals appear to be more sensitive to life events than people without the disorder. The emotional dimension of wellness focuses on developing skills for coping with stress. If the individuals can strengthen their coping skills, they may be able to be less sensitive to stressful life events. See [Box 26.6](#).

Medication Interventions

Medications are essential in bipolar disorder to achieve two goals: rapid control of symptoms and prevention of future episodes or, at least, reduction in their severity and frequency.

Mood-Stabilizing Drugs

The mainstays of pharmacotherapy are the mood-stabilizing drugs, including lithium carbonate (Lithium), divalproex sodium (Depakote), carbamazepine (Tegretol), and lamotrigine (Lamictal). Antidepressant therapy is not recommended in persons with bipolar depression because of a risk of switching from depression to mania.

Lithium Carbonate

Lithium is the most widely used mood stabilizer ([Box 26.7](#)). Combined response rates from five studies demonstrate that 70% of patients experienced at least partial improvement with lithium therapy. However, for many patients, lithium is not a fully adequate treatment for all phases of the illness, and particularly during the acute phase, supplemental use of antipsychotics and benzodiazepines is often beneficial ([Table 26.1](#)).

BOX 26.5 • THERAPEUTIC DIALOGUE: INSTILLING HOPE

Christine is sitting in the dayroom of an inpatient unit with tears in her eyes. She acknowledges that she has bipolar disorder and wishes that she had been taking her medication and told her husband about her previous relapses.

INEFFECTIVE APPROACH

Nurse: Christine, I am glad that you realize that you have bipolar disorder and want to take your medication. You must commit to staying on your

medicine, or you will lose your second husband.

Christine: No one understands what it is like to have this problem. I don't quite understand how this little pill and seeing a shrink will help.

Nurse: Well, medication and therapy will help.

Christine: You don't know what I am talking about.

Effective Approach

Nurse: Christine, I hope that you are feeling better.

Christine: No one understands what it is like to have this problem. I don't quite understand how this little pill and seeing a shrink will help.

Nurse: Let's talk about it. What does it feel like to have bipolar disorder?

Christine: Sometimes it is wonderful—on top of the world, but after the mood goes away, having this problem is terrible. The bad times outweigh the good feelings.

Nurse: Other people have said the same thing. Many people decide to take their medication and “check in” with a mental health provider in order to stay on track and avoid the bad times that can happen after a manic period.

Christine: Really?

Nurse: There are many successful people with bipolar disorder who find that taking medication helps keep order in their life. I can give you information about a support group.

Christine: Ok, I'm willing to try.

Nurse: Now, what about this medication. Are you willing to try it also? This medication is an effective treatment for bipolar disorder and has helped others to control moods.

Christine: Okay, but I want to know more about this medication.

Nurse: It's a deal. We can spend some time talking about your medications after dinner.

Critical Thinking Challenge

- How did the nurse block communication with Christine in the first scenario? Did she seem hopeful after the interaction?
- How did the nurse instill hope in Christine in the second scenario?

BOX 26.6

Wellness Challenges

- Reducing emotional responses to daily stresses
 - Strategies: Re-frame experiences, use problem-focused coping techniques, relaxation
- Supporting positive circadian rhythms consistent with relapse prevention needs
 - Establish sleep hygiene, eating routines
- Establishing a healthy diet with reducing substance use
 - Eat at regular times, maintain a healthy diet
- Seeking pleasant environments that support well-being
 - Strategies: Seek comfortable, relaxing living arrangements, explore community resources that support people with bipolar disorder
- Satisfying current and future financial situations
 - Strategies: Seek financial counseling, protect resources during periods of relapses
- Satisfying and enriching work
 - Strategies: Select job opportunities that are consistent with health promotion activities
- Recognizing the need for physical activity, healthy foods, and sleep
 - Strategies: Encourage regular physical activity, discuss healthy diets, encourage establishing healthy sleep hygiene routines
- Developing a sense of connection, belonging, and a support system
 - Strategies: Explore expanding a positive support system
- Expanding a sense of purpose and meaning in life
 - Strategies: Focus on goals, values, and beliefs; read inspiring stories or essays

BOX 26.7

Drug Profile: Lithium Carbonate

DRUG CLASS: Mood stabilizer

RECEPTOR AFFINITY: Alters sodium transport in nerve and muscle cells, increases norepinephrine uptake and serotonin receptor sensitivity, slightly increases intraneuronal stores of catecholamines, and delays some second messenger systems. Mechanism of action is unknown.

INDICATIONS: Treatment and prevention of manic episodes in bipolar affective disorder.

ROUTES AND DOSAGE: 150-, 300-, and 600-mg capsules. Lithobid, 300-mg slow-release tablets; Eskalith CR, 450-mg controlled-release tablets; lithium citrate, 300-mg/5 mL liquid form.

Adults: In acute mania, optimal response is usually 600 mg TID or 900 mg BID. Obtain serum levels twice weekly in acute phase. Do not rely on serum levels alone. Maintenance: Use lowest possible dose to alleviate symptoms and maintain serum level of 0.6 to 1.2 mEq/L. In uncomplicated maintenance, obtain serum levels every 2 to 3 months. Monitor patient's side effects.

Geriatric: Increased risk for toxic effects; use lower doses; monitor frequently.

Children: 6 to 12 years: 15 to 60 mg/kg/day in 3 to 4 divided doses.

HALF-LIFE (PEAK EFFECT): Mean, 24 hours (peak serum levels in 1 to 4 hours). Steady state reached in 5 to 7 days.

SELECTED ADVERSE REACTIONS: Weight gain.

WARNING: Avoid use during pregnancy or while breastfeeding. Hepatic or renal impairments increase plasma concentration.

SPECIFIC PATIENT/FAMILY EDUCATION

- Avoid alcohol and other CNS depressant drugs.
- Notify your prescriber if pregnancy is possible or planned. Do not breastfeed while taking this medication.
- Notify your prescriber before taking any other prescriptions, OTC medications, or herbal supplements.
- May impair judgment, thinking, or motor skills; avoid driving or other hazardous tasks.
- Do not abruptly discontinue use.
- BID, twice a day; CNS, central nervous system; OTC, over-the-counter; TID, three times a day.

NCLEXNOTE Monitoring blood levels of lithium carbonate and divalproex sodium is an ongoing nursing assessment for patients receiving these medications. Side effects of mood stabilizers vary.

Lithium is a salt; the interaction between lithium levels and sodium levels in the body and the relationship between lithium levels and fluid volume in the body remain crucial issues in its safe, effective use. The higher the sodium levels, the lower the lithium level will be and vice versa. Thus, changes in dietary sodium intake can affect lithium blood levels that, in turn, may affect therapeutic results or increase the incidence and severity of side effects. The same principle applies to fluid volume. If body fluid decreases significantly because of hot weather, strenuous exercise, vomiting, diarrhea, or drastic reduction in fluid intake for any reason, then lithium levels can rise sharply, causing an increase in side effects, progressing to lethal lithium toxicity. The key is to start with a lower dose and then increase it slowly to maximize the therapeutic response and avoid overshooting the therapeutic window. See [Table 26.2](#) for lithium interactions with other drugs. See [Chapter 12](#) for further discussion of lithium's possible mechanisms of action, pharmacokinetics, side effects, and toxicity.

TABLE 26.1 LITHIUM BLOOD LEVELS AND ASSOCIATED SIDE EFFECTS

Plasma Level	Side Effects or Symptoms of Toxicity
--------------	--------------------------------------

<1.5 mEq/L Mild side effects	
---------------------------------	--

	Metallic taste in mouth Fine hand tremor (resting) Nausea Polyuria Polydipsia Diarrhea or loose stools Muscular weakness or fatigue Weight gain Edema Memory impairments
--	---

1.5–2.5 mEq/L Moderate toxicity	
------------------------------------	--

	Severe diarrhea Dry mouth Nausea and vomiting Mild to moderate ataxia Incoordination Dizziness, sluggishness, giddiness, vertigo Slurred speech Tinnitus Blurred vision Increasing tremor Muscle irritability or twitching Asymmetric deep tendon reflexes Increased muscle tone
--	--

>2.5 mEq/L Severe toxicity	
-------------------------------	--

	Cardiac arrhythmias Blackouts Nystagmus Coarse tremor Fasciculations Visual or tactile hallucinations Oliguria, renal failure Peripheral vascular collapse Confusion Seizures Coma and death
--	--

TABLE 26.2 LITHIUM INTERACTIONS WITH MEDICATIONS AND OTHER SUBSTANCES

Substance	Effect of Interaction
ACE inhibitors, such as: <ul style="list-style-type: none"> • Captopril • Lisinopril • Quinapril 	Increase serum lithium; may cause toxicity and impaired kidney function
Acetazolamide	Increases renal excretion of lithium; decreases lithium levels
Alcohol	May increase serum lithium level
Caffeine	Increases lithium excretion; increases lithium tremor
Carbamazepine	Increases neurotoxicity despite normal serum levels and dosage
Fluoxetine	Increases serum lithium levels
Haloperidol	Increases neurotoxicity despite normal serum levels and dosage
Loop diuretics, such as furosemide	Increase lithium serum levels but may be safer than thiazide diuretics; potassium-sparing diuretics (e.g., amiloride, spironolactone) are safest
Methyldopa	Increases neurotoxicity without increasing serum lithium levels
NSAIDs, such as <ul style="list-style-type: none"> • Diclofenac • Ibuprofen • Indomethacin • Piroxicam 	Decrease renal clearance of lithium Increase serum lithium levels by 30%–60% in 3–10 days Aspirin and sulindac do not appear to have the same effect
Osmotic diuretics, such as: <ul style="list-style-type: none"> • Urea • Mannitol • Isosorbide 	Increase renal excretion of lithium and decreases lithium levels
Sodium chloride	High sodium intake decreases lithium levels; low sodium diets

may increase lithium levels and lead to toxicity

Thiazide diuretics, such as Promote sodium and potassium excretion; increase lithium serum levels; may produce cardiotoxicity and neurotoxicity

- Chlorothiazide
- Hydrochlorothiazide

TCAs Increases tremor; potentiates pharmacologic effects of tricyclic antidepressants

Note. ACE, angiotensin-converting enzyme; NSAID, nonsteroidal anti-inflammatory drug; TCA, tricyclic antidepressant.

Lithium toxicity can range from mild to severe, requiring immediate medical attention and prompt intervention. *Mild toxicity* symptoms include lethargy, drowsiness, coarse hand tremor, muscle weakness, nausea, vomiting, and diarrhea. *Moderate toxicity* is associated with confusion, dysarthria, nystagmus, myoclonic twitches, and ECG changes. *Severe toxicity* is life-threatening and associated with grossly impaired consciousness, increased deep tendon reflexes, seizures, syncope, renal insufficiency, coma, and death.

Lithium toxicity can be caused by an overdose (ingesting a large amount at one time) or by other effects of concomitant medications that increase blood concentrations of lithium, such as loop diuretics, ACE inhibitors, or NSAIDs. Chronic kidney disease increases the risk of toxicity, and use of lithium increases the risk of chronic kidney disease. Renal function generally declines with long-term use of lithium. Treatment includes maintaining airway, managing changes in consciousness, inserting a nasogastric tube, and performing gastric lavage. Hemodialysis may be necessary (Tobita et al, 2020).

EMERGENCY CARE ALERT! If symptoms of moderate or severe toxicity (e.g., cardiac arrhythmias, blackouts, tremors, seizures) are noted, withhold additional doses of lithium, immediately obtain a blood sample to analyze the lithium level, and push fluids if the patient can take fluids. Contact the physician for further direction about relieving the symptoms.

Mild side effects tend to subside or can be managed by nursing measures (Table 26.3).

Concept Mastery Alert

Fine tremors are mild side effects of lithium. They are made worse by stress, so the nurse should assist the client in minimizing exposure to stressors. Lithium therapy can continue unless the tremors interfere with the client's quality of life.

TABLE 26.3 INTERVENTIONS FOR LITHIUM SIDE EFFECTS

Side Effect	Intervention
Edema of feet or hands	Monitor intake and output of water; check for possible decreased urinary output Monitor sodium intake Patient should elevate legs when sitting or lying Monitor weight
Fine hand tremor	Provide support and reassurance if it does not interfere with daily activities Tremor worsens with anxiety and intentional movements; minimize stressors Notify prescriber if tremor interferes with patient's work so that compliance may be an issue More frequent smaller doses of lithium may also help
Mild diarrhea	Take lithium with meals Provide for fluid replacement Notify prescriber if it worsens; may need a change in medication preparation or may be early sign of toxicity
Muscle weakness, fatigue, or memory and concentration difficulties	Provide support and reassurance; this side effect will usually pass after a few weeks of treatment. Short-term memory aids such as lists or reminder calls may be helpful Notify prescriber if side effect becomes severe or interferes with the patient's desire to continue treatment
Metallic taste	Suggest sugarless candies or throat lozenges Encourage frequent oral hygiene
Nausea or abdominal discomfort	Consider dividing the medication into smaller doses or giving it at more frequent intervals

Polydipsia	Give medication with meals Reassure patient that this is a normal mechanism to cope with polyuria
Polyuria	Monitor intake and output Provide reassurance and explain the nature of this side effect Explain that this side effect causes no physical damage to the kidneys
Toxicity	Withhold medication Notify prescriber Use symptomatic treatments

Divalproex Sodium

Divalproex sodium (Depakote), an anticonvulsant, has a broader spectrum of efficacy and has about equal benefit for patients with pure mania as for those with other forms of bipolar disorder (i.e., mixed mania, rapid cycling, comorbid substance abuse, and secondary mania) (Box 26.8). The recommended initial dose is 750 mg daily, increase as rapidly as possible to achieve therapeutic response or desired plasma level. The maximum recommended dosage is 60 mg/kg/day (Depakote Prescribing Information, 2019). Divalproex is usually initiated at 250 mg twice a day or lower. In the inpatient setting, it can be initiated in baseline liver function tests and a complete blood count with platelets should be obtained before starting therapy, and patients with known liver disease should not be given divalproex sodium. The black box warns of hepatotoxicity. Optimal blood levels appear to be in the range of 50 to 150 ng/mL. Levels should be obtained weekly until the patient is stable and then every 6 months. Divalproex sodium is associated with increased risk for birth defects. Cases of life-threatening pancreatitis have been reported in adults and children receiving valproate, both initially and after several years of use. Some cases were described as hemorrhagic, with a rapid progression from onset to death. If pancreatitis is diagnosed, valproate use should be discontinued (Depakote Prescribing Information, 2019).

BOX 26.8

Drug Profile: Divalproex Sodium (Depakote)

DRUG CLASS: Antimanic agent.

RECEPTOR AFFINITY: Thought to increase level of inhibitory neurotransmitter, GABA, to brain neurons. Mechanism of action is unknown.

INDICATIONS: Mania, epilepsy, migraine.

ROUTES AND DOSAGE: Available in 125-mg delayed-release capsules, and 125-, 250-, and 500-mg enteric-coated tablets.

Adult Dosage: Dosage depends on symptoms and clinical picture presented; initially, the dosage is low and gradually increased, depending on the clinical presentation.

HALF-LIFE (PEAK EFFECT): 6 to 16 hours (1–4 hours).

SELECTED ADVERSE REACTIONS: Sedation, tremor (may be dose related), nausea, vomiting, indigestion, abdominal cramps, anorexia with weight loss, slight elevations in liver enzymes, hepatic failure, thrombocytopenia, transient increases in hair loss.

BOXED WARNING: Hepatotoxicity, teratogenicity, pancreatitis.

WARNING: Use cautiously during pregnancy and lactation. Contraindicated in patients with hepatic disease or significant hepatic dysfunction. Administer cautiously with salicylates; may increase serum levels and result in toxicity.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Take with food if gastrointestinal upset occurs.
- Swallow tablets or capsules whole to prevent local irritation of mouth and throat.
- Notify your prescriber before taking any other prescription or OTC medications or herbal supplements.
- Avoid alcohol and sleep-inducing OTC products.
- Avoid driving or performing activities that require alertness.
- Do not abruptly discontinue use.
- Keep appointments for follow-up, including blood tests to monitor response.
- GABA, gamma-aminobutyric acid; OTC, over-the-counter.

Carbamazepine

Carbamazepine, an anticonvulsant, also has mood-stabilizing effects. Data from various studies suggest that it may be effective in patients who experience no response to lithium. The most common side effects of carbamazepine are dizziness, drowsiness, nausea, and vomiting, which may be avoided with slow incremental dosing. Carbamazepine has a boxed warning for aplastic anemia and agranulocytosis, but frequent clinically unimportant decreases in white blood cell counts also occur. Estimates of the rate of severe blood dyscrasias vary from 1 in 10,000 patients treated to a more recent estimate of 1 in 125,000 (Schatzberg & DeBattista, 2019). Mild, nonprogressive elevations of liver function test results are relatively common. Carbamazepine is associated with increased risk for birth defects.

In patients older than 12 years, carbamazepine is begun at 200 mg once or

twice a day. The dosage is increased by no more than 200 mg every 2 to 4 days, to 800 to 1,000 mg a day or until therapeutic levels or effects are achieved. It is important to monitor for blood dyscrasias and liver damage. Liver function tests and complete blood counts with differential are the minimal pretreatment laboratory tests, and they should be repeated about 1 month after initiating treatment and at 3 months, 6 months, and yearly. Other yearly tests assessments should include electrolytes, blood urea nitrogen, thyroid function tests, urinalysis, and eye examinations. Carbamazepine levels are measured monthly until the patient is on a stable dosage. Studies suggest that blood levels in the range of 8 to 12 ng/mL correspond to therapeutic efficacy. See [Table 26.4](#) for carbamazepine's interactions with other drugs. See [Chapter 12](#) for further discussion of carbamazepine's possible mechanisms of action, pharmacokinetics, side effects, and toxicity.

EMERGENCY CARE ALERT! Both valproate and carbamazepine may be lethal if high doses are ingested. Toxic symptoms appear in 1 to 3 hours and include neuromuscular disturbances, dizziness, stupor, agitation, disorientation, nystagmus, urinary retention, nausea and vomiting, tachycardia, hypotension or hypertension, cardiovascular shock, coma, and respiratory depression.

TABLE 26.4 SELECTED MEDICATION INTERACTIONS WITH CARBAMAZEPINE

Interaction	Drug Interacting with Carbamazepine
Increased carbamazepine levels	Erythromycin Cimetidine Propoxyphene Isoniazid Calcium channel blockers (verapamil) Fluoxetine Danazol Diltiazem Nicotinamide
Decreased carbamazepine levels	Phenobarbital

Drugs whose levels are decreased by carbamazepine

Primidone
Phenytoin
Oral contraceptives
Warfarin, oral anticoagulants
Doxycycline
Theophylline
Haloperidol
Divalproex sodium
Tricyclic antidepressants
Acetaminophen: increased metabolism but also increased risk for hepatotoxicity

Lamotrigine

For a depressive episode, mood stabilizers such as lamotrigine (Lamictal), which requires a dose titration are frequently prescribed ([Box 26.9](#)). Lamotrigine is approved by the U.S. Food and Drug Administration (FDA) for the maintenance treatment of bipolar disorder. It may be particularly effective for rapid cycling and in the depressed phase of bipolar illness. If lamotrigine is given with valproic acid (Depakote), the dose should be reduced. Valproic acid decreases the clearance of lamotrigine. Lamotrigine does have an FDA black box warning for rash. Nurses should be especially vigilant for the appearance of any rash. If a rash does appear, it is most likely benign. However, it is not possible to predict whether the rash is benign or serious (Stevens–Johnson syndrome).

BOX 26.9

Drug Profile: Lamotrigine (Lamictal)

DRUG CLASS: Antiepileptic

RECEPTOR AFFINITY: Lamotrigine has a weak inhibitory effect on the serotonin 5-HT₃ receptor. It does not exhibit high-affinity binding: adenosine A₁ and A₂; adrenergic α_1 , α_2 , and β ; dopamine D₁ and D₂; GABA-A and -B; histamine H₁; kappa opioid; muscarinic acetylcholine; and serotonin 5-HT₂.

INDICATIONS: Epilepsy, bipolar disorder (acute mood with standard therapy).

ROUTES AND DOSAGE: Available in tablets: 25, 100, 150, and 200 mg scored.

CHEWABLE DISPERSIBLE TABLETS: 2, 5, and 25 mg.

HALF-LIFE (PEAK EFFECT): 32 hours, but can be increased if taking valproate.

SELECTED ADVERSE REACTIONS: Dizziness, somnolence, and other symptoms and signs of CNS depression.

BOXED WARNING: Lamotrigine can cause serious rashes requiring hospitalization and discontinuation of treatment. The incidence of these rashes, which have included Stevens–Johnson syndrome, is approximately 0.3% to 0.8% in pediatric patients (aged 2–17 years) and 0.08% to 0.3% in adults receiving LAMICTAL.

WARNING: Hypersensitivity reaction, multiorgan failure, blood dyscrasias, and suicidal behavior and ideation have occurred.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Do not drive a car or operate other complex machinery until you have gained sufficient experience taking lamotrigine.
- Lamotrigine may cause a serious rash that may cause you to be hospitalized or to stop taking lamotrigine; it may rarely cause death.
- CNS, central nervous system; GABA, gamma-aminobutyric acid.

Antipsychotics

Several atypical antipsychotics that were primarily developed for the treatment of schizophrenia are also FDA approved for treatment of various symptoms of bipolar disorder. See [Table 26.5](#). The dosages for the treatment of patients with bipolar disorder are generally lower than for those for schizophrenia. Recently, these agents have become a mainstay of treatment because they provide some of the broadest efficacy and are more likely used as the only medication to treat bipolar disorder than the mood stabilizers. Complications such as neuroleptic malignant syndrome can occur if antipsychotics are used in treating the mood disorder. An overview of antipsychotics is presented in [Chapter 12](#), and they are discussed in detail in [Chapter 25](#).

Administering and Monitoring Medications

During acute mania, patients may not believe that they have a psychiatric disorder and may refuse to take medication. Because their energy level is still high, they can be very creative in avoiding medication. Through patience and the development of a trusting relationship, patients will more likely begin to participate in a shared decision-making process. It is important for patients to have a sense of empowerment and participation in treatment even during the most acute episodes. After patients begin to take medications, symptom improvement should be evident. If a patient is very agitated, a benzodiazepine may be given for a short period.

Monitoring Side Effects

Patients with bipolar disorder order are usually treated with several medications. In addition, patients may be taking other “nonpsychiatric” medications. In some instances, one agent is used to augment the effects of another, such as supplemental thyroid hormone to boost antidepressant response in depression. Possible side effects for each medication should be listed and cross-referenced. When a side effect appears, the nurse should document the side effect and notify the prescriber so that further evaluation can be made. In some instances, medications should be changed.

Management of Complications

It is a well-established practice to combine mood stabilizers with antidepressants or antipsychotics. The previously discussed drug interactions should be considered when caring for a person with bipolar disorder. One big challenge is monitoring alcohol, drugs, over-the-counter (OTC) medications, and herbal supplements. A complete list of all medications should be maintained and evaluated for any potential interaction.

TABLE 26.5 FOOD AND DRUG ADMINISTRATION-APPROVED ANTIPSYCHOTICS FOR THE TREATMENT OF SYMPTOMS OF BIPOLAR DISORDER

Antipsychotic

Agent	FDA Indication for Bipolar Disorder	Adult Dosage
Aripiprazole (Abilify)	Acute treatment of manic and mixed episodes associated with bipolar disorder	10–30 mg/day
Aripiprazole (Abilify Maintena)	Maintenance monotherapy for treatment for bipolar I disorder in adults	300 mg monthly (extended-release, injectable suspension)
Asenapine (Saphris)	Acute treatment of manic or mixed episodes associated with bipolar I disorder as monotherapy or adjunctive treatment to lithium or valproate	5–10 mg BID
Cariprazine Vraylar	Acute treatment of manic or mixed episodes associated with bipolar I disorder in adults	3–6 mg/day
Lurasidone (Latuda)	Depressive episodes associated with bipolar I disorder as monotherapy or as adjunctive treatment to lithium or valproate	20–120 mg daily with food (comprising 350 calories)

Olanzapine (Zyprexa)	Acute treatment of manic or mixed episodes associated with bipolar I disorder (monotherapy and in combination with lithium or valproate) and maintenance treatment of bipolar I disorder	10–15 mg daily
Quetiapine (Seroquel)	Bipolar I disorder, manic or mixed episodes; bipolar disorder, depressive episodes	300–800 mg daily
Risperidone (Risperdal)	Bipolar mania, combination of risperidone with lithium or valproate for short-term treatment of acute manic or mixed episodes associated with bipolar I disorder	2–6 mg daily
Risperidone (Risperdal Consta)	Monotherapy or adjunctive to lithium or valproate for maintenance treatment of bipolar I disorder	25–50 mg every 2 weeks (extended-release, injectable suspension)
Ziprasidone (Geodon)	Acute manic or mixed episodes associated with bipolar disorder, with or without psychotic features	40–80 mg with food (comprising 500 calories)

Note. FDA, U.S. Food and Drug Administration.

Promoting Adherence

Adherence to a complex medication regimen over months to years is difficult. Yet one of the primary reasons that acute symptoms reappear is because of discontinuation of medications. It is important to recognize that taking medication as prescribed over time is difficult. Nurses can help patients and families incorporate taking medications into their lifestyles by developing realistic plans. The use of pillboxes, reminders, and other cues will increase the likelihood of adherence.

Teaching Points

For patients who are taking lithium, it is important to explain that a change in dietary salt intake can affect the therapeutic blood level. If salt intake is reduced, the body will naturally retain lithium to maintain homeostasis. This increase in lithium retention can lead to toxicity. After the patient has been stabilized on a lithium dose, salt intake should remain constant. This is fairly easy to do except during the summer, when excessive perspiration can occur. Patients should increase salt intake during periods of perspiration, increased exercise, and dehydration. Most mood stabilizers and antidepressants can cause weight gain. Patients should be alerted to this potential side effect and should be instructed to

monitor any changes in eating, appetite, or weight. Weight reduction techniques may need to be instituted. Patients should also be clearly instructed to check with the nurse or physician before taking any OTC medications, herbal supplements, or other complementary and alternative treatment approaches.

Other Somatic Therapies

Electroconvulsive therapy (ECT) may be a treatment alternative for patients with severe mania who exhibit unrelenting, frenzied physical activity. Other indications for ECT are acute mania that is unresponsive to antimanic agents or high suicide risk. ECT is safe and effective in patients receiving antipsychotic drugs. Use of valproate or carbamazepine will elevate the seizure threshold, requiring some adjustments in treatment.

Transcranial magnetic stimulation is another option for bipolar depression. Most of the research has focused on depressive phase rather than the mania episode. There may be cognitive benefits, such as improvement in verbal fluency, memory, and executive functioning. The research is ongoing (Gold et al., 2019).

Psychosocial Interventions

Medications are necessary for treatment of bipolar disorder, but it is only one aspect of recovery. Psychosocial strategies are critical in successful treatment and prevention of relapse.

Therapeutic Interactions

Through therapeutic interaction, treatment and recovery strategies are developed. It is also important to help the patient understand the disorder and manage the mood lability and dysfunctional thoughts that are often precursors to a manic or depressive episode. The nurse partners with the patient in developing strategies to remember to take medications, identify therapeutic and side effects, and know when and how to contact a clinician. Particularly important are enhancing social and occupational functioning, improving quality of life, increasing the patient and family's acceptance of the disorder, and reducing suicide (Crowe et al., 2016).

Enhancing Cognitive and Behavioral Functioning

Individual cognitive-behavioral therapy, individual interpersonal therapy, and adjunctive therapies (such as those for substance use) are all recommended psychotherapeutic approaches.

There is emerging evidence supporting the use of interpersonal and social rhythm therapy and sleep/light manipulation targeting social rhythms to promote mood stability. The goals of this approach are to stabilize daily social rhythms that impact circadian rhythms, understand the link between mood and regularity of social rhythms, and develop self-awareness of bipolar disorder, chronodisruptors, early warning signs, and effective actions to take (Crowe et al., 2016, 2020).

Psychoeducation

Teaching Strategies

Psychoeducation is designed to provide information on bipolar disorder and its successful treatment and recovery. The nurse provides information about the illness and obstacles to recovery. In the interest of improved medication adherence, listening carefully to the patient's concerns about the medication, dosing schedules and dose changes, and side effects helps individualize teaching approaches. Resistance to accepting the illness and taking medication, the symbolic meaning of medication taking, and worries about the future are discussed openly. See [Box 26.10](#).

BOX 26.10

Psychoeducation Checklist: Bipolar I Disorder

When caring for the patient with a bipolar I disorder, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents, including drug action, dosage, frequency, and possible side effects
- Medication regimen adherence
- Recovery plan
- Relapse prevention plan
- Strategies to decrease agitation and restlessness
- Safety measures
- Self-care management
- Follow-up laboratory testing

- Support services

Teaching About Symptoms

Helping the patient recognize warning signs and symptoms of relapse, cope with residual symptoms, and improve functional impairments are important interventions. Watching for early warning signs and triggers can mean early treatment. Family members should be included in developing an emergency plan for recognizing and intervening if relapse symptoms occur. See [Box 26.11](#).

BOX 26.11

Relapse Prevention and Emergency Plan

COMMON INDICATORS FOR RELAPSE

Mania

Reading several books or newspapers at once
Cannot concentrate on one topic
Talking faster than usual
Feeling irritable
Hungry all the time
Friends remark on changes in mood
More energy than usual

Depression

Quit cooking, cleaning, daily chores
Avoid people
Crave foods (e.g., chocolate)

Headaches

Do not care about other people
Sleeping more or restless sleep
People are irritating to be around

EMERGENCY PLAN

Keep a list of emergency contacts (primary health care provider, close family members)
Keep a current list of all medications, including their dosages

Information about other health problems Symptoms that indicate others need to take responsibility for care Treatment preferences (who, where, medications, advanced directive location)

Wellness Strategies

Mental health promotion activities should be the focus during remissions. During this period, patients have an opportunity to learn new coping skills that promote positive mental health. Stress management and relaxation techniques can be practiced for use when needed. A plan for managing emerging symptoms can also be developed during this period.

Social Skills Training

Social skills training may or may not be needed for the person with a bipolar disorder. Even though their social skills will be impaired during periods of mania or depression, once symptoms are controlled, the individual should return to previous level of functioning. There are instances when an individual does need help with social skills, such as learning to listen to others, taking time to finish projects, and organizing daily living demands of cooking, cleaning, and shopping. For these individuals, a social skills group is useful.

Providing Family Education

Family psychoeducation strategies are particularly useful in decreasing the risk of relapse and hospitalization. The sooner the education is begun, the more effective this approach is (Sampogna et al., 2018). Marital and family interventions are often needed at different periods in the life of a person with bipolar disorder. For the family with a child with this disorder, additional parenting skills are needed to manage the behaviors. The goals of family interventions are to help the family understand and cope with the disorder. Interventions may range from occasional counseling sessions to intensive family therapy.

Promoting Safety

The safety issues previously discussed should be addressed with the individual and family before a manic or depressive episode emerges. The nurse can help the individual and family identify specific thoughts and behaviors associated with unsafe situations. For example, during manic episodes, one patient would often threaten airlines and government officials. Within a therapeutic relationship, the nurse and patient agreed that the first call would be to the nurse or another family member who, in turn, would seek more intensive treatment, such as a medication adjustment.

The individual should keep a safety plan for suicidal ideations close at hand to be used when thoughts occur. Firearms, weapons, and unused lethal medication should be removed from the environment.

Convening Support Groups

Support groups are helpful for people with this disorder. Participating in groups allows the person to meet others with the same disorder and to learn management and preventive strategies. Support groups also are helpful in dealing with the stigma associated with mental illness.

Implementing Milieu Therapy

In the hospital or treatment setting, a calm, therapeutic milieu is usually the responsibility of the nurse. An overly stimulating environment can result in behavior escalation for persons with mania. A noisy unit, frequent demands for group and individual participation and lack of privacy cause an escalation in behavior.

Developing Recovery-Oriented Rehabilitation Strategies

The recovery plan should be developed with the patient and should include treatment for the disorder, mental health promotion strategies, and wellness activities. Building on the person's strengths and resilience will foster a healthy lifestyle and well-being.

Evaluation and Treatment Outcomes

Desired treatment outcomes are stabilization of mood and enhanced quality of life. Primary tools for evaluating outcomes are nursing observation and patient self-report. (Nursing Care Plan 26.1—which sets forth a plan of care for Christine, the case study patient in this chapter—is available at <http://thepoint.lww.com/Boyd7e>.)

Continuum of Care

In today's health care climate, with efforts to reduce hospitalization, most patients with bipolar disorder are treated in a community setting. Hospitalizations are usually brief; recovery is emphasized, and medication regimen promotes adherence. Psychoeducation helps in understanding and managing the disorder, and supportive psychotherapy helps these individuals move toward recovery. Patients need extended and continued follow-up to monitor medication trials and side effects, reinforce self-care management, and provide continued psychosocial support.

Emergency Care

Emergency care is necessary during periods of depression or mania, when there are safety issues such as suicidal or homicidal ideation. Agitation and aggression in an emergency department are not unusual, and staff are usually well prepared to de-escalate the situation. Another critical situation when a person is unwillingly brought to the hospital for treatment. Assaults in the emergency departments can lead to patient and staff injuries (Lawrence et al., 2020).

Inpatient-Focused Care

Inpatient hospitalization is necessary for patients who are severely psychotic or who are an immediate threat to themselves or others. In acute mania, nursing interventions focus on patient safety because patients are prone to injury because of hyperactivity and are often unaware of injuries they sustain. Distraction may also be effective when a patient is talking or acting inappropriately. Removal to a quieter environment may be necessary if other interventions have not been

successful, but the patient should be carefully monitored. During acute mania, patients are often impulsive, disinhibited, and interpersonally inappropriate, so the nurse should avoid direct confrontations or challenges.

During manic phases, patients usually violate others' boundaries. For example, roommate selection for patients requiring hospital admittance needs to be carefully considered. If possible, a private room is ideal because patients with bipolar disorder tend to irritate others, who quickly tire of the intrusiveness. These patients may miss the cues indicating anger and aggression from others. The nurse should protect the patient who is manic from self-harm, as well as harm from other patients.

The length of stay in an inpatient unit will be relatively short, 3 to 5 days. The plan of care will focus on medication management, including control of side effects, initiation or revision of a recovery plan, psychoeducation, and promotion of self-care. Nurses should be familiar with drug–drug interactions and with interventions to help control side effects.

Intensive Outpatient Programs

Intensive outpatient programs for several weeks of acute-phase care during a manic or depressive episode are used when hospitalization is not necessary or to prevent or shorten hospitalization. These programs are usually called partial hospitalization. Close medication monitoring and milieu therapies that foster restoration of a patient's previous adaptive abilities are the major nursing responsibilities in these settings.

Setting up frequent office visits and crisis telephone calls are additional nursing interventions that can help shorten or prevent hospitalization during the acute phase of a manic episode. Family sessions or psychoeducation that includes the patient are alternatives. Severely and persistently ill patients may need ongoing intensive treatment, but the frequency of visits can be decreased for patients whose conditions stabilize and who enter the continuation or the maintenance phase of treatment.

Community Care

Persons with bipolar disorder are treated throughout the continuum of care. When symptoms are acute, hospitalization may be necessary. Other times,

minimal interaction with the mental health providers is needed. The individual will need to be seen regularly to monitor symptoms and medications.

Virtual Mental Health Care

The use of telemedicine can be very effective for persons with bipolar disorder during periods of remission. Telephone contacts are a useful strategy for monitoring medication adherence (Basit et al., 2020). The use of telephones is relatively inexpensive and widespread. The use of smartphones allows frequent reminders of medication dosage and is unobtrusive. They can also be used for texting and voice-based mobile interventions.

Integration With Primary Care

There are several reasons that coordination of care is very important for persons with bipolar disorder. A large proportion of persons with bipolar disorder are treated in the primary care setting. There may be an average of 6 to 8 years between onset of symptoms and diagnosis. Because there may be several episodes of depression before there is a manic episode, bipolar disorder is often misdiagnosed as depression in primary care, leading to a delay in treatment. If antidepressants are prescribed for someone with a bipolar disorder, these medications may precipitate a manic episode. The need exists to improve the health of this population. Collaborative care of mental health with primary care increases the likelihood that a person would be screened for bipolar disorder, resulting in an early diagnosis and effective treatment (Cerimele et al., 2019). Patients with bipolar disorder frequently require primary care management for comorbidities, such as cardiovascular and metabolic disorders.

OTHER BIPOLAR AND RELATED DISORDERS

In **bipolar II disorder**, the individual is mostly depressed, which can severely affect their social and occupational life. Even though there are brief periods of elevated, expansive, or irritable moods, bipolar II disorder is not as easily recognized as bipolar I disorder because the symptoms are less dramatic. Hypomania, a mild form of mania, is characteristic of bipolar II disorder.

Judgment remains fundamentally intact.

In a **cyclothymic disorder**, hypomanic symptoms occur alternating with numerous periods of depressive symptoms. However, these symptoms are less severe than the bipolar disorders. To be diagnosed with this disorder, the symptoms have to be present for at least 2 years of numerous periods of hypomanic symptoms.

Illicit drugs, prescription medications, and some medical conditions such as changes in thyroid functioning can be responsible for manic like behavior. These symptoms cause significant distress and impairment in social functioning.

SUMMARY OF KEY POINTS

- Bipolar and related disorders are characterized by one or more manic episodes or mixed mania (co-occurrence of manic and depressive states) that cause marked impairment in social activities, occupational functioning, and interpersonal relationships and may require hospitalization to prevent self-harm.
- In bipolar and related disorders, there are periods of mania or hypomania that alternate with depression. These disorders are classified as bipolar I disorder, bipolar II disorder, or cyclothymic disorder, depending on the severity of the manic and depressive symptoms. Bipolar disorder may also be related to substance abuse, prescription drug use, or a medical condition.
- Manic episodes are periods in which the individual experiences abnormally and persistently elevated, expansive, or irritable mood characterized by inflated self-esteem, decreased need to sleep, excessive energy or hyperactivity, racing thoughts, easy distractibility, and an inability to stay focused. Other symptoms can include hypersexuality and impulsivity.

- Bipolar disorders are underreported and are often misdiagnosed. Bipolar I disorder is more dramatic than bipolar II disorder, so it is easier to diagnose.
- Genetics plays a role in the etiology of bipolar disorders. Risk factors include a family history of mood disorders, prior mood episodes, lack of social support, stressful life events, substance use, and medical problems, particularly chronic or terminal illnesses.
- Mental health nursing assessment includes assessing mood; speech patterns; thought processes and thought content; suicidal or homicidal thoughts; cognition and memory; and social factors, such as patterns of relationships, quality of support systems, and changes in occupational functioning. Several self-report scales are helpful in evaluating depressive symptoms.
- Many symptoms of bipolar depression, such as weight gain and appetite changes, sleep disturbance, decreased energy, and fatigue, are similar to those of medical illnesses. Assessment includes a thorough medical history and physical examination to detect or rule out medical or psychiatric comorbidity.
- Establishing and maintaining a therapeutic nurse–patient relationship is key to successful outcomes. Shared decision-making with the patient leads to positive outcomes. Recovery-oriented nursing interventions that foster the therapeutic relationship include being available in times of crisis, providing understanding and education to patients and their families regarding goals of treatment and recovery, providing encouragement and feedback concerning the patient’s progress, providing guidance in the

patient's interpersonal interactions with others and work environment, and helping to set and monitor realistic goals.

- Pharmacotherapy includes mood stabilizers used alone or in combination with antipsychotics or benzodiazepines to treat psychosis, agitation, or insomnia. Electroconvulsive therapy is a valuable alternative for patients with severe mania that does not respond to other treatments.
- Recent major advances in bipolar disorder treatment research validate the efficacy of integrated psychosocial and pharmacologic treatment involving family or couple therapies, psychoeducational programs, and individual cognitive-behavioral or interpersonal therapies.
- Psychosocial interventions for bipolar disorders include self-care management, cognitive therapy, behavior therapy, interpersonal therapy, patient and family education regarding the nature of the disorder and treatment goals, marital and family therapy, and group therapy that includes medication maintenance support groups and other consumer-oriented support groups.
- The use virtual health care strategies can be very effective in monitoring medication adherence and providing virtual therapy and psychoeducation.

CRITICAL THINKING CHALLENGES

1. A patient tells you that he no longer needs medication because he has special powers that protect him from evil forces. He no longer needs sleep and can see things that others do not see. What approaches would you use to help the

patient decide to take his medication?

2. Describe how you would approach a patient who is expressing concern that the diagnosis of bipolar disorder will negatively affect her social and work relationships.
3. Your patient with mania is experiencing physical hyperactivity that is interfering with his sleep and nutrition. Describe the actions you would take to meet the patient's needs for rest and nutrition.
4. Prepare a hypothetical discussion with a patient with potential bipolar disorder concerning the advantages and disadvantages of lithium versus divalproex sodium for treatment of bipolar disorder.
5. Think about all of the aforementioned situations and relate them to persons from culturally and ethnically diverse populations (e.g., African American, Latinx, or Asian descent; Jewish or Jehovah Witness religions; across the life-span of individuals from children to older adult populations).

Unfolding Patient Stories: Sharon Cole

Part 2

Recall from [Chapter 10](#) Sharon Cole diagnosed with bipolar disorder who is admitted to the orthopedic unit following surgery for a fractured ankle from a fall during a manic episode. She is exhibiting manic behavior postoperatively with grandiose thoughts, irritability, and wanting to leave the hospital. What are the benefits of having a sitter at her bedside? What education would the nurse provide to a sitter without prior experience caring for a client with bipolar disorder and manic behavior? What instructions would promote safety for the patient and the sitter and deter a potentially volatile situation?

Movie Viewing Guides

Silver Linings Playbook (2012). Pat Solatano (Bradley Cooper), a former teacher

and recent divorcee, suffers from bipolar disorder and was recently released from a mental health facility. He moves in with his parents and is determined to win his ex-wife back. This highly acclaimed, romantic comedy depicts the impact of a mental disorder on a person's life and shows that recovery is possible.

SIGNIFICANCE: This movie is a realistic portrayal of the life of someone with bipolar disorder who is struggling to live a happy, healthy, and meaningful life. The viewers can see a day-to-day experience of recovery.

VIEWING POINTS: Identify the role of the courts in the initial treatment of Pat's illness. Discuss the role of nonadherence to medication. How does the illness shape Pat's views of the world? What behaviors are characteristic of persons with bipolar disorder?

Michael Clayton (2007). Arthur Edens (Tom Wilkinson), a successful corporate lawyer, is experiencing the stress of a high-profile legal case and stops taking his medication. Consequently, he has a manic episode with delusions about one of the jurors, whom he eventually contacts. The story traces the attempts by his colleague and friend Michael Clayton (George Clooney) to repair the damage Arthur's behavior has caused to the lawsuit and to get his friend treated before his mania further damages his life.

SIGNIFICANCE: Viewers can gain insight into the devastating impact of mental illness on the successful career of a well-respected attorney. This film depicts the poor judgment, impulsivity, and consequences of a full-blown mania episode.

VIEWING POINTS: Identify the mania symptoms that Arthur displays. What feelings are evoked when you see the strange behavior that he exhibits? If Arthur were your patient, how would you approach him, and what medication would you expect him to be prescribed?

Anxiety Disorders

Nursing Care of Patients with Anxiety, Phobia, and Panic

Mary Ann Boyd

KEY CONCEPTS

- anxiety
- panic
- phobia

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of anxiety and panic in mental disorders.
2. Delineate the clinical symptoms and course of panic disorder, including phobias.
3. Analyze the primary theories explaining panic disorder and their relationship to anxiety.
4. Develop strategies to establish a patient-centered, recovery-oriented

therapeutic relationship with a person with a panic disorder.

5. Apply a person-centered, recovery-oriented nursing process for persons with a panic disorder.
6. Identify medications used to treat people with a panic disorder and evaluate their effectiveness.
7. Develop wellness strategies for persons with a panic disorder.
8. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
9. Discuss the importance of integrated health care for persons with panic disorder.
10. Describe other anxiety disorders.

KEY TERMS

- Agoraphobia
- Depersonalization
- Exposure therapy
- Flooding
- Implosive therapy
- Interoceptive conditioning
- Panic attacks
- Panic control treatment
- Positive self-talk
- Reframing
- Specific phobia disorder
- Social anxiety disorder
- Systematic desensitization

Case Study

Doug is a 50-year-old man who lives with his wife Norma and two sons; Greg, a sophomore in college, and Leon, a high school student. Norma was recently laid off from her job and has been unable to find employment. The family is now experiencing financial and marital problems. Leon was recently expelled from school for drug and alcohol use. Doug had an argument with his boss and is afraid that he will lose his job. He appears at the emergency department for chest pain and is convinced he is having a heart attack. All lab test results are normal. Consider how the nurse can help Doug deal with his health issues.

INTRODUCTION

Anxiety is part of many emotional problems and mental disorders. At one time, most mental conditions with anxiety aspects were categorized as “anxiety disorders,” but today anxiety disorders have been redefined. Trauma–stressor-related disorder and obsessive–compulsive disorder, both previously identified as anxiety disorders, are now categorized as separate disorders (American Psychiatric Association [APA], 2013). Trauma- and stressor-related disorders, as well as dissociative disorders, are discussed in [Chapter 29](#). Obsessive–compulsive disorders are discussed in [Chapter 28](#). In this chapter, panic disorder is highlighted.

NORMAL VERSUS ABNORMAL ANXIETY

RESPONSE

Anxiety is an unavoidable human condition that takes many forms and serves different purposes. Anxiety can be positive and can motivate one to act, or it can produce paralyzing fear, causing inaction. *Normal anxiety* is described as being of realistic intensity and duration for the situation and is followed by relief behaviors intended to reduce or prevent more anxiety (Peplau, 1989). A “normal anxiety response” is appropriate to the situation and can be used to help the individual identify which underlying problem has caused the anxiety.

KEYCONCEPT Anxiety is an uncomfortable feeling of apprehension or dread that occurs in response to internal or external stimuli; it can result in physical, emotional, cognitive, and behavioral symptoms.

During a perceived threat, rising anxiety levels cause physical and emotional changes in all individuals. A normal emotional response to anxiety consists of three parts: physiologic arousal, cognitive processes, and coping strategies. Physiologic arousal, or the fight-or-flight response, is the signal that an individual is facing a threat. Cognitive processes decipher the situation and decide whether the perceived threat should be approached or avoided. Coping strategies are used to resolve the threat. [Box 27.1](#) summarizes many physical, affective, cognitive, and behavioral symptoms associated with anxiety. The factors that determine whether anxiety is a symptom of a mental disorder include the intensity of anxiety relative to the situation, the trigger for the anxiety, and the particular symptom clusters that manifest the anxiety. [Table 27.1](#) describes the four degrees of anxiety and associated perceptual changes and patterns of behavior. Anxiety is a component of all the disorders discussed in this chapter.

PHOBIAS

KEYCONCEPT Phobia is an irrational fear of an object, person, or situation that leads to a compelling avoidance.

The development of a phobia may be the outcome of extreme anxiety. Phobias are often present in anxiety disorders but may also develop into a specific phobia disorder (discussed later).

Defense Mechanisms and Anxiety

Defense mechanisms are used to reduce anxiety by preventing or diminishing unwanted thoughts and feelings. See [Chapter 10](#) for definitions. Defense mechanisms can be helpful in coping with everyday problems, but they become problematic when overused. The first step is identifying a person's use of defense mechanisms. The next step is determining whether the reasons the defense mechanisms are being used support healthy coping or are detrimental to a person's health. What may be healthy for one person may be unhealthy for another. See [Box 27.2](#).

ANXIETY DISORDERS OVERVIEW

The primary symptoms of anxiety disorders are fear and anxiety. Even though symptoms of anxiety disorders can be found in healthy individuals, an anxiety disorder is diagnosed when the fear or anxiety is excessive or out of proportion to the situation. An individual's ability to work and interpersonal relationships may be impaired. Anxiety disorders are differentiated by the situation or objects that provoke fear, anxiety, or avoidance behavior and related cognitive thoughts (APA, 2013).

Anxiety disorders are the most common of the psychiatric illnesses treated by health care providers. Approximately 40 million American adults (older than 18 years old) or about 18.1% of this age group within a given year have an anxiety disorder. Direct and indirect costs of treating anxiety disorders amount to tens of billions of dollars. Women experience anxiety disorders more often than men by a 2:1 ratio. Anxiety disorders may also be associated with other mental or physical comorbidities, such as heart disease, respiratory disease, and mood disorders (Stein et al., 2018). The relationship between depression and anxiety disorders is particularly strong. A single patient may concurrently have more than one anxiety disorder or other psychiatric disorders as well.

Anxiety disorders tend to be chronic and persistent, with full recovery more likely among those who do not have other mental or physical disorders (Andreescu & Lee, 2020). Anxiety disorders tend to first episode in late adolescence or young adult.

Symptoms of Anxiety

PHYSICAL SYMPTOMS

Cardiovascular

Sympathetic

Palpitations

Heart racing

Increased bloodpressure

Parasympathetic

Actual fainting

Decreased bloodpressure

Decreased pulse rate

Respiratory

Rapid breathing

Difficulty getting air

Shortness of breath

Pressure of chest

Shallow breathing

Lump in throat

Choking sensations

Gasping

Spasm of bronchi

Neuromuscular

Increased reflexes

Startle reaction

Eyelid twitching

Insomnia

Tremors

Rigidity

Spasm

Fidgeting

Pacing

Strained face

Unsteadiness

Generalized weakness

Wobbly legs

Clumsy motions

Skin

Flushed face

Pale face

Localized sweating

(palm region)

Generalized sweating

Hot and cold spells

Itching

Gastrointestinal

Loss of appetite

Revulsion about food

Abdominal discomfort

Diarrhea

Abdominal pain

Nausea

Heartburn

Vomiting

Eyes

Dilated pupils

Urinary Tract

Parasympathetic

Pressure to urinate

Increased frequency of

urination

AFFECTIVE SYMPTOMS

Edgy

Impatient

Uneasy

Nervous

Tense

Wound-up

Anxious

Fearful

Apprehensive

Scared

Frightened

Alarmed

Terrified

Jittery

Jumpy

COGNITIVE SYMPTOMS

Sensory-Perceptual

Mind is hazy, cloudy, foggy, dazed

Objects seem blurred or distant

Environment seems different or unreal

Feelings of unreality

Self-consciousness

Hypervigilance

Thinking Difficulties

Cannot recall important things

Confused

Unable to control thinking

Difficulty concentrating

Difficulty focusing

attention

Distractibility

Blocking

Difficulty reasoning

Loss of objectivity and

perspective

Tunnel vision

Conceptual

Cognitive distortion

Fear of losing control

Fear of not being able to

cope

Fear of physical injury or

death

Fear of mental disorder

Fear of

negative evaluations

Frightening visual images

Repetitive fearful ideation

BEHAVIORAL SYMPTOMS

Inhibited

Tonic immobility

Flight

Avoidance

Speech dysfluency

Impaired coordination

Restlessness

Postural collapse

Hyperventilation

TABLE 27.1 DEGREES OF ANXIETY

Effects on Perceptual
Degree of Field and on Ability to

Anxiety	Focus Attention	Observable Behavior
Mild	Perceptual field widens slightly. Able to observe more than before and to see relationships (make connection among data). Learning is possible.	Is aware, alert, sees, hears, and grasps more than before. Usually able to recognize and identify anxiety easily.
Moderate	Perceptual field narrows slightly. Selective inattention: does not notice what goes on peripheral to the immediate focus but can do so if attention is directed there by another observer.	Sees, hears, and grasps less than previously. Can attend to more if directed to do so. Able to sustain attention on a particular focus; selectively inattentive to contents outside the focal area. Usually able to state, "I am anxious now."
Severe	Perceptual field is greatly reduced. Tendency toward dissociation: to not notice what is going on outside the current reduced focus of attention; largely unable to do so when another observer suggests it.	Sees, hears, and grasps far less than previously. Attention is focused on a small area of a given event. Inferences drawn may be distorted because of inadequacy of observed data. May be unaware of and unable to name anxiety. Relief behaviors generally used.
Panic (e.g., terror, horror, dread, uncanniness, awe)	Perceptual field is reduced to a detail, which is usually "blown up," that is, elaborated by distortion (exaggeration), or the focus is on scattered details; the speed of the scattering tends to increase. Massive dissociation, especially of contents of self-system. Felt as an enormous threat to survival. Learning is impossible.	Says, "I'm in a million pieces," "I'm gone," or "What is happening to me?" Perplexity, self-absorption. Feelings of unreality. Flights of ideas or confusion. Fear. Repeats a detail. Many relief behaviors used automatically (without thought). The enormous energy produced by panic must be used and may be mobilized as rage. May pace, run, or fight violently. With dissociation of contents of self-system, there may be a very rapid reorganization of the self, usually going along pathologic lines (e.g., a "psychotic break" is usually preceded by panic).

Box 27.2

Consequences of Decreasing Anxiety Using Defense Mechanisms

Defense

Mechanism

Positive Consequences

Negative Consequences

Altruism	Satisfies internal needs through helping others	Prevents examination of underlying fears or concerns
Denial	Avoids feelings associated with recognizing a problem	Avoidance of major problem that should be addressed
Displacement	By taking out frustrations on an unsuspecting	Does not deal with problem and

	or vulnerable person, animal, or object, anxiety is reduced and the individual is protected from anticipated retaliation from the source of the frustration	inappropriately expresses feelings towards a more vulnerable person or object
Intellectualization	Able to analyze events in a distant, objective, analytical way	Inability to acknowledge feelings that may be interfering with relationships
Projection	By assigning unwanted thoughts, feelings or behaviors to another person or object, the individual does not have to acknowledge undesirable or unacceptable thoughts or feelings	Does not acknowledge undesirable or unwanted feelings or thoughts and can act on inaccurate interpretation of the other person's thoughts and behaviors
Rationalization	Avoids anxiety by explaining an unacceptable or disappointing behavior or feeling in a logical, rational way. May protect self-esteem and self-concept	Avoids the reality of a situation, which may be detrimental to the individual
Reaction Formation	Reduces anxiety by taking the opposite feeling. Hides true feelings, which may be appropriate in many situations	Unable to acknowledge personal feelings about others, which leads to negative consequences
Regression	When stressed, abandons effective coping strategies and reverts to behaviors used earlier in development. These strategies are comfortable and may be effective	May reengage in detrimental behaviors such as smoking, drinking, or inappropriate interpersonal responses leading to ineffective coping
Repression	Avoids unwanted thoughts and anxiety by blocking thoughts, experiences from conscious awareness	Cannot recall traumatic events that should be addressed to be healthy (i.e., rape)
Sublimation	Avoids anxiety and channels maladaptive feelings or impulses into socially acceptable behaviors. Maintains socially acceptable behavior	By not recognizing maladaptive feelings, the individual cannot address underlying feelings
Suppression	Reduces anxiety by intentionally avoiding thinking about disturbing problems, wishes, feelings, or experiences. Useful in many situations such as test-taking situations	Avoiding problem situation prevents finding a solution to the problem

Anxiety Disorders Across the Life Span

Prompt identification, diagnosis, and treatment of individuals with anxiety disorders may be difficult for special populations such as children and older adult patients. Often, the symptoms suggestive of anxiety disorders may go unnoticed by caregivers or are misdiagnosed because they mimic cardiac or

pulmonary pathology rather than a psychological disturbance. Children and adolescents are discussed in [Chapter 37](#); older adults are discussed in [Chapter 38](#).

Children and Adolescents

Anxiety disorders are among the most common conditions of children and adolescents. If left untreated, symptoms persist and gradually worsen and sometimes lead to suicidal ideation and suicide attempts, early parenthood, drug and alcohol dependence, and educational underachievement later in life (Carballo et al., 2020).

Separation anxiety disorder (i.e., excessive fear or anxiety concerning separation from home or attachment figures) usually first occurs in childhood. Affected children experience extreme distress when separated from home or attachment figures, worry about them when separated from them, and worry about untoward events (i.e., getting lost) and what will happen to them. This disorder is discussed in [Chapter 37](#).

A rare disorder typically seen in childhood is selective mutism, in which children do not initiate speech or respond when spoken to by others (APA, 2013). Children with this disorder are often very anxious when asked to speak in school or read aloud. They may suffer academic impairment because of their inability to communicate with others.

Older Adults

Generally speaking, the prevalence of anxiety disorders declines with age. However, in the older adult population, rates of anxiety disorders are as high as mood disorders, which commonly co-occur. This combination of depressive and anxiety symptoms has been shown to decrease social functioning, increase somatic (physical) symptoms, and increase depressive symptoms (Meuret et al., 2020). In one study, nearly half of primary care patients with chronic pain had at least one attendant anxiety disorder. Detecting and treating anxiety is an important component of pain management (Kroenke et al., 2019). Because the older adult population is at risk for suicide, special assessment of anxiety symptoms is essential.

PANIC DISORDER

Panic is an extreme, overwhelming form of anxiety often experienced when an individual is placed in a real or perceived life-threatening situation. Panic is normal during periods of threat but is abnormal when it is continuously experienced in situations that pose no real physical or psychological threat. Some people experience heightened anxiety because they fear experiencing another panic attack. This type of panic interferes with the individual's ability to function in everyday life and is characteristic of panic disorder.

KEYCONCEPT **Panic** is a normal but extremely overwhelming form of anxiety, often experienced when an individual is placed in a real or perceived life-threatening situation.

Clinical Course

The onset of panic disorder is typically between 20 and 24 years of age. The disorder usually surfaces in childhood but may not be diagnosed until later. Panic disorder is treatable, but studies have shown that even after years of treatment, many people remain symptomatic. In some cases, symptoms may even worsen (APA, 2013).

Panic Attacks

Panic attacks are characteristic of panic disorder. A panic attack is a sudden, discrete period of intense fear or discomfort that reaches its peak within a few minutes and is accompanied by significant physical discomfort and cognitive distress (APA, 2013). Panic attacks usually peak in about 10 minutes but can last as long as 30 minutes before returning to normal functioning. The physical symptoms include palpitations, chest discomfort, rapid pulse, nausea, dizziness, sweating, paresthesias (burning, tickling, pricking of skin with no apparent reason), trembling or shaking, and a feeling of suffocation or shortness of breath. Cognitive symptoms include disorganized thinking, irrational fears, **depersonalization** (being detached from oneself), and a decreased ability to communicate. Usually, feelings of impending doom or death, fear of going crazy or losing control, and desperation ensue.

The physical symptoms can mimic those of a heart attack. Individuals often seek emergency medical care because they feel as if they are dying, but most have negative cardiac workup results. People experiencing panic attacks may also believe that the attacks stem from an underlying major medical illness (APA, 2013). Even with medical testing and assurance of no underlying disease, they often remain unconvinced.

Remember Doug?

He had chest pains and believed he was having a heart attack. How can you help Doug recognize that even though he is not having a heart attack, his symptoms are serious and that his panic attack could indicate an underlying anxiety disorder? Why wouldn't you tell him that everything is normal?

KEYCONCEPT Physical symptoms of panic attack are similar to cardiac emergencies. These symptoms are physically taxing and psychologically frightening to patients. Recognition of the seriousness of panic attacks should be communicated to the patient.

In a panic disorder, recurrent unexpected panic attacks are followed by persistent concern about experiencing subsequent panic attacks. Because of fear of future attacks, these affected individuals modify normal behaviors to avoid future attacks (APA, 2013). Panic attacks are either expected with an obvious cue or trigger or unexpected with no such obvious cue. The first panic attack is usually associated with an identifiable cue (e.g., anxiety-provoking medical conditions, such as asthma, or in initial trials of illicit substance use), but subsequent attacks are often unexpected without any obvious cue ([Box 27.3](#)). Panic attacks not only occur in panic disorder but can also occur in other mental

disorders such as depression, bipolar disease, eating disorders, and some medical conditions such as cardiac or respiratory disorders (APA, 2013).

Diagnostic Criteria

Panic disorder is a chronic condition that has several exacerbations and remissions during the course of the disease. The disabling panic attacks often lead to other symptoms, such as phobias.

Other diagnostic symptoms include palpitations, sweating, shaking, shortness of breath or smothering, sensations of choking, chest pain, nausea or abdominal distress, dizziness, derealization or depersonalization, fear of going crazy, fear of dying, paresthesias, and chills or hot flashes (APA, 2013) (see Key Diagnostic Characteristics 27.1).

BOX 27.3 CLINICAL VIGNETTE

Panic Disorder

Susan, a 22-year-old female, has experienced several life changes, including a recent engagement, loss of her father to cancer and heart disease, graduation from college, and entrance to the workforce as a computer programmer in a large inner-city company. Because of her active lifestyle, her sleep habits have been poor. She frequently uses sleeping aids at night and now drinks a full pot of coffee to start each day. She continues to smoke to “relieve the stress.” While sitting in heavy traffic on the way to work, she suddenly experienced chest tightness, sweating, shortness of breath, feelings of being “trapped,” and foreboding that she was going to die. Fearing a heart attack, she went to an emergency department, where her discomfort subsided within a half hour. After several hours of testing, the doctor informed her that her heart was healthy. During the next few weeks, she experienced several episodes of feeling trapped and slight chest discomfort on her drive to work. She fears future “attacks” while sitting in traffic and while in her crowded office cubicle.

What Do You Think?

- What risk factors does Susan have that might contribute to the development of panic attacks?
- What lifestyle changes do you think would help Susan reduce stress?

Disorder Across the Life Span

Children

Panic disorder is more likely to occur in adolescents than in younger children. It is estimated that panic disorder is experienced by 1% of adolescents aged 15 to 19. Children and adolescents with panic disorder are most likely experiencing another anxiety or mood disorder. Panic disorder has a significant impact on social and academic functioning and normal development (Baker & Waite, 2020).

Older Adults

Panic disorder occurs in the older adult, but it is an understudied disorder. It is unclear whether the disorder was present, but undiagnosed in early or middle adulthood or had its onset in the later years. In the older adult, panic disorder is associated with significant functional impairment, which compounds any functional issues associated with other comorbid disorders such as dementia (Pace et al., 2020).

Epidemiology and Risk Factors

Panic disorder has a moderately high lifetime prevalence in the general population with 1% to 2% 1-year prevalence rate and 4.8% lifetime rate (Olaya et al., 2018). Increased risk is associated with being female, middle aged, of low socioeconomic status, and widowed, separated, or divorced. The estimates of isolated panic attacks may affect 22.7% of the population. Panic disorders occur in several cultures, but the panic symptoms may be experienced differently across racial/ethnic groups (Assari, 2017).

KEY CHARACTERISTICS 27.1 • PANIC DISORDER

Diagnostic Criteria

- A. Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following

symptoms occur:

Note: The abrupt surge can occur from a calm state or an anxious state.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feelings of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, light-headed, or faint
9. Chills or heat sensations
10. Paresthesias (numbness or tingling sensations)
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
12. Fear of losing control or “going crazy”
13. Fear of dying

Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming, or crying) may be seen. Such symptoms should not count as one of the four required symptoms.

- B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
1. Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”)
 2. A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations)
- C. The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug or substance use disorder, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders)
- D. The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder).

Target Symptoms

Discrete period of intense fear or discomfort with four (or more) of the following symptoms that develop abruptly and reach a peak within 10 minutes:

- Palpitations, pounding heart, or accelerated heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or smothering
- Feelings of choking

- Chest pain or discomfort
- Nausea or vomiting
- Feeling dizzy, unsteady, light-headed, or faint
- Derealization (feeling of unreality) or depersonalization (being detached from oneself)
- Fear of losing control or going crazy
- Fear of dying
- Paresthesias (numbness or tingling sensations)
- Chills or hot flushes
- Great apprehension about the outcome of routine activities and experiences
- Loss or disruption of important interpersonal relationships
- Demoralization
- Possible major depressive episode

Associated Findings

- Nocturnal panic attack (waking from sleep in a state of panic)
- Constant or intermittent feelings of anxiety related to physical and mental health
- Pervasive concerns about abilities to complete daily tasks or withstand daily stressors
- Excessive use of drugs or other means to control panic attacks

Associated Physical Examination Findings

- Transient tachycardia
- Moderate elevation of systolic blood pressure

Associated Laboratory Findings

- Compensated respiratory alkalosis (decreased carbon dioxide, decreased bicarbonate levels, almost normal pH)

Other Targets for Treatment

- Loss or disruption of important interpersonal or occupational activities
- Demoralization
- Possible major depressive episode

—

Family history, alcohol use disorder and substance and stimulant use disorder, smoking tobacco, and severe stressors are risk factors for panic disorder. People who have several anxiety symptoms and those who experience separation anxiety during childhood often develop panic disorder later in life. Early life traumas and adverse events, self-stigma, a history of physical or sexual abuse, socioeconomic or personal disadvantages, and behavioral inhibition have also been associated with an increased risk for anxiety disorders in children

(Bourdon et al., 2019; Kolek et al., 2019).

Comorbidity

Patients may experience other anxiety disorders, depression, eating disorder, substance use disorder, or schizophrenia (Meuret et al., 2020). Although people with panic disorder are thought to have more somatic complaints than the general population, panic disorder does correlate with some medical conditions, including vertigo, cardiac disease, gastrointestinal disorders, asthma, and those related to cigarette smoking.

Etiology

Biologic Theories

There appears to be a substantial familial predisposition to panic disorder with an estimated heritability of 48% (Forstner et al., 2019). Studies show brain abnormalities in the “fear network” (amygdala, hippocampus, thalamus, midbrain, pons, medulla, and cerebellum) and changes in volume in different brain areas (Asok et al., 2019).

Serotonin and Norepinephrine

Serotonin and norepinephrine are both implicated in panic disorders. Norepinephrine effects act on those systems most affected by a panic attack—the cardiovascular, respiratory, and gastrointestinal systems. Serotonergic neurons are distributed in central autonomic and emotional motor control systems regulating anxiety states and anxiety-related physiologic and behavioral responses (Hornboll et al., 2018).

Gamma-Aminobutyric Acid

Gamma-aminobutyric acid (GABA) is the most abundant inhibitory neurotransmitter in the brain. GABA receptor stimulation causes several effects, including neurocognitive effects, reduction of anxiety, and sedation. GABA

stimulation also results in increased seizure threshold. Abnormalities in the benzodiazepine–GABA–chloride ion channel complex have been implicated in panic disorder (Asok et al., 2019).

Hypothalamic–Pituitary–Adrenal Axis

Research implicates a role of the hypothalamic–pituitary–adrenal axis in panic disorders (Quagliato & Nardi, 2018). A current explanation is that as stress hormones are activated, anxiety increases, which can lead to a panic attack. See [Chapter 19](#).

Psychosocial Theories

Psychoanalytic and Psychodynamic Theories

Psychodynamic theories examine anxiety that develops after separation and loss. Many patients link their initial panic attacks with recent personal losses. However, the empirical evidence remains inadequate for a psychodynamic explanation. It remains unclear why some patients develop panic disorder, whereas others with similar experiences develop other disorders (Cackovic et al., 2020).

Cognitive-Behavioral Theories

Learning theory underlies most cognitive-behavioral explanations of panic disorder. Classic conditioning theory suggests that one learns a fear response by linking an adverse or fear-provoking event, such as a car accident, with a previously neutral event, such as crossing a bridge. One becomes conditioned to associate fear with crossing a bridge. Applying this theory to people with panic disorder has limitations. Phobic avoidance is not always developed secondary to an adverse event.

Further development of this theory led to an understanding of **interoceptive conditioning**, an association between physical discomforts, such as dizziness or palpitations, and an impending panic attack. For example, during a car accident, the individual may experience rapid heartbeat, dizziness, shortness of breath, and panic. Subsequent experiences of dizziness or palpitations, unrelated to an

anxiety-provoking situation, incite anxiety and panic. Furthermore, people with panic disorder may misinterpret mild physical sensations (e.g., sweating, dizziness) as being catastrophic, causing panic as a result of learned fear (catastrophic interpretation). Some researchers hypothesize that individuals with a low sense of control over their environment or with a particular sensitivity to anxiety are vulnerable to misinterpreting normal stress. Controlled exposure to anxiety-provoking situations and cognitive countering techniques has proven successful in reducing the symptoms of panic.

Family Response to Disorder

Persons with a panic disorder may inadvertently cause excessive fears, phobias, or excessive worry in other family members. Families may limit social functions to prevent a panic attack. Those affected need a tremendous amount of support and encouragement from significant others.

RECOVERY-ORIENTED CARE FOR PERSONS WITH PANIC DISORDER

Teamwork and Collaboration: Working Toward Recovery

Nurses are pivotal in providing a safe and therapeutic inpatient environment and teaching patients strategies for managing anxiety and fears. The nurse also administers prescribed medication, monitors its effects, and provides medication education. Advanced practice nurses, licensed clinical social workers, or licensed counselors provide individual psychotherapy sessions as needed. Often, a clinical psychologist gives psychological tests and interprets the results to assist in diagnosing and treating the panic disorder.

Panic Control Treatment

Panic control treatment involves intentional exposure (through exercise) to panic-invoking sensations such as dizziness, hyperventilation, tightness in the chest, and sweating. Identified patterns become targets for treatment. Patients are

taught to use breathing training and cognitive restructuring to manage their responses and are instructed to practice these techniques between therapy sessions to adapt the skills to other situations.

Systematic Desensitization

Systematic desensitization, another exposure method used to desensitize patients, exposes the patient to a hierarchy of feared situations that the patient has rated from least to most feared. The patient is taught to use muscle relaxation as levels of anxiety increase through multisituational exposure. Planning and implementing exposure therapy require special training. Because of the multitude of outpatients in the treatment for panic disorder and agoraphobia (discussed later in chapter), exposure therapy is a useful tool for home health psychiatric nurses. Outcomes of home-based exposure treatment are similar to clinic-based treatment outcomes.

Implosive Therapy

Implosive therapy is a provocative technique useful in treating panic disorder and agoraphobia in which the therapist identifies phobic stimuli for the patient and then presents highly anxiety-provoking imagery to the patient, describing the feared scene as dramatically and vividly as possible. **Flooding** is a technique used to desensitize the patient to the fear associated with a particular anxiety-provoking stimulus. Desensitizing is done by presenting feared objects or situations repeatedly without session breaks until the anxiety dissipates. For example, a patient with ophidiophobia (i.e., a morbid fear of snakes) might be presented with a real snake repeatedly until the patient's anxiety decreases.

Exposure Therapy

Many of the treatment approaches used for panic disorder are effective for phobias (discussed in later chapters). **Exposure therapy** is the treatment of choice for phobias. The patient is repeatedly exposed to real or simulated anxiety-provoking situations until they become desensitized and anxiety subsides.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is a highly effective tool for treating individuals with panic disorder. It is considered a first-line treatment for those with panic and other anxiety disorders and is often used in conjunction with medications, including selective serotonin reuptake inhibitors (SSRIs) (Bilet et al., 2020). The goals of CBT include helping the patient to manage their anxiety and correcting anxiety-provoking thoughts through interventions, including cognitive restructuring, breathing training, and psychoeducation.

Safety Issues

Panic attack symptoms mimic a heart attack—chest pain, palpitations, dyspnea. It is important to rule out any cardiac problems prior to diagnosing and treating a panic attack. Research shows that persons with panic disorder have higher oxidative stress due to impaired serotonin metabolism, which is related to heart disease (Aghayan et al., 2020).

Panic disorder is associated with an increased risk of suicide. A 3-year prevalence of suicide attempt in a sample of adults with panic disorder is 4.6%. Factors that independently predicted suicide attempts include psychopathology, prior history of suicide attempts, lower physical health-related quality of life, and greater number of stressful life events in the past year (Scheer et al., 2020).

EVIDENCE-BASED NURSING CARE OF PERSONS WITH PANIC DISORDER

Individuals often first seek help in the emergency department for their physical symptoms, but they are told that there are no life-threatening cardiac or neurologic causes for the severe physical symptoms. Although no laboratory tests exist to confirm anxiety disorders, a careful clinical assessment will reveal the presence of an anxiety disorder. See Nursing Care Plan 27.1.

NURSING CARE PLAN 27.1

The Patient with Panic Disorder

Douglas is a 50-year-old man who is being evaluated in the emergency department by a nurse from the mental health crisis team. Doug was brought into the emergency department by his wife after experiencing chest pain early in the evening. He arrived in a state of severe level of anxiety and believed that he was having a heart attack. An ECG and laboratory values were normal.

Setting: Day Treatment Program, Adult Psychiatric Services

Baseline Assessment: Doug arrived at the ED trembling, dizzy, pale, experiencing tachycardia, nausea, and feelings of dread. He could not follow directions and responded poorly to redirection. His attention and thoughts are scattered.

Associated Psychiatric Diagnosis	Medications
Panic disorder	Paroxetine CR (Paxil) 12.5 mg every day
History of hypertension	Lisinopril (Zestril) 20 mg daily

Lorazepam (Ativan) 1 mg q6h PRN for extreme anxiety

Priority of Nursing Care: Anxiety

Important Characteristics

Trembling, increased pulse
Fearful, irritable, scared, worried
Apprehensive

Associated Considerations

Impending panic attacks
Panic attacks

Outcomes

Initial

Develop skills to decrease impact of panic attack

Long-term

Carry out normal daily living and social activities outside of the house

Interventions

Interventions

Meet daily with Doug to assess whether he has had a panic attack within the last 24 hours.

Using a calm reassuring approach, encourage verbalization of feelings, perceptions, and fears. Identify periods of time when anxiety level is at its highest.

Rationale

Asking Doug to monitor panic attacks will provide data regarding potential antecedents to attacks.

Discussing the experience of anxiety will help the patient notice when his

Ongoing Assessment

Determine whether Doug has had a panic attack.

Explore the antecedents and determine whether he was able to practice

	anxiety increases.	techniques from education programs.
Teach Doug how to perform relaxation techniques.	Having strategies to deal with impending panic attack will decrease the intensity of the experience.	Observe effectiveness of his technique and changes in anxiety/panic episodes.
Teach Doug about the actions and side effects of paroxetine. Explain the purposes of the medication. Track the number of PRN medications that are used for anxiety. Also, monitor for use of alcohol and herbal supplements.	Panic attacks are neurobiologic occurrences that respond to medications.	Determine whether panic attacks decrease over time and whether there are side effects. Determine his commitment to living a more normal life.
Evaluation		
Outcomes	Revised Outcomes	Interventions
Doug's panic attacks decreased to once a week. Attended day treatment program every day. Able to go to grocery store.	Increase social activity outside of house.	Meet with Doug twice a week to monitor progress. Continue to reinforce the use of strategies in managing anticipatory anxiety.

Panic Attack Assessment

The assessment of the person with a panic disorder focuses on identifying the characteristics of the panic attack and the individual's strengths and problems. If the panic attack occurs in the presence of the nurse, direct assessment of the symptoms should be made and documented. Questions to ask the patient might include the following:

- What were you doing when the panic attack occurred?
- What did you experience before and during the panic episode, including physical symptoms, feelings, and thoughts?
- When did you begin to feel that way? How long did it last?
- Do you have an explanation for what caused you to feel and think that way?
- Have you experienced these symptoms in the past? If so, under what circumstances?
- Has anyone in your family ever had similar experiences?
- What do you do when you have these experiences to help you to feel safe?
- Have the feelings and sensations ever gone away on their own?

Physical Health

Key assessment areas of physical health that could have precipitated the panic attack include sleep patterns, activity levels, and health conditions.

Sleep Patterns and Physical Activity

Sleep is often disturbed in patients with panic disorder. In fact, panic attacks can occur during sleep, so the patient may fear sleep for this reason. Nurses should closely assess the impact of sleep disturbance because fatigue may increase anxiety and susceptibility to panic attacks. Panic disorder can be improved through active participation in a routine exercise program. If the patient does not exercise routinely, define the barriers to it. If exercise is avoided because of chronic muscle tension, poor muscle tone, muscle cramps, general fatigue, exhaustion, or shortness of breath, the symptoms may indicate poor physical health.

Nutrition

A nutritional assessment is important because people with panic disorder have increased rates of eating disorder behavior when compared to individuals without panic disorder (Garcia et al., 2020). The assessment is especially in women who are more likely to have a comorbid eating disorder than men. The nurse should inquire about the food and drink intake on a typical day and also include questions about binge or fasting behavior.

Medication

Several medications can cause anxiety. Bronchodilators, oral contraceptives, amphetamines (i.e., methylphenidate), steroids, thyroid medication, and several other medications can increase anxiety. Additionally, medicines that contain caffeine, such as some pain and anti-inflammatory agents, decongestants (i.e., phenylephrine), and some illegal drugs (cocaine), also increase anxiety.

Substance Use

Caffeine, pseudoephedrine, amphetamines, cocaine, or other stimulants are associated with panic disorder and may stimulate a panic attack. Tobacco use can also contribute to the risk for panic symptoms. Many individuals with panic disorder use alcohol or central nervous system (CNS) depressants in an effort to self-medicate anxiety symptoms; withdrawal from CNS depressants may produce symptoms of panic.

Other Physical Assessment Areas

Recent changes in physical status should be assessed. For example, pregnant patients should be assessed carefully for an underlying panic disorder. Although pregnancy may actually protect the mother from developing panic symptoms, postpartum onset of panic disorder requires particular attention. During a time that tremendous effort is spent on family, postpartum onset of panic disorder negatively affects lifestyle and decreases self-esteem in affected women, leading to feelings of overwhelming personal disappointment.

Psychosocial Assessment

A psychosocial assessment includes the patient's report of the symptoms and a careful cognitive, behavioral, and social assessment. The assessment should include the following behavioral responses, self-concept, stress and coping patterns, social network, functional status, and support systems. See [Chapter 11](#).

Self-Report Scales

Self-evaluation is difficult in panic disorder. Often the memories of the attack and its triggers are irretrievable. Several tools are available to characterize and rate the patient's state of anxiety. Examples of these symptom and behavioral rating scales are provided in [Box 27.4](#). All of these tools are self-report measures and as such are limited by the individual's self-awareness and openness. However, the Hamilton Rating Scale for Anxiety, provided in [Table 27.2](#), is an example of a scale rated by the clinician (Hamilton, 1959). This 14-item scale reflects both psychological and somatic aspects of anxiety.

BOX 27.4

Rating Scales for Assessment of Panic Disorder and Anxiety Disorders

PANIC SYMPTOMS

Panic-Associated Symptom Scale (PASS)

Argyle, N., Delito, J., Allerup, P., Maier, W., Albus, M., Nutzinger, D., et al. (1991). The Panic-Associated Symptom Scale: Measuring the severity of panic disorder. *Acta Psychiatrica Scandinavica*, 83, 20–26.

Acute Panic Inventory

Dillon, D. J., Gorman, J. M., Liebowitz, M. R., Fyer, A. J., & Klein, D. F. (1987). Measurement of lactate-induced panic and anxiety. *Psychiatry Research*, 20, 97–105.

National Institute of Mental Health Panic Questionnaire (NIMH PQ)

Scupi, B. S., Maser, J. D., & Uhde, T. W. (1992). The National Institute of Mental Health Panic Questionnaire: An instrument for assessing clinical characteristics of panic disorder. *Journal of Nervous and Mental Disease*, 180, 566–572.

COGNITIONS

Anxiety Sensitivity Index

Reiss, S., Peterson, R. A., & Gursky, D. M. (1986). Anxiety sensitivity, anxiety frequency, and the prediction of fearfulness. *Behaviour Research and Therapy*, 24, 1–8.

Agoraphobia Cognitions Questionnaire

Chambless, D. L., Caputo, G. C., Bright, P., & Gallagher, R. (1984). Assessment of fear in agoraphobics: The Body Sensations Questionnaire and the Agoraphobic Cognitions Questionnaire. *Journal of Consulting and Clinical Psychology*, 52, 1090–1097.

Body Sensations Questionnaire

Chambless, D. L., Caputo, G. C., Bright, P., & Gallagher, R. (1984). Assessment of fear in agoraphobics: The Body Sensations Questionnaire and the Agoraphobic Cognitions Questionnaire. *Journal of Consulting and Clinical Psychology*, 52, 1090–1097.

PHOBIAS

Mobility Inventory for Agoraphobia

Chambless, D. L., Caputo, G. C., Jasin, S. E., Gracely, E., & Williams, C. (1985). The mobility inventory for agoraphobia. *Behavior Research and Therapy*, 23, 35–44.

Fear Questionnaire

Marks, I. M., & Matthews, A. M. (1979). Brief standard self-rating for phobic patients. *Behaviour Research and Therapy*, 17, 263–267.

ANXIETY

State-Trait Anxiety Inventory (STAI)

Spielberger, C. D., Gorsuch, R. L., & Luchene, R. E. (1976). *Manual for the State-Trait Anxiety Inventory*. Consulting Psychologists Press.

Penn State Worry Questionnaire (PSWQ)

16 items developed to assess the trait of worry.

Meyer, T., Miller, M., Metzger, R., & Borkovec, T. (1990). Development and validation of the Penn State Worry Questionnaire. *Behaviour Research and Therapy*, 28(6), 487–495.

Beck Anxiety Inventory

21 items rating the severity of symptoms on a 4-point scale.

Beck, A., Epstein, N., Brown, G., & Steer, R. (1988). An inventory for measuring clinical anxiety: The Beck Anxiety Inventory. *Journal of Consulting and Clinical Psychology*, 56, 893–897.

Mental Status Examination

During a mental status examination, individuals with panic disorder may exhibit anxiety symptoms, including restlessness, irritability, poor concentration, and apprehensive behavior. Disorganized thinking, irrational fears, and a decreased ability to communicate often occur during a panic attack. Assess by direct questioning whether the patient is experiencing suicidal thoughts, especially if they are abusing substances or taking antidepressant medications.

Cognitive Thought Patterns

Catastrophic misinterpretations of trivial physical symptoms can trigger panic symptoms. After they have been identified, these thoughts should serve as a basis for individualizing patient education to counter such false beliefs. [Table 27.3](#) presents a scale to assess catastrophic misinterpretations of the symptoms of panic.

Several studies have found that individuals who feel a sense of control have less severe panic attacks. Individuals who fear loss of control during a panic attack often make the following type of statements:

- “I feel trapped.”
- “I’m afraid others will know or that I’ll hurt someone.”
- “I feel alone. I can’t help myself.”
- “I’m losing control.”

These individuals also tend to show low self-esteem, feelings of helplessness, demoralization, and overwhelming fears of experiencing panic attacks. They may have difficulty with assertiveness or expressing their feelings.

TABLE 27.2 HAMILTON RATING SCALE FOR ANXIETY

Max Hamilton designed this scale to help clinicians gather information about anxiety states. The symptom inventory provides scaled information that classifies anxiety behavior and assists the clinician in targeting behaviors and achieving outcome measures. Provide a rating for each indicator based on the following scale:

- 0 = None
- 1 = Mild
- 2 = Moderate
- 3 = Severe
- 4 = Severe, grossly disabling

Item	Symptoms	Rating
Anxious mood	Worries, anticipation of the worst, fearful anticipation, irritability	
Tension	Feelings of tension, fatigability, startle response, moved to tears easily, trembling, feelings of restlessness, inability to relax	
Fear	Of dark, strangers, being left alone, animals, traffic, crowds	
Insomnia	Difficulty in falling asleep, broken sleep, unsatisfying sleep, and fatigue on waking; dreams, nightmares, night terrors	
Intellectual (cognitive)	Difficulty concentrating, poor memory	
Depressed mood	Loss of interest, lack of pleasure in hobbies, depression, early waking, diurnal swings	

Somatic (sensory)	Tinnitus, blurring of vision, hot and cold flushes, feelings of weakness, prickly sensation
Somatic (muscular)	Pains and aches, twitching, stiffness, myoclonic jerks, grinding of teeth, unsteady voice, increased muscular tone
Cardiovascular symptoms	Tachycardia, palpitations, pain in chest, throbbing of vessels, fainting feelings, missing beat
Respiratory symptoms	Pressure or constriction in chest, choking feelings, sighing, dyspnea
Gastrointestinal symptoms	Difficulty in swallowing, gas, abdominal pain, burning sensation, abdominal fullness, nausea, vomiting, looseness of bowels, loss of weight, constipation
Genitourinary symptoms	Frequency of micturition, urgency of micturition, amenorrhea, menorrhagia, development of frigidity, premature ejaculation, loss of libido, impotence
Autonomic symptoms	Dry mouth, flushing, pallor, tendency to sweat, giddiness, tension headache, raising of hair
Behavior at interview	Fidgeting, restlessness or pacing, tremor of hands, furrowed brow, strained face, sighing or rapid respiration, facial pallor, swallowing, belching, brisk tendon jerks, dilated pupils, exophthalmos

Reprinted from Hamilton, M. (1959). The assessment of anxiety states by rating. *British Journal of Medical Psychology*, 32, 54.

Social Network

Marital and parental functioning can be adversely affected by panic disorder. During the assessment, the nurse should try to grasp the patient's understanding of how panic disorder with or without severe avoidance behavior has affected their life, along with that of the family. Pertinent questions include the following:

- How has the disorder affected your family's social life?
- What limitations related to travel has the disorder placed on you or your family?
- What coping strategies have you used to manage symptoms?
- How has the disorder affected your family members or others?

Cultural Factors

Cultural competence calls for the understanding of cultural knowledge, cultural awareness, cultural assessment skills, and cultural practice. Therefore, cultural differences must be considered in the assessment of panic disorder. Different cultures interpret sensations, feelings, or understandings differently. For example, symptoms of anxiety might be seen as witchcraft or magic (APA,

2013). Several cultures do not have a word to describe *anxiety* or *anxious* and instead may use words or meanings to suggest physical complaints. (Moitra, 2018). Many over-the-counter (OTC) herbal remedies contain substances that may induce panic by increasing the heart rate, basal metabolic rate, blood pressure, and sweating (see [Chapter 11](#)).

TABLE 27.3: PANIC ATTACK COGNITIONS QUESTIONNAIRE

Rate each of the following thoughts according to the degree to which you believe each thought contributes to your panic attack.

1 = Not at all 3 = Quite a lot

2 = Somewhat 4 = Very much

1. I'm going to die.	1	2	3	4
2. I'm going insane.	1	2	3	4
3. I'm losing control.	1	2	3	4
4. This will never end.	1	2	3	4
5. I'm really scared.	1	2	3	4
6. I'm having a heart attack.	1	2	3	4
7. I'm going to pass out.	1	2	3	4
8. I don't know what people will think.	1	2	3	4
9. I won't be able to get out of here.	1	2	3	4
10. I don't understand what is happening to me.	1	2	3	4
11. People will think I am crazy.	1	2	3	4
12. I'll always be this way.	1	2	3	4
13. I am going to throw up.	1	2	3	4
14. I must have a brain tumor.	1	2	3	4
15. I'll choke to death.	1	2	3	4
16. I'm going to act foolish.	1	2	3	4
17. I'm going blind.	1	2	3	4
18. I'll hurt someone.	1	2	3	4
19. I'm going to have a stroke.	1	2	3	4
20. I'm going to scream.	1	2	3	4
21. I'm going to babble or talk funny.	1	2	3	4
22. I'll be paralyzed by fear.	1	2	3	4
23. Something is physically wrong with me.	1	2	3	4

24. I won't be able to breathe.	1	2	3	4
25. Something terrible will happen.	1	2	3	4
26. I'm going to make a scene.	1	2	3	4

Adapted from Clum, G. A. (1990). *Panic attack cognitions questionnaire*. *Coping with panic: A drug-free approach to dealing with anxiety attacks*. Pacific Grove, CA: Brooks/Cole. Reprinted with permission from Dr. George A. Clum.

Strength Assessment

During the assessment, the patient's strengths will emerge. For example, a patient may tell you that he does not drink alcohol or use tobacco. Another may relate that he would like to exercise. Still another patient has a supportive partner or family member. The nurse can support these positive behaviors.

CLINICAL JUDGMENT

Suicide prevention is the first priority when caring for a person with a panic disorder. People with panic disorder are often depressed and consequently are at high risk for suicide. Adolescents with panic disorder are at higher risk for suicidal thoughts or may attempt suicide more often than other adolescents. Panic symptoms in early adolescence predict high risk for late adolescent depression and suicide ideation (Barzilay et al., 2020).

Once the nurse establishes that there is no indication of a risk for suicide, the nurse assesses whether the individual may be depressed, lonely, and socially isolated. Panic attacks may be unpredictable, leading the person to be fearful of another attack. Self-esteem may be low as feelings of powerlessness emerge. The patient may be experiencing physical panic symptoms, such as dizziness and hyperventilation. Because the whole family is affected by one member's symptoms, the family's needs may need to be considered.

The patient's strengths should be considered in planning care. For example, the person may be motivated to gain more control through making lifestyle changes. There may be evidence of family support. Outcomes will depend upon the particular health care issue and the interventions that are agreed upon by the patient and nurse.

THERAPEUTIC RELATIONSHIP

The therapeutic relationship is a critical aspect of helping the person work toward recovery. These individuals may appear to be very nervous or anxious throughout the interaction. The nurse should help the patient relax and be comfortable with discussing fears and anxiety. A calm, understanding approach in a comfortable environment will help the person relax and be willing to engage in a therapeutic relationship.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Mental Health and Wellness Goals

The course of panic disorder culminates in phobic avoidance as the affected person attempts to avoid situations that increase panic. Even though identifying and avoiding anxiety-provoking situations are important during therapy, drastically changing lifestyle to avoid situations does not aid recovery. Goals and interventions that focus on developing a healthy lifestyle, supporting a sense of accomplishment and control, and reducing anxiety and panic are particularly helpful in reducing the number and severity of the attacks.

Physical Care

COVID-19 causes additional fear and anxiety in persons with panic disorder. Physical distancing may exacerbate feeling of seclusion and lead to detrimental prolonged health effects. Quarantine and social isolation can easily prevent an individual with panic disorder from following up with medical issues, such as changes in cardiac functioning. Fears of being infected may prevent the person from picking up regular medications from the local pharmacy or grocery shopping (Pera, 2020).

Psychiatric mental health nurses who make home visits often provide the person with both medical and mental health care. Nurses should consider providing care that is usually given by other nurses.

Teaching Breathing Control

Hyperventilation is common. Often, people are unaware that they take rapid shallow breaths when they become anxious.

Teaching patients breathing control can be helpful. Focus on the breathing and help them to identify the rate, pattern, and depth. If the breathing is rapid and shallow, reassure the patient that exercise and breathing practice can help change this breathing pattern. Then, assist the patient in practicing abdominal breathing by performing the following exercises:

- Instruct the patient to breathe deeply by inhaling slowly through the nose. Have them place a hand on the abdomen just beneath the rib cage.
- Instruct the patient to observe that when one is breathing deeply, the hand on the abdomen will actually rise.
- After the patient understands this process, ask them to inhale slowly through the nose while counting to five, pause, and then exhale slowly through pursed lips.
- While the patient exhales, direct attention to feeling the muscles relax, focusing on “letting go.”
- Have the patient repeat the deep abdominal breathing for 10 breaths, pausing between each inhalation and exhalation. Count slowly. If the patient complains of light-headedness, reassure them that this is a normal feeling while deep breathing. Instruct the patient to stop for 30 seconds, breathe normally, and then start again.
- The patient should stop between each cycle of 10 breaths and monitor normal breathing for 30 seconds.
- This series of 10 slow abdominal breaths followed by 30 seconds of normal breathing should be repeated for 3 to 5 minutes.
- Help the patient to establish a time for daily practice of abdominal breathing.

Abdominal breathing may also be used to interrupt an episode of panic as it begins. After patients have learned to identify their own early signs of panic, they can learn the four-square method of breathing, which helps divert or decrease the severity of the attack. Patients should be instructed as follows:

- Advise the patient to practice during calm periods and to begin by inhaling

slowly through the nose, count to four, and then hold the breath for a count of four.

- Direct the patient to exhale slowly through pursed lips to a count of four and then rest for a count of four (no breath).
- Finally, the patient may take two normal breaths and repeat the sequence.

After patients practice the skill, the nurse should assist them in identifying the physical cues that will alert them to use this calming technique.

Teaching Nutritional Planning

Maintaining regular and balanced eating habits reduces the likelihood of hypoglycemic episodes, light-headedness, and fatigue. To help teach the patient about healthful eating and ways to minimize physical factors contributing to anxiety:

- Advise the patient to reduce or eliminate substances in the diet that promote anxiety and panic, such as food coloring, monosodium glutamate, and caffeine (withdrawal from which may stimulate panic). Patients need to plan to reduce caffeine consumption and then eliminate it from their diet. Many OTC remedies are now used to boost energy or increase mental performance; some of these contain caffeine. A thorough assessment should be made of all OTC products used to assess the potential of anxiety-provoking ingredients.
- Instruct the patient to check each substance consumed and note whether symptoms of anxiety occur and whether the symptoms are relieved by not consuming the product.

Teaching Relaxation Techniques

Teaching the patient relaxation techniques is another way to help individuals with panic and anxiety disorders. Some are unaware of the tension in their bodies and first need to learn to monitor their own tension. Isometric exercises and progressive muscle relaxation are helpful methods to learn to differentiate muscle tension from muscle relaxation. This method of relaxation is also useful when patients have difficulty clearing the mind, focusing, or visualizing a scene,

which are often required in other forms of relaxation, such as meditation. [Box 27.5](#) provides one method of progressive muscle relaxation.

BOX 27.5

Teaching Progressive Muscle Relaxation

Choose a quiet, comfortable location where you will not be disturbed for 20 to 30 minutes. Your position may be lying or sitting, but all parts of your body should be supported, including your head. Wear loose clothing, taking off restrictive items, such as glasses and shoes.

Begin by closing your eyes and clearing your mind. Moving from head to toe, focus on each part of your body and assess the level of tension. Visualize each group of muscles as heavy and relaxed.

Take two or three slow abdominal breaths, pausing briefly between each breath. Imagine the tension flowing from your body.

Each muscle group listed subsequently should be tightened (or tensed isometrically) for 5 to 10 seconds and then abruptly released; visualize this group of muscles as heavy, limp, and relaxed for 15 to 20 seconds before tightening the next group of muscles. There are several methods to tighten each muscle group, and suggestions are provided subsequently. Each muscle group may be tightened two to three times until relaxed. Do not overtighten or strain. You should not experience pain.

- Hands: tighten by making fists
- Biceps: tighten by drawing forearms up and “making a muscle”
- Triceps: extend forearms straight, locking elbows
- Face: grimace, tightly shutting mouth and eyes
- Face: open mouth wide and raise eyebrows
- Neck: pull head forward to chest and tighten neck muscles
- Shoulders: raise shoulders toward ears
- Shoulders: push shoulders back as if touching them together
- Chest: take a deep breath and hold for 10 seconds
- Stomach: suck in your abdominal muscles
- Buttocks: pull buttocks together
- Thighs: straighten legs and squeeze muscles in thighs and hips
- Calves: pull toes carefully toward you, avoid cramps
- Feet: curl toes downward and point toes away from your body

Finally, repeat several deep abdominal breaths and mentally check your body for tension. Rest comfortably for several minutes, breathing normally, and visualize your body as warm and relaxed. Get up slowly when you are finished.

Promoting Increased Physical Activity

Physical exercise can effectively decrease the occurrence of panic attacks by

reducing muscle tension, increasing metabolism, increasing serotonin levels, and relieving stress. Exercise programs reduce many of the precipitants of anxiety by improving circulation, digestion, endorphin stimulation, and tissue oxygenation. In addition, exercise lowers cholesterol levels, blood pressure, and weight. After assessing for contraindications to physical exercise, assist the patient in establishing a routine exercise program. Engaging in 10- to 20-minute sessions on treadmills or stationary bicycles two to three times weekly is ideal during the winter months. Casual walking or bike riding during warmer weather promotes health. Help the patient to identify community resources that promote exercise.

Wellness Challenges

Many of the strategies that promote wellness are the same as those used to treat anxiety. For the person who is anxious or fearful, the individual may be more comfortable with a gradual incorporation of the strategies. Many wellness strategies for the person who is anxious should focus on physical health. See [Box 27.6](#).

BOX 27.6

Wellness Challenges for the Person with Anxiety

WELLNESS CHALLENGES

- Coping effectively with daily stresses without excessive worry
 - Strategies: Develop a daily schedule, allow time to relax, avoid trying to multitask, deep breathing, mindfulness
- Satisfying and enriching work
 - Strategies: Choose activities that are consistent with your skills and knowledge, consider other possibilities if job is too stressful.
- Incorporate physical activity, healthy foods, and adequate sleep into daily life
 - Strategies: Schedule regular physical activity, make a weekly menu of healthy meals, establish healthy sleep hygiene routines
- Developing a sense of connection, belong, and a support system
 - Strategies: Join a support group, seek out recreational activities with friends and families
- Expanding a sense of purpose and meaning in life
 - Strategies: Focus on goals, values, and beliefs, read inspiring stories or essays

Medication Interventions

Some antidepressants (e.g., SSRIs and serotonin–norepinephrine reuptake inhibitors [SNRIs]) and antianxiety medication (e.g., benzodiazepines) are U.S. Food and Drug Administration, approved for treating people with panic disorders (see [Table 27.4](#)).

Selective Serotonin Reuptake Inhibitors

The SSRIs are recommended as the first drug option in the treatment of patients with panic disorder. They have the best safety profile, and if side effects occur, they tend to be present early in treatment before the therapeutic effect takes place. Hence, the SSRIs should be started at low doses and titrated every 5 to 7 days. Antidepressant therapy is recommended for long-term treatment of the disorder and antianxiety as adjunctive treatment (Zugliani et al., 2019). The SSRIs produce anxiolytic effects by increasing the transmission of serotonin by blocking serotonin reuptake at the presynaptic cleft. The initial increase in serotonergic activity with SSRIs may cause temporary increases in panic symptoms and even panic attacks. After 4 to 6 weeks of treatment, anxiety subsides, and the antianxiety effect of the medications begins (see [Chapter 12](#)). Increased serotonin activity in the brain is believed to decrease norepinephrine activity. This decrease lessens cardiovascular symptoms of tachycardia and increased blood pressure, which are associated with panic attacks. See [Chapter 25](#) for administration and monitoring side effects.

NCLEXNOTE Psychopharmacologic treatment is almost always needed. Antidepressants are the medications of choice. Antianxiety medication is used only for short periods of time.

TABLE 27.4 MEDICATION FOR PANIC DISORDER

Medication	Starting Dose (mg/day)	Therapeutic Dose	Side Effects
SSRIs			Class effects: nausea, anorexia, tremors, anxiety, sexual dysfunction, jitteriness, insomnia, suicidality
Fluoxetine (Prozac)	10	20–60	Class effects

Sertraline (Zoloft)	25	50–200	Class effects, loose stools
Paroxetine (Paxil)	10	10–60	Class effects, drowsiness, fatigue
Paroxetine (controlled release) (Paxil CR)	12.5	12.5–75	Class effects
SNRIs			Class effects: nausea, sweating, dry mouth, dizziness, insomnia, somnolence, sexual dysfunction, hypertension
Venlafaxine (extended release)	37.5	75–300	Class effects
Benzodiazepines			Class effects: sedation, cognitive slowing, physical dependence
Clonazepam (Klonopin)	0.25 TID	0.5–2.0 BID	Class effects
Alprazolam (Xanax)	0.25 TID	0.5–1.5 TID	Class effects

BID, two times a day; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TID, three times a day.

Serotonin–Norepinephrine Reuptake Inhibitors

The SNRIs increase levels of both serotonin and norepinephrine by blocking their reuptake presynaptically. Classified as antidepressants, the SNRIs are also used in anxiety disorders. Venlafaxine is the most commonly used SNRI (see [Table 27.4](#)). These medications have been shown to reduce the severity of panic and anticipatory anxiety. Similar to the SSRIs, they should not be abruptly discontinued (see [Chapter 12](#)).

Benzodiazepine Therapy

The high-potency benzodiazepines have produced antipanic effects; their therapeutic onset is much faster than that of antidepressants (see [Table 27.4](#)). Therefore, benzodiazepines are tremendously useful in treating intensely distressed patients. Alprazolam (Xanax), lorazepam (Ativan), and clonazepam (Klonopin) are widely used for panic disorder. They are well tolerated but carry the risk for withdrawal symptoms upon discontinuation of use (see [Box 27.7](#)). The benzodiazepines are still commonly used for panic disorder even though the SSRIs are recommended for first-line treatment of panic disorder (Quagliato et al., 2018).

BOX 27.7

Alprazolam (Xanax)

DRUG CLASS: Antianxiety agent

RECEPTOR AFFINITY: Exact mechanism of action is unknown; believed to increase the effects of γ -aminobutyrate.

INDICATIONS: Management of anxiety disorders, short-term relief of anxiety symptoms or depression-related anxiety, panic attacks with or without agoraphobia.

ROUTES AND DOSAGES: Available in 0.25-, 0.5-, 1-, and 2-mg scored tablets.

Adults: For anxiety: Initially, 0.25 to 0.5 mg PO TID titrated to a maximum daily dose of 4 mg in divided doses. For panic disorder: Initially, 0.5 mg PO TID increased at 3- to 4-day intervals in increments of no more than 1 mg/day.

Geriatric Patients: Initially, 0.25 mg BID to TID, increased gradually as needed and tolerated.

HALF-LIFE (PEAK EFFECT): 12 to 15 hours (1 to 2 hours).

SELECTED ADVERSE REACTIONS: Transient mild drowsiness, initially; sedation, depression, lethargy, apathy, fatigue, light-headedness, disorientation, anger, hostility, restlessness, headache, confusion, crying, constipation, diarrhea, dry mouth, nausea, and possible drug dependence.

WARNINGS: Contraindicated in patients with psychosis, acute narrow-angle glaucoma, shock, acute alcoholic intoxication with depressed vital signs, pregnancy, labor and delivery, and breastfeeding. Use cautiously in patients with impaired hepatic or renal function and severe debilitating conditions. Risk for digitalis toxicity if given concurrently with digoxin. Increased CNS depression if taken with alcohol, other CNS depressants, and propoxyphene (Darvon).

SPECIFIC PATIENT AND FAMILY EDUCATION

- Avoid using alcohol, sleep-inducing drugs, and other OTC drugs.
- Take the drug exactly as prescribed, and do not stop taking the drug without consulting your primary health care provider.
- Take the drug with food if gastrointestinal upset occurs.
- Avoid driving a car or performing tasks that require alertness if drowsiness or dizziness occurs.
- Report any signs and symptoms of adverse reactions.
- Notify your primary health care provider if severe dizziness, weakness, or drowsiness persists or if rash or skin lesions, difficulty voiding, palpitations, or swelling of the extremities occurs.
- BID, two times a day; CNS, central nervous system; OTC, over-the-counter; PO, oral; TID, three times a day.

Administering and Monitoring Benzodiazepines

Treatment may include administering benzodiazepines concurrently with antidepressants for the first 4 weeks and then tapering the benzodiazepine to a

maintenance dose. This strategy provides rapid symptom relief but avoids the complications of long-term benzodiazepine use. Benzodiazepines with short half-lives do not accumulate in the body, but benzodiazepines with half-lives of longer than 24 hours tend to accumulate with long-term treatment, are removed more slowly, and produce less intense symptoms on discontinuation of use (see [Chapter 12](#)).

Short-acting benzodiazepines, such as alprazolam, are associated with rebound anxiety, or anxiety that increases after the peak effects of the medication have decreased. Medications with short half-lives (alprazolam, lorazepam) should be given in three or four doses spaced throughout the day, with a higher dose at bedtime to allay anxiety-related insomnia. Clonazepam, a longer-acting benzodiazepine, requires less frequent dosing and has a lower risk for rebound anxiety.

Because of their depressive CNS effects, benzodiazepines should not be used to treat patients with comorbid sleep apnea. In fact, these drugs may actually decrease the rate and depth of respirations. Exercise caution in older adult patients for these reasons. Discontinuing medication use requires a slow taper during a period of several weeks to avoid rebound anxiety and serious withdrawal symptoms. Benzodiazepines are not indicated in the chronic treatment of patients with substance use disorder but can be useful in quickly treating anxiety symptoms until other medications take effect.

Symptoms associated with withdrawal of benzodiazepine therapy are more likely to occur after high doses and long-term therapy. They can also occur after short-term therapy. Withdrawal symptoms manifest in several ways, including psychological (e.g., apprehension, irritability, agitation).

Monitoring Side Effects

SSRIs should not be given with monoamine oxidase inhibitors (MAOIs) because of potential drug interaction. Drugs that interact with benzodiazepines include the tricyclic antidepressants (TCAs) and digoxin; interaction may result in increased serum TCA or digoxin levels. Alcohol and other CNS depressants, when used with benzodiazepines, increase CNS depression. Their concomitant use is contraindicated. Histamine-2 blockers (e.g., cimetidine) used with benzodiazepines may potentiate sedative effects. Monitor closely for effectiveness in patients who smoke; cigarette smoking may increase the clearance of benzodiazepines.

Management of Complications

The side effects of benzodiazepine medications generally include headache, confusion, dizziness, disorientation, sedation, and visual disturbances. Sedation should be monitored after beginning medication use or increasing the dose. The patient should avoid operating heavy machinery until the sedative effects are known.

Concurrent use of SSRIs and the MAOIs is contraindicated. These antidepressants should not be given together.

Teaching Points

Warn patients to avoid alcohol because of the chance of CNS depression. In addition, warn them not to operate heavy machinery until the sedative effects of the medication are known.

Psychosocial Interventions

Therapeutic Interactions

Peplau (1989) devised general guidelines for nursing interventions that might be successful in treating patients with anxiety. These interventions help the patient attend to and react to input other than the subjective experience of anxiety. They are designed to help the patient focus on other stimuli and cope with anxiety in any form (Table 27.5). These general interventions apply to all anxiety disorders and therefore are not reiterated in subsequent sections.

Enhancing Cognitive Functioning

Distraction

After patients can identify the early symptoms of panic, they may learn to implement distraction behaviors that take the focus off the physical sensations. Some activities include initiating conversation with a nearby person or engaging in physical activity (e.g., walking, gardening, or housecleaning). Performing

simple repetitive activities such as snapping a rubber band against the wrist, counting backward from 100 by 3s, or counting objects along the roadway might also deter an attack.

Reframing

Reframing is a cognitive technique that can change the way a situation, event, or person is viewed and reduce the impact of anxiety-provoking thoughts. People with anxiety disorders often view themselves negatively and use “should statements” and “negative labels.” Should statements lead to rigid rules and unrealistic expectations? By encouraging patients to avoid the use of should statements and reframe their views, they can change their beliefs to be more realistic. For example, if a patient says, “I should be a better parent” or “I’m a useless failure,” the nurse could ask the person to identify the positive aspects of parenting and other successes.

TABLE 27.5 NURSING INTERVENTIONS BASED ON DEGREES OF ANXIETY

Degree of Anxiety Nursing Interventions

Mild	Assist patient to use the energy anxiety provides to encourage learning.
Moderate	Encourage patient to talk: to focus on one experience, to describe it fully, and then to formulate the patient’s generalizations about that experience.
Severe	Allow relief behaviors to be used but do not ask about them. Encourage the patient to talk: ventilation of random ideas is likely to reduce anxiety to a moderate level.
Panic	Stay with the patient. Allow pacing and walk with the patient. No content inputs to the patient’s thinking should be made by the nurse. (They burden the patient, who will distort them.) Be direct with the fewest number of words: e.g., “Drink this” (give liquids to replace lost fluids and to relieve dry mouth); “Say what’s happening to you,” “Talk about yourself,” or “Tell what you feel now” (to encourage ventilation and externalization of inner, frightening experience). Pick up on what the patient says, for example, Patient: “What’s happening to me—how did I get here?” Nurse: “Say what you notice.” Use short phrases to the point of the patient’s comment. Do not touch the patient; patients experiencing panic are very concerned about survival, are experiencing a grave threat to self, and usually distort intentions of all invasions of their personal space.

Adapted from Peplau, H. (1989). Theoretical constructs: Anxiety, self, and hallucinations. In A. O’Toole & S. Welt (Eds.), *Interpersonal theory in nursing practice: Selected works of Hildegard E. Peplau*. Springer

Consider This:

Could distraction and reframing help Doug reduce his anxiety and frequency of his panic attacks? What interventions would you recommend and why?

Positive Self-Talk

During states of increased anxiety and panic, individuals can learn to counter fearful or negative thoughts by using another cognitive approach. **Positive self-talk** involves planning and rehearsing positive coping statements “This is only anxiety, and it will pass,” “I can handle these symptoms,” and “I’ll get through this” are examples of positive self-talk. These types of positive statements can give the individual a focal point and reduce fear when panic symptoms begin. Handheld cards that offer positive statements can be carried in a purse or wallet so the person can retrieve them quickly when panic symptoms are felt (Box 27.8).

BOX 27.8 • Therapeutic Dialogue Panic disorder

Doug is admitted to an inpatient unit following another severe panic attack.

He had an argument with his high school son, who continues to use alcohol and marijuana. Financial problems are also escalating.

INEFFECTIVE APPROACH

Nurse: Oh.... Why are you crying?

Doug: (Looks up, gives a nervous chuckle.) Obviously, because I'm upset. I am tired of living this way. I just want to be normal again. I can't even remember what that feels like.

Nurse: You look normal to me. Everyone has bad days. It'll pass.

Doug: I've felt this way longer than you've been alive. I've tried everything, and nothing works.

Nurse: You're not the first depressed person that I've taken care of. You just need to go to groups and stay out of your room more. You'll start feeling better.

Doug: (Angrily) Oh, it's just that easy. You have no idea what I'm going through! You don't know me! You're just a kid.

Nurse: I can help you if you help yourself. A group starts in 5 minutes, and I'd like to see you there.

Doug: I'm not going to no damn group! I want to be alone so I can think!

Nurse: (Looks about anxiously.) Maybe I should come back after you've calmed down a little.

EFFECTIVE APPROACH

Nurse: Doug, I noticed that you are staying in your room more today. What's troubling you?

Doug: (Looks up) I feel like I've lost complete control of my life. I'm so anxious, and nothing helps. I'm tired of it.

Nurse: I see. That must be difficult. Can you tell me more about what you are feeling right now?

Doug: I feel like I'm going crazy. I worry all the time about having panic attacks. They make me scared I'm going to die. Sometimes I think I'd be better off dead.

Nurse: (Remains silent, continues to give eye contact.)

Doug: Do you know what it's like to be a prisoner to your emotions? I can't even go to work sometimes, and when I do, it's terrifying. I don't know what

to think anymore.

Nurse: Doug, you have lived with this disorder for a long time. You say that the medications do not work to your liking, but what has helped you in the past?

Doug: Well, I learned in relaxation group that panic symptoms are probably caused by chemicals in my brain that are not working correctly. I learned that medications can help, but they don't work well for me. I tried an exposure plan and relaxation techniques to deal with my fears of leaving the house and my chronic anxiety. That did help some, but it's scary to do.

Nurse: It sounds like you have learned a lot about your illness, one that can be treated, so that you don't always have to feel this way.

Doug: This is easier to say right now when I'm here and can get help if I need it. It's hard to remember this when I'm in the middle of a panic attack and think I'm dying.

Nurse: It's harder when you're alone?

Doug: Much harder! And I'm alone so much of the time.

Nurse: Let's talk about some ways you can manage your panics when you're alone. Tell me some of the techniques you've learned.

CRITICAL THINKING CHALLENGE

- What tone is established by the nurse's opening question in the first scenario?
- Which therapeutic communication techniques did the nurse use in the second scenario to avoid the pitfalls encountered in the first scenario?
- What information was uncovered in the second scenario that was not touched on in the first?
- What predictions can you make about the interpersonal relationship likely to develop between the nurse and the patient in each scenario?

NCLEXNOTE Cognitive interventions give patients with anxiety a sense of control over the recurring threats of panic and obsessions.

Psychoeducation

Psychoeducation programs help to teach patients and families about the symptoms of panic. Individuals with panic disorder legitimately fear going crazy, losing control, or dying because of their physical symptoms. Attempting to convince a patient that such fears are groundless only heightens anxiety and impedes communication. Information and physical evidence (e.g., electrocardiogram results, laboratory test results) should be presented in a caring and open manner that demonstrates acceptance and understanding of their situation.

Box 27.9 suggests topics for individual or small-group discussion. It is especially important to cover such topics as the differences between panic attacks and heart attacks, the difference between panic disorder and other psychiatric disorders, and the effectiveness of various treatment methods.

Wellness Strategies

Individuals with panic disorder, especially those with significant anxiety sensitivity, may need assistance in reevaluating their lifestyle. Time management can be a useful tool. In the workplace or at home, underestimating the time needed to complete a chore or being overly involved in several activities at once increases stress and anxiety. Procrastination, lack of assertiveness, and difficulties with prioritizing or delegating tasks intensify these problems.

Writing a list of chores to be completed and estimating time to complete them provide concrete feedback to the individual. Crossing out each activity as it is completed helps the patient to regain a sense of control and accomplishment. Large tasks should be broken into a series of smaller tasks to minimize stress and maximize sense of achievement. Rest, relaxation, and family time—frequently omitted from the daily schedule—must be included.

BOX 27.9

Panic Disorder

When caring for a patient with panic disorder, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents (anxiolytics or antidepressants) if ordered, including drug action, dosage, frequency, and possible adverse effects
- Breathing control measures
- Nutrition
- Exercise
- Progressive muscle relaxation
- Distraction behaviors
- Exposure therapy
- Time management
- Positive coping strategies

Providing Family Education

In addition to learning the symptoms of panic disorder, nurses should have information sheets or pamphlets available concerning the disorder and any medications prescribed. Parents, especially single parents, will need assistance in child-rearing and may benefit from services designed to provide some respite. Moreover, the entire family will need support in adjusting to the disorder. A referral for family therapy is indicated, because involving the entire family in the therapy process is imperative. Families experience the symptoms, treatments, clinical setbacks, and recovery from chronic mental illnesses as a unit. Misunderstandings, misconceptions, false information, and the stigma of mental illness, singly or collectively, impede recovery efforts.

Convening Support Groups

Participation in supportive groups is helpful in managing anxiety and fears (Barkowski et al., 2020). Persons with panic disorders are usually comfortable in groups with individuals who have other mental disorders and issues. As they participate in a group, they are able to share their fears of an impending panic attack and identify strategies to deal with their fears.

Developing Recovery-Oriented Rehabilitation

Strategies

Recovery begins with an understanding of the components of recovery discussed in Chapters 2 and 9. As the components of recovery are explained, the nurse should continue to engage the person in a collaborative decision-making process. The nurse's role in developing recovery-oriented strategies is to negotiate the most effective, evidence-based strategies. The nurse should encourage healthy behaviors supporting wellness as well as strategies directed toward illness management. Empowering the person to make choices that best match the individual's lifestyle increases the likelihood of treatment adherence and recovery. It will also foster a feeling of hopefulness. Some treatment recommendations will not be followed. For example, some persons will attend support groups, but others only want individual psychotherapy. The nurse should encourage the patient to commit to as many recovery strategies that are realistic.

Evaluation and Treatment Outcomes

Although many researchers consider panic disorder a chronic, long-term condition, the positive results from outcome studies should be shared with patients to provide encouragement and optimism that patients can learn to manage these symptoms. Outcome studies have demonstrated success with panic control treatment, CBT therapy, exposure therapy, and various medications specific to certain symptoms.

Continuum of Care

Emergency Care

Because individuals with panic disorder are likely to first present for treatment in an emergency department or primary care setting, nurses working in these settings should be involved in early recognition and referral. Consultation with a psychiatrist or mental health professional by the primary care physician can decrease both costs and overall patient symptoms. Several interventions may be useful in reducing the number of emergency department visits related to panic symptoms. Psychiatric consultation and nursing education can be provided in the

emergency department to explore other avenues of treatment. Remembering that the patient experiencing a panic attack is in crisis, nurses can take several measures to help alleviate symptoms, including the following:

- Stay with the patient and maintain a calm demeanor. (Anxiety often produces more anxiety, and a calm presence will help calm the patient.)
- Reassure the patient that you will not leave, that this episode will pass, and that they are in a safe place. (The patient often fears dying and cannot see beyond the panic attack.)
- Give clear concise directions using short sentences. Do not use medical jargon.
- Walk or pace with the patient to an environment with minimal stimulation. (The patient in panic has excessive energy.)
- Administer PRN (i.e., as-needed) anxiolytic medications as ordered and appropriate. (Pharmacotherapy is effective in treating those patients with acute panic attack.)

After the panic attack has resolved, allow the patient to vent their feelings. This often helps the patient in clarifying their feelings.

Inpatient-Focused Care

Inpatient settings provide control for the stabilization of the acute panic symptoms and initiation of recovery-oriented strategies. Medication use often is initiated here because patients who show initial panic symptoms require in-depth assessment to determine the cause. As recovery begins, crisis stabilization, medication management, milieu therapy, and psychotherapies are introduced, and outpatient discharge linkage appointments are set.

Community Care

Most individuals with panic disorder are treated on an outpatient basis. Referral lists of community resources and support groups are useful in this setting. A discussion about the recovery and the importance of the 10 components helps healing begin (see Chapters 2 and 9). Nurses are more directly involved in treatment, conducting psychoeducation groups on relaxation and breathing

techniques, symptom management, and anger management. Advanced practice nurses conduct CBT and individual and family psychotherapy. In addition, medication monitoring groups reemphasize the role of medications, monitor for side effects, and enhance treatment compliance overall.

As with any disorder, a continuum of patient care across multiple settings is crucial. Patients are treated in the least restrictive environment that will meet their safety needs. As the patient progresses through treatment, the environment of care changes from an emergency or inpatient setting to outpatient clinics or individual therapy sessions.

Virtual Mental Health Care

Virtual mental health services are more important now because of the impact of the coronavirus pandemic. The pandemic increased anxieties, depression, and grief. Face-to-face therapies increase anxiety about the risk of infection in individuals who already have significant anxieties. Virtual treatment is ideal. Most therapies discussed in this chapter are available in a virtual format. The patient needs to be cautioned about selecting services that are credible. Support groups such as the National Alliance on Mental Illness and the Anxiety and Depression Association of America are easily accessed online and provide resources for clinicians and patients.

Integration With Primary Care

Coordination of care between mental health and primary care leads to safer management of anxiety disorders. Some groups are more likely to seek out care in primary care rather than in mental health clinics. People with anxiety disorders are often treated in the primary care environment, particularly those who experience panic disorder. Because panic attacks mimic cardiac difficulties, it is important that the patient continues to seek health care monitoring with medical clinicians. Primary care providers are often asked to treat the physical consequences of anxiety, such as hypertension and obesity (Penninx & Lange, 2018). Anxiety can be caused by physical health issues, such as immune, metabolic, and cardiovascular problems. Many prescription and non-prescription drugs can cause anxiety such as asthma, blood pressure, steroid, and thyroid medications. Without coordination of care, the clinicians will not be able to

make a meaningful assessment, which could lead to the wrong treatment (Love & Love, 2019).

GENERALIZED ANXIETY DISORDER

Generally speaking, patients with generalized anxiety disorder (GAD) feel frustrated, disgusted with life, demoralized, and hopeless. They may state that they cannot remember a time that they did not feel anxious. They experience a sense of ill-being and uneasiness and a fear of imminent disaster. Over time, they may recognize that their chronic tension and anxiety are unreasonable.

Clinical Course

The onset of GAD is insidious. Many patients complain of being chronic worriers. GAD affects individuals of all ages. About half of individuals with GAD report an onset in childhood or adolescence, although onset after 20 years of age is also common. Adults with GAD often worry about matters such as their job, household finances, health of family members, or simple matters (e.g., household chores or being late for appointments). The intensity of the worry fluctuates and stress tends to intensify the worry and anxiety symptoms (APA, 2013).

Patients with GAD may exhibit mild depressive symptoms, such as dysphoria. They are also highly somatic, with complaints of multiple clusters of physical symptoms, including muscle aches, soreness, and gastrointestinal ailments. In addition to physical complaints, patients with GAD often experience poor sleep habits, irritability, trembling, twitching, poor concentration, and an exaggerated startle response. People with this disorder often are seen in a primary care setting with somatic symptoms (DeMartini et al., 2019).

Diagnostic Criteria

GAD is characterized by excessive worry and anxiety (apprehensive expectation) for at least 6 months. The anxiety does not usually pertain to a specific situation; rather, it concerns several real-life activities or events. Ultimately, excessive worry and anxiety cause great distress and interfere with

the patient's daily personal or social life.

BOX 27.10

Generalized Anxiety Disorder

When caring for the patient with GAD, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents (benzodiazepines, antidepressants, nonbenzodiazepine anxiolytics, β -blockers) if ordered, including drug action, dosage, frequency, and possible adverse effects
- Breathing control
- Nutrition and diet restriction
- Sleep measures
- Progressive muscle relaxation
- Time management
- Positive coping strategies

Nursing Care

Nursing care for the person with GAD is similar to the care of the individual with a panic disorder. In many instances, antidepressants and an antianxiety agent will be prescribed. Nursing interventions should focus on helping the person target specific areas of anxiety and reducing the impact of the anxiety. See [Box 27.10](#).

OTHER ANXIETY DISORDERS

Other disorders exist that have anxiety as their defining feature. These include generalized phobia, agoraphobia, specific phobias, and social anxiety disorder.

Agoraphobia

Agoraphobia is fear or anxiety triggered by about two or more situations such as using public transportation, being in open spaces, being in enclosed places, standing in line, being in a crowd, or being outside of the home alone (APA, 2013). When these situations occur, the individual believes that something

terrible might happen and that escape may be difficult. The individual may experience panic like symptoms or other embarrassing symptoms (e.g., vomiting, diarrhea) (APA, 2013). Agoraphobia leads to avoidance behaviors. Such avoidance interferes with routine functioning and eventually renders the person afraid to leave the safety of home. Some affected individuals continue to face feared situations but with significant trepidation (i.e., going in public only to pay bills or to take children to school). Agoraphobia may occur with panic disorder but is considered a separate disorder.

Specific Phobia

Specific phobia disorder is marked by persistent fear of clearly discernible, circumscribed objects or situations, which often leads to avoidance behaviors. Phobic objects can include animals (e.g., spiders, snakes), natural environment (e.g., heights, storms), blood injection injury (e.g., fear of blood, injections), and situational (e.g., elevators, enclosed spaces). The lifetime prevalence rates range from 7% to 9%, and the disorder generally affects women twice as much as men (APA, 2013). It has a bimodal distribution, peaking in childhood and then again in the 20s. The focus of the fear in specific phobia may result from the anticipation of being harmed by the phobic object. For example, dogs are feared because of the chance of being bitten or automobiles are feared because of the potential of crashing. The focus of fear may likewise be associated with concerns about losing control, panicking, or fainting on exposure to the phobic object.

Anxiety is usually felt immediately on exposure to the phobic object; the level of anxiety is usually related to both the proximity of the object and the degree to which escape is possible. For example, anxiety heightens as a cat approaches a person who fears cats and lessens when the cat moves away. At times, the level of anxiety escalates to a full panic attack, particularly when the person must remain in a situation from which escape is deemed to be impossible. Fear of specific objects is fairly common, and the diagnosis of specific phobia is not made unless the fear significantly interferes with functioning or causes marked distress. Assessment differentiates simple phobia from other diagnoses with overlapping symptoms. [Box 27.11](#) lists a number of specific phobias. Among adult patients who are seen in clinical settings, the most-to-least common phobias are situational phobias, natural environment phobias, blood injection, injury phobia, and animal phobias (APA, 2013).

BOX 27.11

Common Phobias

- Acrophobia: fear of heights
- Agoraphobia: fear of open spaces
- Ailurophobia: fear of cats
- Algophobia: fear of pain
- Arachnophobia: fear of spiders
- Brontophobia: fear of thunder
- Claustrophobia: fear of closed spaces
- Cynophobia: fear of dogs
- Entomophobia: fear of insects
- Hematophobia: fear of blood
- Microphobia: fear of germs
- Nyctophobia: fear of night or dark places
- Ophidiophobia: fear of snakes
- Phonophobia: fear of loud noises
- Photophobia: fear of light
- Pyrophobia: fear of fire
- Topophobia: fear of a place, like a stage
- Xenophobia: fear of strangers
- Zoophobia: fear of animal or animals

Blood injection injury phobia merits special consideration because the phobia involves medical treatments. The physiologic processes that are exhibited during phobic exposure include a strong vasovagal response, which significantly increases blood pressure and pulse, followed by deceleration of the pulse and lowering of blood pressure in the patient. Monitor closely when giving required injections or medical treatments.

About 75% of patients with blood injection injury phobia report fainting on exposure. Factors that may predispose individuals to specific phobias may include traumatic events; unexpected panic attacks in the presence of the phobic object or situation; observation of others experiencing a trauma; or repeated exposure to information warning of dangers, such as parents repeatedly warning young children that dogs bite.

Phobic content must be evaluated from an ethnic or cultural background. In many cultures, fears of spirits or magic are common. They should be considered part of a disorder only if the fear is excessive in the context of the culture, causes

the individual significant distress, or impairs the ability to function. Psychotropic drugs have not been effective in the treatment of specific phobia. Anxiolytics may give short-term relief of phobic anxiety, but no evidence confirms that they affect the course of the disorder. The treatment of choice for specific phobia is exposure therapy. Patients who are highly motivated can experience success with treatment (Böhnlein et al., 2020).

Social Anxiety Disorder (Social Phobia)

Social anxiety disorder involves a persistent fear of social or performance situations in which embarrassment may occur. Exposure to a feared social or performance situation nearly always provokes immediate anxiety and may trigger panic attacks. People with social anxiety disorder fear that others will scrutinize their behavior and judge them negatively. They often do not speak up in crowds out of fear of embarrassment. They go to great lengths to avoid feared situations. If avoidance is not possible, they suffer through the situation with visible anxiety (APA, 2013).

People with social anxiety disorder appear to be highly sensitive to disapproval or criticism, tend to evaluate themselves negatively, and have poor self-esteem and a distorted view of their personal strengths and weaknesses. They may magnify their personal flaws and underrate any talents. They often believe others would act with more assertiveness in a given social situation. Women are more likely to have social anxiety disorder, but both men and women tend to have difficulties with dating and with sexual relationships (Asher et al., 2017). Children tend to underachieve in school because of test-taking anxiety. This is an important area that should be assessed in all patients. See [Box 27.12](#).

Generalized social anxiety disorder is diagnosed when the individual experiences fears related to most social situations, including public performances and social interactions. These individuals are likely to demonstrate deficiencies in social skills, and their phobias interfere with their ability to function (Asher et al., 2017).

People with social anxiety disorder fear and avoid only one or two social situations. Classic examples of such situations are eating, writing, or speaking in public or using public bathrooms. The most common fears for individuals with social anxiety disorder are public speaking, fear of meeting strangers, eating in public, writing in public, using public restrooms, and being stared at or being the center of attention.

Pharmacotherapy is a relatively new area of research in treating patients with social anxiety disorder. SSRIs are used to treat those with social anxiety disorder because they significantly reduce social anxiety and phobic avoidance. Benzodiazepines are also used to reduce anxiety caused by phobias. Providing referrals for appropriate psychiatric treatment is a critical nursing intervention.

BOX 27.12

A Mental Health Recovery Journey

Hickmott, J., & Raeburn, T. (2020). *Mouse to man, a mental health recovery journey*. *Journal of Psychiatric and Mental Health Nursing*, 27(6), 844–849. <https://doi.org/10.1111/jpm.12621>

THE QUESTION: What are the insights that can be gained from narratives written by people with lived experience of mental illness?

METHODS: A lived experience about recovery from a social anxiety disorder that began in childhood is written in first person.

FINDINGS: Recovery is an ongoing process of growth and development. His symptoms began at age 11 years when his parents divorced and he began missing school, not communicating with teachers, and avoiding doctors. The author did not recognize that he needed help until after he attended a clinic at age 16 years. He experienced treatment in a variety of settings for social anxiety. He did not really engage in recovery until he began seeing a nurse who was more like a coach and he was the player. Within this collaborative relationship, he learned a lot about what was going on with him. He gained insight, finished university, and is now a Peer Worker.

IMPLICATIONS FOR NURSING: This narrative supports the need for recovery-oriented mental health nursing and the hypothesis that recovery is possible. Hope was important throughout his journey. Recovery takes time. In this instance, it was 2 years of frequent visits. This narrative emphasizes that individuals with mental health issues are more than symptoms. It is important to see the whole person.

SUMMARY OF KEY POINTS

- Anxiety is an unavoidable human condition. Anxiety becomes an anxiety disorder when anxiety and fear significantly interferes with social and occupational functioning.
- Anxiety-related disorders are the most common of all psychiatric disorders and comprise several disorders, including panic disorder.

- The anxiety disorders share the common symptom of recurring anxiety but differ in symptom profiles. Panic attacks can occur in many different disorders. Physical symptoms can mimic a heart attack.
- Panic disorder can occur throughout the lifespan but is most common in adulthood. Those experiencing anxiety disorders have a high level of physical and emotional illness and often experience dual diagnoses with other anxiety disorders, substance use disorder, or depression. These disorders often render individuals unable to function effectively at home or at a job.
- There appears to be a familial predisposition to panic disorders. Serotonin and norepinephrine are both implicated in panic disorders. The hypothalamic–pituitary–adrenal axis and activation of the stress hormones are also implicated in the expression of this disorder.
- Patients with panic disorder are often seen in various health care settings, frequently in hospital emergency departments or clinics, presenting with a confusing array of physical and emotional symptoms. Skillful assessment is required to eliminate possible life-threatening causes.
- Treatment approaches for all anxiety-related disorders are somewhat similar, including pharmacotherapy, psychological treatments, or often a combination of both.
- Antidepressants are the first-line medication treatment and are often included in psychosocial therapies such as cognitive-behavior therapy, and exposure therapy. Virtual mental health strategies such

as telehealth, mobile apps provide most of the same therapies as face-to-face therapies.

- Nursing interventions include helping patients manage a panic attack, promoting healthy diet, exercise and sleep hygiene habits, medication administration and monitoring, psychoeducation, and cognitive interventions.
- Many persons with panic disorders have other health problems that are treated in primary care. Mental and physical health needs should be integrated with both primary and mental health services.

CRITICAL THINKING CHALLENGES

1. A patient is unable to focus on your directions. He does not seem to notice others in the room; instead, he is intent on cutting his food into small pieces. Applying Peplau stages of anxiety, what level of anxiety is he experiencing?
2. Compare and contrast the following treatment modalities for anxiety disorders: systematic desensitization, implosive therapy, exposure therapy, and CBT.
3. Identify the major nursing assessment areas for a person experiencing a panic disorder.
4. A patient asks you how to prevent hyperventilation. How would you answer her question?
5. Delineate the differences in treatment effects of antidepressants versus antianxiety medication in the treatment of panic disorder.
6. Compare the various phobias that people experience. What interventions should a nurse use for a person who has a blood injection injury phobia?
7. How might one differentiate shyness from social anxiety disorder?

available at <http://thepoint.lww.com/Boyd7e>.

Unfolding Patient Stories: Linda Waterfall • Part 2

Recall from Unit II Linda Waterfall, a 48-year-old Native American diagnosed with an aggressive form of breast cancer. The recommended treatment is a mastectomy followed by chemotherapy, which she refused. What is the association between her illness and episodes of severe anxiety since diagnosis? How

can a secondary mental health disorder contribute to her physical decline from cancer? What psychosocial assessments and interventions should the nurse incorporate into the plan of care to manage her anxiety?

Care for Linda and other patients in a realistic virtual environment: (thepoint.lww.com/vSimMentalHealth). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Obsessive-Compulsive and Related Disorders

Nursing Care of Persons with Obsessions and Compulsions

Patricia E. Freed

KEYCONCEPTS

- compulsions
- obsessions

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of obsessions and compulsions in mental disorders.
2. Delineate clinical symptoms and course of obsessive-compulsive disorders.
3. Analyze theories of obsessive-compulsive disorders.
4. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with obsessions and compulsions.
5. Apply a person-centered, recovery-oriented nursing process for persons with obsessive-compulsive disorders.

6. Identify medications used to treat people with obsessions and compulsions and evaluate their effectiveness.
7. Develop wellness strategies for persons with obsessions and compulsions.
8. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
9. Discuss the importance of integrated health care for persons with obsessions and compulsions.
10. Describe other related obsessive-compulsive disorders.

KEY TERMS

- Circumferential speech
- Conditioned stimuli
- Cyberchondria
- Dissociative absorption
- Family accommodation
- Isolation
- Reaction formation
- Rituals
- Scrupulosity
- Undoing

Case Study: Tim

Tim, a 32-year-old engineer, was diagnosed with OCD as a teenager when his obsession with cleanliness and compulsively washing his hands interfered with his friendships and school work.

INTRODUCTION

Most of us experience times when we are preoccupied with specific thoughts or ideas. Many also find that routines or rituals are important in organizing our work and home life. When these preoccupations and rituals interfere with daily life, they become abnormal and may represent symptoms of a mental disorder. This chapter explains obsessions and compulsions and their role in obsessive-compulsive disorders. Obsessive-compulsive disorder (OCD) is highlighted in this chapter.

OBSESSIONS AND COMPULSIONS

When preoccupied thoughts become excessive, intrusive, or unwanted, such thoughts are considered to be obsessions.

KEYCONCEPT Obsessions are excessive, unwanted, intrusive, and persistent thoughts, impulses, or images that cause anxiety and distress.

Obsessions are not under the person's control and are inconsistent with the person's usual thought patterns.

Common obsessions include fears of contamination, pathologic doubt, the need for symmetry and completion, thoughts of hurting someone, and thoughts of sexual images.

Routines are a part of everyday life. Getting up in the morning at the same time and going to work or school structures our lives and helps us be productive. When routines become ritualistic and interfere with normal daily activity, they become compulsions.

KEYCONCEPT Compulsions are repetitive behaviors and mental acts performed in a ritualistic fashion with the goal of preventing or relieving anxiety and distress caused by obsessions.

For example, making sure a stove is turned off before leaving the house can be a safety routine, but being late for work because of making several trips to the stove before leaving the house is a compulsion. Common compulsions include

handwashing, excessive cleaning, checking, arranging things, counting, ordering, and hoarding.

OBSESSIVE-COMPULSIVE AND RELATED DISORDERS: OVERVIEW

Obsessions and compulsions are characteristic of obsessive-compulsive and related disorders. These disorders include OCD, body dysmorphic disorder (BDD; perceived flaws or defects in one's physical appearance), hoarding disorder (excessive accumulation and/or difficulty discarding possessions), trichotillomania (i.e., compulsively pulling out one's hair), excoriation disorder (skin picking), and substance/medication-induced OCD. These disorders are closely related to anxiety disorders (American Psychiatric Association [APA], 2013).

OBSESSIVE-COMPULSIVE DISORDER

In OCD, affected persons may have both obsessions and compulsions and believe that they have no control over them, which results in devastating consequences for affected individuals. Because of the nature of the disorder, nurses who work in settings other than psychiatric settings or in-home health care may be among the first to identify an individual's symptoms as OCD and make the appropriate referrals. Symptoms of OCD can be grouped under four dimensions: contamination and germs, responsibility for unintentional harm, blasphemous or immoral thoughts, and concerns with symmetry, counting, or completion. Many individuals have good or fair insight regarding the accuracy of their beliefs. However, some show an absence of insight, similar to delusional beliefs, which has been linked to worse long-term outcomes (APA, 2013). Though obsessive beliefs may be irrational, they are not as fixed and unyielding as delusions, and insight regarding these beliefs may change over the course of the disorder. Symptoms of OCD are often less severe than those in delusional disorder, and individuals with OCD generally have higher levels of educational attainment and experience higher quality of life (QOL) than those with delusional disorders.

While it may seem that some symptoms of OCD overlap with obsessive-compulsive personality disorder (OCPD), they are separate disorders (OCPD is discussed in [Chapter 30](#)). A major difference between these two disorders is that the repeated irrational behaviors of those with OCD are driven by underlying anxiety and have no apparent aim or purpose. OCD symptoms also fluctuate according to the individual's state of anxiety, and the individual is often driven to seek professional help to find relief.

Clinical Course

OCD follows a chronic waxing and waning course. Symptoms of OCD (nonclinical or subclinical) often begin in childhood, but many receive treatment only after the disorder has significantly affected their lives. In preschool-age children, OCD is often misdiagnosed as separation anxiety disorder (Miyawaki et al., 2018). Onset in early or middle childhood is associated with a better outcome than later onset (Sharma & Math, 2019).

Subclinical symptoms can be distressing and cause some impairment. Escalation of subclinical symptoms takes on average 7 years. Predisposition to escalation is associated with being a male, younger age of symptom assessment, being in a new romantic relationship, having more severe sexual/religious symptoms, and having low rates of hoarding (Thompson et al., 2020).

Individuals with OCD may become incapacitated by their symptoms and spend most of their waking hours locked in a cycle of obsessions and compulsions. They may even become unable to complete a task as simple as walking through a door without performing rituals. Interpersonal relationships suffer, and the person may actively isolate and withdraw from contact with others. Individuals with OCD often engage in **dissociative absorption**, a tendency to become excessively absorbed in fantasy (movies, online gaming), leading to decreased self-awareness and inattention to their surroundings. Dissociative absorption may predict the onset of obsessive-compulsive symptoms, though this possible link is still being investigated (Soffer-Dudek, 2019).

Remember Tim?

When Tim was in high school, he was unable to eat at the school cafeteria because he was afraid the other students' germs would contaminate his food. He avoided touching doorknobs and would wash his hands for 3 minutes if he inadvertently touched a doorknob.

Diagnostic Criteria

OCD is diagnosed when recurrent obsessions or compulsions (or both) take up more than 1 hour a day or cause considerable stress to the individual. These obsessions or compulsions are not caused by substance or medication use or other disorders. Some individuals recognize that these obsessions or compulsions are excessive and unrealistic; others have limited insight and are unsure whether the obsessive thoughts are true but continue to have the thoughts and feel compelled to perform the actions. Another group of individuals are convinced that their obsessive thoughts are true. These thoughts and compulsive behaviors are stressful and interfere with normal daily routines (APA, 2013).

Obsessions

Obsessions create tremendous anxiety. Some individuals have obsessions surrounding aggressive acts of hurting someone or themselves. After hitting a bump in the road, for example, they may obsess for hours over whether they have hit someone. Parents may have recurrent intrusive thoughts that they may hurt their child. The most common obsession is fear of contamination and results in compulsive handwashing. Fear of contamination usually focuses on dirt or germs, but other materials may be feared as well, such as toxic chemicals, poison, radiation, and heavy metals. Individuals with contamination obsessions report anxiety as their most common effect, but shame and disgust, linked with

embarrassment and guilt, also are experienced. Still, others obsess over following the letter of the law, or over the meaning of sin.

Scrupulosity is a specific OCD dimension in which symptoms center on religious or morally intrusive thoughts, followed by repetitive actions, such as going to confession or repeatedly asking for forgiveness. Diagnosis of scrupulosity is not made unless the thoughts or rituals clearly exceed cultural or religious norms, occur at inappropriate times as described by members of the same religion or culture, or interfere with social obligations (APA, 2013). Although it might be difficult to have a conversation centering on religious concerns and family practices, recent findings show that youth with religious obsessions benefit from treatment (Wu et al., 2018b). Somatic obsessions, such as persistent attention to normal bodily processes like breathing, blinking, and swallowing, can also be present and can become intrusive, terrifying thoughts which can interfere with everyday activities.

Compulsions

Compulsions are often performed to relieve the anxiety created by the obsession. Worries about contamination and germs or catching infectious diseases are common. Thoughts about how to protect ourselves should be crossing our minds, especially during the COVID-19 pandemic. For most people, these are fleeting thoughts, and the actions we are taking, via public service announcements, laws, and other friendly reminders, have become part of our expected common-sense approach to public protection. These actions are not pathologic compulsions.

Rituals are common compulsions in which objects must be in a certain order, motor activities are performed in a rigid fashion, or things must be arranged in perfect symmetry. A ritualized behavior may be driven by obsessive thoughts or may be attributed to a distinctive urge that creates tension and pressure throughout the body. A ritual consumes a great deal of time to complete, interfering with even the simplest task. Some individuals experience discontent, rather than anxiety, when things are not symmetrical or perfect. Others think magically and perform compulsive rituals to ward off an imagined disaster, such as repeatedly turning on and off the alarm clock to prevent disaster. Those who hoard are compelled to check their belongings repeatedly to see that all are accounted for and check the garbage to make sure that nothing of value has been

discarded.

Cyberchondria, characterized by excessive online searching for health information, is under investigation as another type of compulsive behavior. Excessive searching might provide some temporary reassurance while leading to ever-worsening anxiety and distress (Vismara et al., 2020).

Concept Mastery Alert

Certain actions, such as making sure that all doors are locked before going to bed, are safety considerations in which the associated anxiety is protective. This is a normal activity and concern, not a pathologic compulsion.

Obsessive-Compulsive Disorder Across the Life Span

Although OCD is relatively common, it is still under-recognized and undertreated. OCD affects people of all ages. Identification, diagnosis, and treatment of OCD are necessary for recovery and optimal functioning.

Disorders Across the Life Span

Children and Adolescents

Because children subscribe to myths, superstition, and magical thinking, obsessive and ritualistic behaviors may go unnoticed. Behaviors such as touching every third tree, avoiding cracks in the sidewalk, or consistently verbalizing fears of losing a parent in an accident may have some underlying pathology but are common behaviors in childhood. Obsessions and compulsions in children are more likely to change/evolve as well as to wax and wane, compared to the course of the disorder in adults. Typically, parents notice that a child's grades begin to fall as a result of decreased concentration and a great amount of time spent performing rituals. Children often have at least one other mental disorder and are less likely than adults to recognize the irrationality of their symptoms. A link between infection with β -hemolytic streptococci and other infections and a subset of acute-onset OCD has been established. The condition is known as pediatric acute-onset neuropsychiatric syndrome. First signs may be

the dramatic (2 or 3 days) onset of obsessions and compulsions and overwhelming anxiety (fears). Some children develop sudden eating restrictions and personality changes. Treatments such as antibiotics and immunomodulatory interventions have been suggested, but further study is needed to reach consensus about how best to treat the immunologic response and eliminate (or diminish) the symptoms (Sigra et al., 2018).

Older Adults

Among older adults, OCD most likely began in childhood, but there are some older adults whose onset (beginning of individual distress and interference in work, family, and social activities associated with obsessions and compulsions) began later in life. In the older adult, continuing symptoms are linked to higher rates of depression and poorer mental and social functioning (Dell’Osso et al., 2017). Older adults who engage in checking compulsions and hoarding may have more thought disturbances and communication difficulties than those who engage in other types of compulsive behaviors (Lo Monaco et al., 2020; [Box 28.1](#)).

Epidemiology and Risk Factors

The lifetime prevalence of OCD among U.S. adults over 18 was 2.3%, with slightly higher rates in females during adolescence and adulthood (Mathes et al., 2019). Identifying those at risk for more rapid symptom escalation may lessen the heavy public health burden of this chronic disorder for the more than 60 million people in the United States who experience OCD symptoms without meeting the formal criteria for diagnosis (Beyond OCD, 2020). In most people, this chronic condition is associated with moderate to severe disability and carries a heavy health burden for the patient and family. In 2017, the World Health Organization listed this condition among the sixth-largest contributors to nonfatal global health loss (OCD UK, 2020).

Age of Onset

The onset of the illness has a bimodal peak—in early adolescence and early adulthood (Sharma & Math, 2019). Males were thought to have a higher rate of childhood onset, but it may be that males experience greater symptom severity at a younger age for which they seek treatment (Mathes et al., 2019; Torresan et al., 2013). Occurrence over the age of 35 is rare (APA, 2013). While subclinical symptoms may not lead to a formal diagnosis of OCD, they may still be troubling and contribute to some level of impairment. Obsessional thinking styles might have an effect on cognitive performance, and knowing this could help tailor cognitive-behavior therapy (CBT) for those with subclinical symptoms.

BOX 28.1 CLINICAL VIGNETTE

Older Adult

Louise, a 76-year-old retired accountant, resides in an assisted living complex with her husband. Always very neat and organized, she recently began cleaning excessively, sometimes in the middle of the night. She developed a routine where she had to have everything cleaned before she could eat. Her husband expressed his concern to their primary care provider, who referred them to a geriatric psychiatrist. A diagnosis of OCD was made. Louise recognizes that her behavior has changed and is interfering with her life but says she gets too nervous if she doesn't carry out her routine.

What Do You Think?

- Are there indications that Louise may have had subclinical OCD symptoms?
- What symptoms of OCD is Louise experiencing?

Gender Differences

Gender and age differences in OCD are being clarified and sometimes challenging earlier studies. Female adults are more likely to experience symptoms related to contamination or to have aggressive thoughts toward the child after a birth (Torresan et al., 2013), while males are more likely to report

blasphemous obsessions (Mathes et al., 2019). However, these differences may be a product of the way genders report symptoms. Males report a broad range of symptoms, and females tend to report only one or two symptoms (Raines et al., 2015). One study that did consider both age and gender differences found that the risk of OCD in daughters (rather than sons) born to older (rather than younger) parents was higher (Janecka et al., 2019).

A recent literature review found no gender differences in outcomes of behavioral or pharmacologic treatment or in the likelihood of experiencing comorbidities. However, gender may influence the specific type of comorbid condition. Reproductive hormones may play a central role in the differences found between males and females (Karpinski et al., 2017; Mathes et al., 2019).

Family, Ethnicity, and Culture Differences

The core features of OCD are thought to be relatively independent of cultural variation, but there has been little investigation into the impact of culture on symptom expression. An exception is religious affiliation, which appears to influence the content of obsessions and the severity of OCD symptoms. Among individuals who identify as Catholics, there is a higher risk of developing scrupulosity than in persons identifying with other religious affiliations or having no religious affiliation (Buchholz et al., 2019). Other factors related to culture, such as poverty, educational background, and access to health services, have not been investigated (Nicolini et al., 2017).

Culture, ethnic, and family beliefs shape the perception and influence the treatment of OCD. The symptoms are interpreted and manifested within culturally accepted norms. At times, cultural or religious beliefs and practices may be misunderstood and mistaken for obsessions or compulsions. These beliefs and actions must be evaluated in the context of the individual's culture. If these beliefs are consistent with the patient's social, family, or cultural environment; are not harmful to the individual or others; and do not interfere with individual functioning in that environment, they should not be considered symptoms of OCD.

Comorbidity

High rates of comorbid conditions can be found in populations with OCD, most commonly, anxiety disorders, mood disorders, and other related obsessive-compulsive disorders (Brakoulias, 2017). Having any comorbid condition is associated with a longer course of illness, and having two or more contributes to symptom severity and chronicity. Worsening levels of suicidality (thoughts) and suicide attempts are related to the severity of comorbid depression, anxiety and obsessive symptoms, feeling hopeless and to having a history of suicide attempts (Eskander et al., 2020).

OCD and eating disorders (EDs), such as anorexia and bulimia, are highly comorbid and share similarities such as obsessional thinking, ritualized behaviors, and perfectionism (Meier et al., 2020). The presence of an ED complicates the treatment of OCD. In both disorders, individuals have difficulty controlling their thoughts. In OCD, there is difficulty controlling obsessional thoughts and in EDs, there is weight overvaluation, fear of loss of control, and concerns that other see one eats (Meier et al., 2020).

More than half of children with OCD have one or more comorbid conditions and though understudied, Tics/Tourette syndrome, attention deficit hyperactivity disorder (ADHD), and OCD frequently occur together, though symptom severity of each disorder decreases with age (Groth et al., 2017).

Obsessive-compulsive symptoms are common in persons who have migraines and in individuals with schizophrenia, who are experiencing anxiety, mood symptoms, and psychosis. Although treatable, when obsessive-compulsive symptoms appear along with schizophrenia, they often go unrecognized and remain untreated (Bener et al., 2018; Jeyagurunathan et al., 2020).

As a child, Tim frequently went to the school nurse about multiple physical symptoms. Later, he was unable to engage in sexual relations with a long-time girlfriend because the thought of the sex act made him feel nauseous, and twice he experienced severe vomiting. At the time, he sought emergency treatment but ultimately no physical reason was discovered.

Etiology

During the 1990s, research evidence from neuroimaging studies, neurochemical studies, and treatment advances substantiated a predominantly neurobiologic basis for OCD. The following sections provide a brief overview of these findings and evidence pointing to genetic vulnerability. Psychological factors are also discussed because of their contributions to the disorder. Because no single explanation accounts for all aspects of OCD, a combination of factors will probably be found to produce the disorder.

Biologic Theories

Genetic, neuropathologic, and biochemical research, reviewed in this section, suggests that OCD has a biologic basis involving several neuroanatomic structures.

Genetic Factors

Family and twin studies demonstrate that OCD is a multifactorial familial condition that involves multiple genes and environmental risk factors (Pauls et al., 2014; Purty et al., 2019). OCD occurs more often in people who have first-degree relatives with OCD or with Tourette syndrome than it does in the general population. Some studies show an increased prevalence of anxiety and mood disorders in relatives of individuals who have OCD. Twin studies indicate that OCD occurs more frequently in siblings of twins. There appears to be an elevated risk of suicide attempts among the relatives of those with OCD, and the odds increase with closer relationships (Sidorchuk et al., 2021). Some symptom dimensions may have more familiarity than others (hoarding, contamination, symmetry related). These discoveries may lead to breakthroughs in pharmacologic treatments of OCD.

Neuropathologic Theories

Neuroimaging studies of individuals with OCD have shown excessive activity in the frontal cortex and subcortical structures of the brain that correlate with clinical symptoms and cognition and brain function (Nakao et al., 2014). A link between activity in specific brain circuits and reduction of OCD symptoms after successful pharmacologic or psychological treatment has been confirmed via meta-analysis (van der Straten et al., 2017). Because there are broader brain areas involved than originally thought, OCD is assumed to be a heterogeneous condition with several abnormal neurobiologic circuits (Nakao et al., 2014).

Currently, OCD has been conceptualized as a dysfunction in stopping the dynamics of normal brain networks, which evolved to handle danger (Woody et al., 2019). Simply put, this means that sufferers may realize there are errors in their behavior but have no inhibitory control (disconnected brakes, metaphorically). Note that these studies don't confirm the neurologic etiology of OCD, but they make it possible to match responders to specific treatments. For instance, in cases of severe, disabling OCD, where neurosurgery is an emerging option, the neurosurgeon will have a better idea of which brain region to target, either by disconnecting an area of the brain with a tiny burst of energy or by inserting a tiny probe to stimulate (activate) a specific area.

Biochemical Theories

Biochemical theories address imbalances of chemicals in the brain, but there is no persuasive evidence that any mental illness is caused by a single biochemical imbalance. Serotonin has been the most extensively studied neurotransmitter in relation to OCD, largely through challenge tests in which serotonin agonists were administered to persons with OCD and with control subjects. The most convincing evidence for serotonin's role is that serotonin-specific antidepressants relieve the symptoms of OCD for about 40% to 60% of those who take them. Conventional and novel antipsychotic medications and mood stabilizers are used in conjunction with serotonin-targeting medications to treat refractory symptoms, indicating that other biochemical processes exist (Del Casale et al., 2019). When chemical balances are identified, it is still difficult to understand how they relate to precise mechanisms of OCD, nor is it possible to know if the chemical changes caused the symptoms or presented because of the symptoms (chicken and egg confound). Prolonged treatment with selective serotonin reuptake inhibitor (SSRI), combined with CBT or with exposure and response prevention (ERP) therapy, is the most effective treatment (Del Casale et

al., 2019). New treatments for refractory OCD are needed, and likely candidates will be based on pharmacogenetics (Del Casale et al., 2019).

Psychological and Psychosocial Theories

Although psychological theories of OCD have not been scientifically tested, the rich literature describing clinical examples and case histories helps us understand the symptoms and behaviors related to OCD. In addition, behavioral treatment of individuals with severe compulsions improves symptoms. CBT, which should be considered in every treatment plan, is associated with lower relapse rates (Richter & Ramos, 2018).

Psychosocial Theories

Psychodynamic Factors

The psychodynamic theory hypothesizes that OCD symptoms and character traits arise from three unconscious defense mechanisms: **isolation** (separation of affect from a thought or impulse), **undoing** (an act performed with the goal of preventing consequences of a thought or impulse), and **reaction formation** (behavior and consciously stated attitudes that oppose underlying impulses). Classic psychoanalytic theory describes OCD as regression from the oedipal phase to the anal phase of development, which includes preoccupations with anger and dirt (see [Chapter 7](#)). This regression occurs when the patient becomes anxious about retaliation or loss of love.

Behavioral Factors

Behavioral explanations for OCD stem from learning theory. From this viewpoint, obsessions are seen as **conditioned stimuli**. Though being associated with noxious events, stimuli that are usually considered neutral become anxiety provoking. The individual then engages in activities to escape or avoid the anxiety. Compulsions develop as the individual discovers behaviors that successfully reduce the obsessional anxiety. As the principles of operant

conditioning indicate, the more the behaviors decrease the anxiety, the more likely the individual is to continue using them. However, the rituals or behaviors preserve the fear response because the person avoids the initial stimuli and thus never extinguishes the compulsion. Interrupting this cycle is the focus of behavioral therapy in treating an individual with OCD. Nurses often use behavioral approaches to reinforce and encourage acceptable behaviors, to set limits, and to impose structure on the environment to make people feel safe, which can reduce anxiety and confusion.

Family Response to Obsessive-Compulsive Disorder

OCD poses a considerable caregiving burden on families, which is heightened by severe symptoms, functional impairment, and comorbid psychopathologies in the child or caregiver (Wu et al., 2018a). Severity of symptoms has been linked to family distress. Families often accommodate a family member's symptoms by taking part in rituals or by modifying their daily routines. Levels of **family accommodation** should be carefully tracked and monitored, because reducing the family's involvement in compulsions may improve treatment outcomes (La Buissonniere-Ariza, et al., 2018).

Family assessment will reveal the amount of education and support needed and will begin the partnership among the individual, family, and treatment team. Evaluate the family's understanding of the disorder and of proposed treatments. Are they able and willing to help the individual practice cognitive and behavioral techniques? Are they knowledgeable about prescribed medicines? These questions offer a wonderful opportunity for individual and family education.

Family members offer a perspective on the severity of the individual's illness. Family members are experts in the patient's rituals and may observe subtle changes. Evaluate the family's response to changes in the individual's behavior as treatment progresses. You may have to discuss how the family will manage the changes brought about by a decrease in rituals. If obsessions and compulsions make it difficult for the individual to leave home or function at work, financial difficulties may result. These factors should be assessed and appropriate assistance obtained through social services when necessary. Adverse family functioning is strongly associated with pediatric OCD, though its role

remains unclear (Murphy & Flessner, 2015).

Tim's Family

Tim's parents recognized their son had unusual behaviors that interfered with his normal growth and development. When he was in high school, his parents took him to a psychiatrist who prescribed medication and offered brief counseling. Tim was able to successfully complete high school with honors and was accepted into a highly respected college. He was able to function when taking medications.

RECOVERY-ORIENTED CARE FOR PERSONS WITH OBSESSIVE-COMPULSIVE DISORDER

Teamwork and Collaboration: Working Toward Recovery

OCD can be difficult to treat because obsessions and compulsions consistently interfere with recovery efforts. OCD is treated with medications, CBT, and supportive therapy. Prolonged treatment with SSRI, combined with CBT or with ERP therapy, is the most effective treatment (Del Casale et al., 2019). The overall goal is for the patient to recover and to decrease the symptoms. Staff may have differing opinions about the amount of control the individual has over the behavior, but these differences of opinion must be resolved. All staff must be consistent in their expectations and acceptance of the patient's behaviors to keep these patients from becoming frustrated or confused regarding expectations during treatment (see [Box 28.2](#)).

BOX 28.2 CLINICAL VIGNETTE

More Teamwork Needed

Robert, a 32-year-old man, is a new patient at a local psychiatric unit. He admitted himself to have his medicines evaluated because his obsessive thoughts and depression have worsened since his recent divorce. While in the hospital, he has quickly become viewed as a “problem patient” because he hoards linens and demands a new bar of soap for each of his five daily showers. He is compelled to open and close his door five times when he leaves or enters his room but does not know why. This behavior has led to arguments with his roommate. In an effort to “help him,” the psychiatric technicians locked his bathroom door to prevent him from showering so frequently. He tried to enter his bathroom to shower and panicked when the technicians refused to allow him to shower, telling him, “You can live without it.” After receiving PRN medication for extreme anxiety, Robert signed out of the hospital against medical advice because of embarrassment and anger toward the nursing staff.

What Do You Think?

- How could the technicians have handled the situation differently so as to not disrupt Robert’s or the unit’s clinical care?
- What nursing interventions might be appropriate in providing Robert’s care?

Electroconvulsive Therapy

The effect of electroconvulsive therapy (ECT) on decreasing obsessions and compulsions cannot be confirmed or refuted. Authors who reviewed the literature concluded that it may have no role in the routine treatment of OCD (Fontenelle et al., 2015). Previous reports of high success may have been compromised by poorly defined treatment resistance, less than optimal treatment, and other specific differences between the population studied (Fontenelle et al., 2015). A recent case report described complete remission after a course of ECT in a patient with anorexia and disabling OCD, which did not

recur during the first year of follow-up (Sag˘lam et al., 2018). Although it is too early to draw a definite conclusion, future research may identify the effectiveness of ECT under certain circumstances or for those with specific comorbid conditions. Nursing’s role in caring for the individual undergoing ECT is outlined in [Chapter 12](#).

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS), a noninvasive procedure that uses magnetic fields to stimulate brain cells, has recently been approved by the U.S. Food and Drug Administration (FDA) for the treatment of OCD. The procedure is contraindicated for patients with implanted metallic objects or implanted stimulator devices in or near the head. Those with a history of seizure disorder may be cautiously considered for treatment. During treatment, the patient wears earplugs to reduce exposure to the loud noises made by the device. Headache is the most commonly reported side effect of treatment, and other muscle discomforts or pain at the application site resolve shortly after treatment (FDA, 2018). There is emerging evidence that TMS may be effective in treatment-resistant cases of BDD (Hong, 2019).

Psychosurgery

Psychosurgery is sometimes used to treat extremely severe OCD that has not responded to prolonged and intensive drug treatment, behavioral therapy, or a combination of the two. Modern stereotactic surgical techniques that produce lesions of the cingulum bundle (a bundle of connective tissue) or anterior limb of the internal capsule (a region near the thalamus and part of the circuit connecting to the cortex) may bring about substantial clinical benefit in some individuals without causing significant morbidity (Pepper et al., 2019). Other treatment options include radiotherapy and deep brain stimulation, in which electrical current is applied through an electrode inserted into the brain (Szechtman et al., 2020).

Safety Issues

As with any individual with a mental disorder, a suicide assessment must be completed. Although individuals with OCD do not usually become suicidal as a direct result of anxiety, the disorder greatly distresses the person, who realizes the pointlessness and absurdity of the behaviors. Often, the person has tolerated symptoms for quite some time before seeking treatment. The person may feel a sense of hopelessness and helplessness and may contemplate suicide to end the suffering. An additional risk for suicide is created by the high probability of major depression and substance abuse, which often accompanies OCD. Patients may feel a need to punish themselves for their intrusive thoughts (e.g., religious coupled with sexual obsessions). Some persons have aggressive obsessions, so that external limits may have to be imposed for the protection of others.

EVIDENCE-BASED NURSING CARE OF PERSONS WITH OCD

Persons with OCD may be of any age; many have other disorders. Nursing care involves a careful assessment of the impact of the mental health disorder on an individual and a family. Nursing Care Plan 28.1—which sets forth a plan of care for Tim, the case study patient in this chapter—is available at <http://thepoint.lww.com/Boyd7e>.

NURSING CARE PLAN 28.1

The Person with Obsessive-Compulsive Disorder (OCD)

Tim, a 32-year-old engineer, is admitted to an inpatient unit for compulsively washing his hands and being unable to go to work. His wife is with him and is quite upset about his behavior. He was being successfully treated for OCD with clomipramine and sertraline but stopped taking his medications 3 months ago, shortly after his marriage. He denies suicidal ideation.

Setting: Acute Mental Health Unit

Baseline Assessment: Tim is a casually dressed, clean-shaven man. Hands are very red with small abrasions. He reports washing his hands several times a day to protect himself from germs. If he does not wash his hands, he gets very anxious. He has a specific routine for washing his hands that has interfered with his job. He stopped taking his medication and does not want to resume taking the same medications. He is concerned that his wife will leave him if he does not get better. He does understand that his behavior is unusual and is symptomatic of his disorder. He denies using alcohol or other substances. He works out regularly at a gym but has been unable to keep up with his routine because of his need to wash his hands. He is 6'2", weighs 190, BMI 24.4; BP 135/70; P70, R 16. His goal is to manage his symptoms and resume his life.

Strengths: Wife wants him to get better and is supportive. He is motivated for change, does not use substances, and wants to return to exercise. Nutrition is excellent.

Associated Psychiatric Diagnosis	Medications
Obsessive-compulsive disorder	None

Priority of Care: Inability to Manage OCD Symptoms

Important Characteristics

Acceleration of symptoms of illness
Lack of attention to illness
Verbalizes desire to manage illness
Verbalizes difficulty with prescribed regimen

Associated Considerations

Discontinuation of medication

Outcomes

Initial

*Recognize the need to treat symptoms
*Identify acceptable strategies for managing symptoms

Long term

*Reduce OCD symptoms
*Return to work and resume normal lifestyle activities

Interventions

Interventions

*Initiate a nurse–patient relationship by using an accepting, nonjudgmental approach.
*Encourage Tim to identify OCD symptoms.
*Explore with Tim the reasons he discontinued taking his medications.
* Discuss with Tim the evidence-based options for treating OCD, including other medications, and cognitive-behavior therapy.

Rationale

A therapeutic relationship will provide an opportunity for Tim to understand the reason for not discontinuing medication.
By identifying symptoms, Tim will be able to discuss options for treatment.
There are a variety of reasons individuals stop taking medications. Understanding the reasons will help the nurse explore other alternatives.
Collaboration with patient is important in planning for successful outcomes.

Ongoing Assessment

Determine the extent to which Tim is willing to trust and engage in a therapeutic relationship.
Assess Tim’s recognition of his symptoms and level of understanding of their relationship to his current distress.
Identify the reason(s) Tim discontinued taking his medication.
Make sure that Tim takes his medication. Monitor for improvement in OCD symptoms and side effects (e.g., nervousness, nausea).

Priority of Care: Motivated to Learn New Coping Skills

Defining Characteristics

Aware of possible environmental changes
Defines stressors as manageable
Seeks knowledge of new strategies

Related Factors

Recognition that he needs symptom management

Outcomes

Initial

*Commit to strategies to improve symptoms.

Long-term

*Implement strategies that control symptoms.

Interventions

* Discuss evidence-based strategies for managing OCD, including medications.
*Based on Tim's medication side effects, discuss other medication options.
*Discuss psychotherapy opportunities, including cognitive-behavior therapy (CBT), supportive therapy.

Rationales

Evidence-based strategies include medication and psychotherapy.
Medications have helped Tim in the past and will probably work again.
CBT can improve symptoms.

Ongoing Assessment

*Determine whether Tim discusses all possibilities.
*Determine whether Tim is open to taking other medications and monitoring side effects.
*Determine if Tim has the time and commitment to CBT.

Mental Health Nursing Assessment

The nurse should assess the type and severity of the person's obsessions and compulsions. If the assessment occurs in a hospital, remember that some individuals with OCD experience a transient decrease in symptoms when admitted to a hospital; therefore, sufficient time must be allowed for an accurate assessment. If that time is unavailable, family members or significant others may provide an important source of information, with the individual's permission.

Physical Health and Functioning

Individuals with OCD do not have a higher prevalence of physical disease than others. However, they may report multiple physical symptoms. With late-onset OCD (i.e., after 50 years of age) and with symptoms that occur with a febrile illness, cerebral pathology should be considered. Each person with OCD should be assessed for dermatologic lesions caused by repetitive handwashing, excessive cleaning with caustic agents, or bathing. Osteoarthritic joint damage secondary to cleaning rituals may also be observed. Undetected somatic compulsions, such as persistent nausea and vomiting, can contribute to diminished QOL and pose diagnostic challenges for clinicians.

Nutrition

Unless OCD is accompanied by an ED (which occurs in around 10% to 17%) or another comorbid disorder that interferes with eating or metabolism, nutrition is usually not a recognized problem. Improving eating habits and nutritional status would, however, certainly contribute to overall well-being. Vitamin D and other vitamin deficiencies could be risks for developing OCD (Esnafoğlu & Yaman, 2017) and may play a role in the development of pediatric acute-onset neuropsychiatric syndrome (the pediatric autoimmune disorder), with dramatic onset of obsessive-compulsive symptoms (Çelik et al., 2016).

Medication

A careful assessment of current and past medication helps in understanding and predicting the best medications. Persons with OCD have been prescribed a variety of medications to treat symptoms in addition to over-the-counter vitamins and herbal substances.

Substance Use

Many individuals self-medicate to relieve the anxiety produced by obsessive thoughts. About one-third experience substance abuse or dependence in their lifetime. In addition, some individuals may abuse benzodiazepines and other

prescription medications. OCD and substance use disorder are frequently comorbid, but there is a complex relationship between the severity of the illness and the use of substances. Since compulsivity plays a central role in both OCD and addictions, there may be a common brain circuit dysfunction in these two disorders, which can help in identifying appropriate prevention and treatment targets (Figee et al., 2016). Social isolation can also lead to drug use, as sufferers avoid being around others, and avoid social or family events, because they are shamed and embarrassed by behaviors that they realize are irrational.

Psychosocial Assessment

A psychosocial assessment involves gathering by interviewing and talking with the patient, family, and reviewing prior medical records.

Mental Status and Appearance

Most individuals appear neatly dressed and groomed, cooperative, and eager to answer questions. Speech should be at normal rate and volume, but often, individuals with an obsessional, ruminative style of thinking exhibit **circumferential speech**. This speech, loaded with irrelevant details, eventually addresses the question. Listening may be frustrating and require considerable patience, but remember that such speech, which expresses the individual's thinking, is part of the disorder and may be beyond the person's awareness. Continually interrupting and redirecting them can interfere with establishing a therapeutic relationship, especially in the initial assessment. Redirection should be done in a gentle and noncritical manner to allow the patient time to refocus.

Self-Concept

Children and adults with OCD often have low self-concept. Their compulsive behaviors and obsessive thoughts are often internalized as personality quirks instead of understanding them as symptoms. They recognize that others do not have the same types of thoughts and behaviors and want to hide them. Their

constant worrying contributes to low self-esteem (Pedley et al., 2019).

Stress and Coping Patterns

An exploration of typical levels of stress and general mood states of the individual is essential. Gather information about the presence of stress in daily life and stress related to OCD symptoms and determine how the individual has coped. Current changes in levels of stress from crisis, life-transitions, or other reasons must also be explored as these can exacerbate symptoms. Be sure to include taking a trauma history, which is often neglected, as a growing body of evidence shows that past traumas can complicate treatment and that some obsessive-compulsive symptoms may have developed as a way of coping with trauma (Tibi et al., 2020).

Social Network/Support Systems

An individual's social networks and support systems should be assessed. While no studies show that lack of social support predicts relapse, empathy and positive interactions are associated with maintenance of gains, while negative family interactions (like anger and criticism) could lead to poorer outcomes. A review of literature found that levels of social support correlated with symptom severity, and in two studies, marital adjustment was correlated with less severe symptoms, though that finding remains inconclusive (Palardy et al., 2018).

Functional Assessment

Identifying the degree to which the OCD symptoms interfere with the patient's daily functioning is important. Several rating scales can be used to identify symptoms and monitor improvement. Some of these scales are to be used by the nurse; others are self-rating scales for the patient, child, or family member. The Maudsley Obsessive-Compulsive Inventory is a 30-item, true-false, self-assessment tool that may help the individual recognize symptoms. See [Table 28.1](#) for more information about psychometrically valid scales, recommended as

the cornerstone to evidence-based treatment (Rapp et al., 2016).

It is also important to assess for secondary complications related to compulsive behaviors (like skin chaffing, high use of soap and paper towels, unexplained utility bills, frequent checking on family members) as these factors need to be addressed in planning care. Also, be sure to explore the person’s level of insight about the accuracy of their obsessions and feelings about being able to control them as this plays a role in treatment planning and outcomes (see [Table 28.1](#)).

Quality of Life

Experiencing comorbid depressive symptoms is a strong predictor of poor QOL in adults with OCD. Children with OCD compared to those without OCD have overall decreased QOL in social and school-related settings (Coluccia et al., 2016). OCD symptoms can impact specific domains of functioning. For example, contamination fears and the need for things to be perfect, exact, or symmetrical contribute to lower satisfaction in social relationships. These fears can interfere with leisure activities and sexual functioning which in turn can negatively impact relational intimacy (Schwartzman et al., 2017).

TABLE 31.1 EVIDENCE-BASED ASSESSMENT TOOLS FOR OBSESSIVE-COMPULSIVE DISORDER

Rating Scale	Description
Yale-Brown Obsessive Compulsive Scale Y-BOCS/y-BOCS-II/CY-BOCS	A clinician-rated, 16-item scale with separate subtotals for the severity of obsessions and compulsions. Scoring changes after repeated measurement are used to identify response to treatment.
The Sheehan Disability Scale (SDS)	Brief, self-rated, 3-item, visual analog scale to assess disability. A global measure of functioning can be determined. Recommended for tracking functional changes over time.
Family Accommodation Scale for Obsessive-Compulsive Disorder (FAS-SR)	This self-rated, 19-item rating scale can be used by the parent, child, or others to track and monitor the family’s response to symptoms during treatment.
The Brown Assessment of Beliefs Scale (BABS)	A self-rated scale that scores on six dimensions: conviction, perception of other’s views, explanation of differing views, idea fixity, attempts to reject beliefs, and insight.

Helps rate the degree of conviction and insight patients have concerning their obsessions.

Source: Rapp, et al., 2018.

Strengths Assessment

The personal and social strengths of the person should emerge during the assessment interview. Questions to ask could include: Does the child or adult enjoy good physical health? Is the person motivated for treatment? Does the person recognize that obsessions or compulsions are unusual or abnormal? Are there social supports, safe and stable housing? Does the person have unique talents, interests, and character strengths? All this information will be useful in establishing a personalized recovery plan.

CLINICAL JUDGMENT

Patients with OCD may present with various problems, depending on the particular obsession and the compulsions that have evolved to cope with that obsession. As a result, nursing priorities could run the gamut from psychologic issues related to anxiety, poor self-concept, and loneliness to physical issues such as skin integrity. Outcomes are determined collaboratively after the issues have been identified. Do not forget that a suicide assessment is an essential part of care, and an emergency plan for that contingency as well as for other possible adverse events (medication side effects) should be in place before a client leaves the acute care setting. Recovery plans may take longer to generate, but the acute care nurse can collaborate and begin to develop a recovery plan. The patient should be encouraged to commit to follow-up for long-term treatment and recovery.

THERAPEUTIC RELATIONSHIP

Establishing a therapeutic relationship with a person with OCD requires patience and active listening. The individual may go to great lengths to explain some minute aspect of their life. It is important not to interrupt or rush these

explanations. Being unable to finish thoughts increases the patient's anxiety and frustration. See [Box 28.3](#).

MENTAL HEALTH NURSING INTERVENTIONS

Recovery-oriented goals include mental health and wellness components. Goals are collaboratively determined within the context of a therapeutic nurse–client relationship. Ideally the client will want to reduce symptoms, learn about the disorder and treatment, manage health-related issues, and seek a higher level of wellness.

The nurse's interpersonal skills are crucial to successful intervention with the patient who has OCD. Nurses must control their own anxiety. The nurse should interact with the individual in a calm, nonauthoritarian fashion without exhibiting any disapproval of the patient or the patient's behaviors while demonstrating empathy about the distress that the disorder has caused. This approach is one of the most effective means available for communicating appreciation for the individual as separate from the illness.

Establishing Recovery and Wellness Goals

Despite reports of remission rates ranging from 32% to 70%, this disorder is persistent and disabling; but recovery is a realistic goal. Nurses should advocate for policies that facilitate early diagnosis, stepped-care techniques, and a personalized approach that will help in achieving a recovery orientation for persons with OCD L (Burchi et al., 2018).

BOX 28.3 • THERAPEUTIC DIALOGUE: OBSESSIVE-COMPULSIVE DISORDER

Tim is admitted to an inpatient unit; an initial assessment is currently being conducted.

INEFFECTIVE APPROACH

Nurse: Could you tell me what brings you here?

Tim: What? Oh, sorry I get distracted easily. What did you say?

Nurse: I said, why are you here? What do you hope to accomplish while you are here?

Tim: Well, this is how I see it. We need to make sure everyone is healthy, and I want to make sure...

Nurse: (interrupts) No, you don't understand what I am asking. *Why* are you here?

Tim: Forget it. I want to see my wife.

EFFECTIVE APPROACH

Nurse: Tim, how can I help you?

Tim: Well, I am not sure. My wife thinks I am doing strange things. See, I want everyone to be protected, and I think that it is important to stay healthy. There is an outbreak of staph infections, and I want to make sure that my family is safe, and I am just trying to figure things out.

Nurse: OK, it sounds like you are concerned about your family and you are trying to protect them.

Tim: Yes, it is all of the germs. They are everywhere.

Nurse: And you are trying to get rid of them?

Tim: Yes, my wife thinks I am going overboard and wants me to take my medication.

Nurse: Your medication?

Tim: Yes, I used to take medication when I felt like this.

Nurse: You don't take your medication anymore?

Tim: No, I don't need it.

Nurse: I see. But your wife thinks you do?

Tim: Yes, but I don't like the side effects.

Nurse: Such as?

Tim: Well, to tell you the truth, I'd rather not talk about it.

Nurse: OK. While you are here, we can look at different options to help you feel more comfortable.

CRITICAL THINKING CHALLENGE

- How did the first nurse's interaction block communication and increase

Tim's frustration?

- What effective communication techniques did the nurse use in the second scenario?

Physical Care

Interventions focus on the physical consequences of the compulsion as well as the psychosocial aspects. The next section provides an overview of biopsychosocial interventions, including medications.

Maintaining Skin Integrity

For the patient with cleaning or handwashing compulsions, attention to skin condition is necessary. Encourage the individual to use tepid water when washing and hand cream after washing. Remove harsh abrasive soaps and replace them with moisturizing soaps. Attempt to decrease the frequency of washing by agreeing on a time schedule and time-limited washing.

Relaxation Techniques

Individuals with OCD experience insomnia because of heightened anxiety levels. Relaxation exercises may be helpful in improving sleep patterns. These exercises do not affect OCD symptoms, but they may be used to decrease anxiety. The nurse may also teach and encourage the person to use other relaxation measures, such as deep breathing, taking warm baths, going for a walk, enjoying music, or engaging in other quiet activities

Wellness Challenges

Healthy living is a challenge for persons who worry excessively, especially about health-related issues or who spend most of their waking hours cleaning. A

wellness plan takes into account all of the dimensions of wellness: physical, mental, spiritual, emotional, intellectual, social, occupational, financial, and environmental. Helping the person develop healthy eating habits and exercising regularly should be included in the recovery plan. Obsessional thinking can interfere with sleep and become a major issue for some with OCD. Sleep hygiene habits can help reduce some of the OCD symptoms as well as enhance overall well-being. Some specific challenges people with OCD face and some broad coping directions can be seen in [Table 28.2](#).

Medication Interventions

SSRIs, including fluoxetine, fluvoxamine, paroxetine, sertraline, and clomipramine, a tricyclic antidepressant, are approved by the FDA for treatment of OCD (Del Casale et al., 2019). These drugs are generally recommended along with concurrent CBT consisting of ERP, though if CBT is not accessible, monotherapy with an SSRI is adequate. Clomipramine is approved for children aged 10 years and over, and of the SSRIs, fluoxetine, fluvoxamine, and sertraline are approved for even younger children (Mallinckrodt, 2019). SSRIs or clomipramine lead to improvement in 40% to 60% of people who take them for OCD. SSRIs are recommended over clomipramine because of its unfavorable side effects and over venlafaxine, a serotonin norepinephrine reuptake inhibitor, because there is less support for its effectiveness. Relapse rates vary widely, possibly because of study inconsistencies, but APA practice guidelines recommend that those who respond adequately should continue on the same SSRI for at least 1 to 2 years (see [Table 28.3](#)).

TABLE 28.2 WELLNESS CHALLENGES	
Challenge	Coping Strategy
To cope effectively with daily obsessions/compulsions	Practice resisting urges to perform compulsive behaviors such as internet health searching; develop strategies to avoid obsessive thoughts, reframe thoughts
To seek environments that reduce the need for using compulsive behaviors	Seek safe living arrangement; maintain a structured living environment
To find satisfying and enriching work that can accommodate obsessive/compulsive behaviors	Satisfying and enriching work that can accommodate obsessive/compulsive behaviors

To recognize the need for physical activity, healthy foods, and sleep	Balance the need for regular physical activity; discuss healthy diets; encourage establishing healthy sleep hygiene routines
To developing a sense of connection, belonging, and a support system	Explore availability of support groups, family psychoeducation
To expanding a sense of purpose and meaning in life	Focus on goals, values, and beliefs; read inspiring stories or essays

Medication Treatment Response

A *successful response* to drug treatment is indicated by a reduction in the baseline score on a standardized instrument like the Yale-Brown Obsessive-Compulsive scale (YBOCS). A 35% or more reduction in YBOC scores indicates a successful response. Switching to another SSRI before an adequate trial can further diminish treatment response (Del Casale et al., 2019). Because patients may become discouraged with a perceived lack of effect, they should be informed that these medications may take 10 to 12 weeks before their effects are realized (Del Casale et al., 2019). All patients should be warned not to stop taking prescribed antidepressant medications abruptly. See [Chapter 12](#) for more information.

TABLE 28.3 ADMINISTRATION AND COURSE OF TREATMENT FOR OBSESSIVECOMPULSIVE DISORDER

Medications Suggested Therapeutic Dose Ranges

Selective Serotonin Reuptake Inhibitors

Fluoxetine*	40 to 80 mg/day
Fluvoxamine*	200 to 300 mg/day
Paroxetine*	40 to 60 mg/day
Sertraline*	50 to 200 mg/day
Citalopram**	Up to 40 mg/day; (20 mg in those older than 60)
Escitalopram**	20 to 40 mg/day

Tricyclic Antidepressant

Clomipramine*	100 to 250 mg/day
---------------	-------------------

Serotonin-Norepinephrine Uptake Inhibitors

Venlafaxine **	225 to 350 mg/day
----------------	-------------------

SSRI's Administration and Safe Handling

Start at a low dose to enhance tolerability, and the dose can be increased every week or every other week as tolerated. Maintain at therapeutic level for at least 6 weeks before concluding the patient is nonresponsive to the drug.

SSRIs given in higher doses lead to greater response rates and/or greater mean rate of improved compared with lower doses. However, higher doses are associated with higher dropouts due to side effects.

Patients who respond to an adequate trial of a serotonergic antidepressant should stay on that medication for at least 1 to 2 years.

To discontinue, slow taper at 10% to 25% every 1 to 2 months.

Refer to manufacturer's information. In general, tablets are kept dry and stored away from light.

*FDA Approved for OCD;

** Used off-label for OCD.

Source: Forest Laboratories. (2009). Escitalopram Prescribing Information. Retrieved October 10, 2020.

Treatment resistance means that there is a minimal or absent response to treatment with an SSRI, and these individuals are given another trial with a different SSRI, clomipramine or venlafaxine, though only about a half respond. A *refractory response* means there has been no response to a trial of two or more SSRIs. For those who are treatment refractory, there are a number of alternatives being trialed. For instance, N-acetyl cysteine along with vitamin D supplementation may be a promising nutraceutical approach that is much more tolerable and is thought to play a protective role against obsessive-compulsive symptoms by modulating inflammatory pathways in the brain (di Michele et al., 2018).

Augmentation with a neuroleptic agent (haloperidol, risperidone, or aripiprazole) can be considered for partial responders (YBOC reductions of 20% to 35%), refractory OCD, and those with psychotic or schizotypal symptoms, rather than switching to a different SSRI (Del Casale et al., 2019), though their use remains off-label. Clozapine, an atypical antipsychotic, and other related drugs are not indicated for OCD, having shown poor efficacy and an association with worsening or new onset of OC symptoms in those with comorbid psychotic disorders (Grover et al., 2015). If neuroleptics are used to augment treatment, they should be prescribed in low doses and administered with careful consideration of the benefits and risks of long-term use (Del Casale et al., 2019; Janardhan Reddy et al., 2017).

Administering and Monitoring Medications

Antidepressants used to treat persons with OCD are often given in higher doses than those normally used to treat depressed patients. The most common route of administration is oral. For refractory OCD, high dose, intravenous treatment with antidepressant drugs may be indicated to bring the symptoms quickly under control. Medication effects must be closely monitored, including being alert to signs of toxicity, to provide safe and adequate care.

Monitoring for Drug Interactions

Because of the extensive list of drug–drug interactions associated with antidepressant medications, a prudent nurse will consult a drug reference or consult with a pharmacist before administering any other medications. As antidepressant treatment occurs over an extended period of time, the probability of a patient experiencing a drug interaction is high. Metabolic drug interactions can result in additive, synergistic, or antagonistic effects. For instance, fluoxetine can cause an increase in plasma concentrations of traditional antipsychotics and may interfere with the elimination of atypical antipsychotics and benzodiazepines. These patients must be monitored for the onset of akathisia or parkinsonian symptoms requiring anticholinergic medication. Quick recognition of signs and symptoms of interactions or toxic reactions is imperative for safe care. Allergic reactions are rare but can occur and can be fatal. Anaphylactic reactions (bronchospasm, angioedema) and/or the presence of urticaria (rash and intense itching) should alert the nurse to hold the next dose of medication and contact the primary care provider.

Management of Complications

Though all antidepressants have a black box warning for suicidality in children, adolescents, and young adults, there is no current evidence to show that adults (over the age of 18) treated with SSRIs are at an increased risk of suicide (Fornaro et al., 2019). Treatment with tricyclic antidepressants and the SSRI, citalopram poses the greatest risk for sudden death related to a specific type of

ventricular tachycardia (Rochester et al., 2018). Symptoms include heart palpitations, rapid pulse, dizziness, chest pain, cold sweats, low blood pressure, and shortness of breath. Since other factors may contribute to this life-threatening cardiac condition known as torsade de points, a baseline ECG should be completed prior to initiating any type of antidepressant treatment. Sertraline and paroxetine are usually considered safest for breastfeeding because they have a low level of excretion in breast milk, but any antidepressant taken during pregnancy may endanger the fetus, or cause complications in the newborn, such that the benefits of treatment over the risks should always be carefully weighed. See [Chapters 12](#) and [25](#) for further discussion. Common side effects of the SSRIs can be seen in [Box 28.4](#).

Psychosocial Nursing Interventions

Psychosocial interventions are crucial to successful treatment of OCD. Nurses engage with patients who are receiving therapy, sit-in on group therapy sessions to provide support and reinforcement, and monitor progress toward outcomes. Nurses can reinforce CBT strategies their patients are learning in therapy and help them practice and use them when anxiety is escalating. Nurses use other complementary strategies to help clients manage anxiety, such as relaxation techniques, mindfulness, cue cards (to help with obsessive thinking), and basic behavioral interventions to reinforce change and avoid adding unnecessary stress to their patient's lives. Nurses are also responsible for providing clients and their families with psychoeducation, which provides information and resource needed to manage the illness in future, establish continuing support, and develop effective coping strategies. Some great sources of self-help for those with OCD are available on the internet. These offer information about treatment, opportunities to be involved in clinical trials, to learn more about the disorders, many self-help strategies, links to support groups, and even events and personal stories about the disorders. See [Table 28.4](#) for some helpful internet resources nurses can share with patients and families.

Therapeutic Interactions

Interactions with persons who are experiencing symptoms of COD require a calm, nonjudgmental approach. It is important to validate the thoughts the person is experiencing and be sensitive to their feelings. If they are experiencing anxiety, they may not be able to concentrate on verbal conversations or able to sit still. The nurse can initiate a discussion about the triggers for the anxiety and the behaviors that the patient is using to control the anxiety. The nurse supports the patient as positive behaviors and thoughts replace the symptomatic obsessions and compulsions.

Enhancing Cognitive Functioning: Cognitive Restructuring

Cognitive restructuring based in CBT is a method of teaching the person to restructure dysfunctional thought processes by defining and testing them. The goal of treatment is to alter the person’s immediate, dysfunctional appraisal of a situation and perception of long-term consequences. The individual is taught to monitor automatic thoughts and then to recognize the connection between thoughts, emotional response, and behaviors. The distorted thoughts are examined and tested by for-or-against evidence presented by the nurse, which helps the individual to realistically assess the likelihood that the feared event will happen if the compulsive behavior is not performed. The person begins to analyze their thoughts as incongruent with reality. For example, even if the alarm clock is not checked 30 times before going to bed, it will still go off in the morning, and the person will not be disciplined for tardiness at work. Maybe it needs to be checked only once or twice.

Personalized Cue Cards/Cognitive Coping Cards

Nurses may introduce clients to the use of cue cards to help restructure thoughts. With the help of the nurse, the client generates cards with a few words on them that pertain specifically to the individual's obsessions and compulsions or other goal statements the patient finds to be inspiring. The cards are ordered to represent least to most anxiety-provoking symptoms, so the patient can use them effectively. The cards can help reinforce positive beliefs or other helpful statements or reminders. Practice is important, and family can help by reminding the person to use them when they are anxious. Some examples of what to write on cue cards can be seen in [Box 28.5](#).

Exposure and Response Prevention

For those who perform ritualized (time-consuming) compulsions, ERP may be a very effective strategy. The person is exposed to situations or objects that are known to trigger (induce) anxiety but is asked to refrain from performing the ritualized behavior. The goal is to help the person understand that resisting the ritual is less anxiety producing and time consuming than performing rituals. Another goal is to confound the expectation of distressing outcomes, which eventually extinguish the compulsive behaviors. About half of those who receive ERP with or without supplemental medication achieve symptom reduction, but because some people do not respond, development of alternative strategies that

build on genetic and neurobiologic approaches continues to be needed (Hezel & Simpson, 2019).

BOX 28.5

Examples of Cue Cards/Coping Card Statements

- “It is the OCD, not me.”
- “These are only OC thoughts, OC thoughts don’t mean action, I will not act on the thoughts.”
- “My anxiety level goes up but will always go down.”
- “I never sat with the anxiety long enough to see that it would not harm me.”
- “Trust myself.”
- “I did it right the first time.”
- “Checking the locks again won’t keep me safe. I am really safe in the world.”

Acceptance and Commitment Therapy

Nurses may have clients who are engaged in acceptance and commitment therapy (ACT), which is a form of CBT. ACT is, however, somewhat different than CBT or ERP in that it focuses more on altering obsessional thinking and the way it is experienced. Strategies here help the person accept thoughts and anxiety without allowing them to interfere with life (Roche, 2020). Better functioning can be achieved without changing the frequency or severity of symptoms. ACT was particularly helpful for patients who relapsed after a course of ERP or CBT (Buchholz & Abramowitz, 2019). While reports are positive, this CBT-based therapy is still under investigation.

Behavioral Interventions and Interactions

Although most patients with OCD are treated in outpatient settings, some are hospitalized with comorbidities and are unable to care of themselves or pose a substantial risk of harm to self or others. Some general behavioral-based strategies that can be used in any setting include the following:

- Unit routines must be carefully and clearly explained to decrease fear of the unknown.

- Assess and monitor the level of anxiety and disability.
- Monitor for psychiatric comorbidities and suicide risk.
- At least initially, do not prevent the individual from engaging in rituals because the person's anxiety level will increase.
- Recognize the significance of the rituals to the person and empathize with the person's need to perform them.
- Make reasonable demands and set reasonable limits, avoid situations that provoke or increase frustration.
- Encourage discussions that identify disturbing topics that may relate to underlying anxiety or fear.
- Assist the individual in arranging a schedule of activities that not only incorporates some private time but also integrates the person into normal unit activities.
- Help the person recognize triggers to obsessive thoughts and ritualistic behaviors and the relationship between them.
- Give positive reinforcement for non-ritualistic behavior and to acknowledge the person's progress, strengths, and accomplishments
- Reinforce the use of cognitive strategies, including constructive self-talk and cognitive restructuring.

Mindfulness

Mindfulness means paying attention to the present moment. For persons with OCD, this might be difficult as they struggle with painful, intrusive thoughts and sensations that lead to self-judgment. But nurses can teach patients who are interested in learning as to how to practice mindfulness. In mindfulness, no attempt is made to neutralize internal experiences with compulsions, and the nurse helps the client accept and become aware that these are mental events, capable of being observed (perhaps reframing them as well-intentioned, but “just a thought”). One study found that mindfulness added to traditional CBT produced significantly larger gains in QoL and symptom improvement (at 6 months), compared with a group which received only psychoeducation (Külz et al., 2019). Improvements in this study were self-reported, and clinicians did not

rate OC symptoms improvement (Kulz et al., 2019). Perhaps it is more difficult for the therapist to observe improvement when therapy is delivered online. While further study is needed, in general, clients with OCD who learn to use mindfulness find the practice beneficial.

Psychoeducation

Psychoeducation is a crucial nursing intervention for the person with OCD. Knowledge is power; the more the person knows about their disorder, the more control they will have over symptoms. The individual should be instructed not only about the biologic components of OCD but also about its treatments and disease course. Treatment is a shared responsibility between the individual and the health care provider; the individual should be included in the medication and treatment decision-making processes. If local support groups are available, the person should be referred to reduce feelings of uniqueness and embarrassment about the disease. See [Box 28.6](#) for components to include in psychoeducation for those with OCD.

Teaching Strategies

Educating children, youth, and adults who have OCD requires some special consideration. Modifying the environment can help the child manage anxiety, be less distracted, and ultimately prevent disruptions. In a school setting, teachers are encouraged to structure seating arrangements, provide private testing rooms, extend test times, have books on tape, provide access to laptops for writing, and break homework down into small chunks. Teachers should be aware of the child's triggering events, give advance notice of any change whenever possible, and have a plan that the child can use when things become too overwhelming (Child Mind Institute, 2020). These tips translate well to pediatric settings, where nurses frequently work with hospitalized children who have the triad of OCD-ADHD-Tics/Tourette syndrome.

BOX 28.6

Psychoeducation Checklist: Obsessive-Compulsive Disorder

When caring for the patient with OCD, be sure to include the family. If appropriate, address the following topic areas in the teaching plan.

- Explanation of mechanisms underlying OCD and selected therapies including length of treatment and expected outcomes.
- Psychopharmacologic agents (*SSRIs *MAOIs, lithium, anxiolytics, antipsychotics) as prescribed, including drug actions, dose, frequency, possible side effects, and common interactions with food or other drugs)
- Skin care measures or problem resolution for other secondary consequences of OCD
- Alternative to ritualistic behaviors
- Cognitive restructuring strategies
- Mindfulness and relaxation techniques
- Recovery strategies
- Community resources and supports

*SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor.

Many of the same strategies can be used for adults. Adults often deal with intrusive thoughts, which makes concentration difficult and frustrating. Avoid overloading them with too much information and keep things short, simple, and well organized.

Another learning consideration involves insight regarding the accuracy of obsessional beliefs. Children's insight into their condition is generally limited, but the same is not usually true of adults. When constructing a teaching plan for adults, be sure to consider their level of insight because it will determine your strategy in discussing and exploring the relationship between obsessions and compulsions. The more insight the person has, the more disclosure and self-analysis can be expected. Adults and children with OCD can learn to re-evaluate their thinking and gain a different perspective on their symptoms.

Wellness Strategies

Wellness strategies for those with OCD are not too different than those for other persons. Stress management, relaxation, and anxiety reduction strategies can best

help the person manage day-to-day stress. Structured QOL assessments can give the nurse a more accurate picture of mood states and information about other health domains. Self-help strategies can be introduced to help the person manage symptoms and live with OCD, and these strategies are being identified as helpful in ways not previously known. For instance, running (predetermined bouts of running as exercise) reduced the frequency and intensity of OC symptoms and improved mood (Abrantes et al., 2019).

Providing Family Education

The families of persons with OCD need to be educated about the causes of the disorder and to learn about biologic and psychological treatment approaches. Understanding the biologic basis of the disorder should decrease some of the stigma and embarrassment they may feel about the bizarre nature of the patient's obsessions and compulsions. Families also need to learn how to be supportive and to avoid accommodating to a compulsion to the extent that their good intentions impede the person's recovery. The International OCD Foundation offers families some excellent guidelines on what families can do to help them live with the person who has OCD and to make life better for the whole family as well as how they can contribute to recovery and management of symptoms.

Family assistance in monitoring symptom remission and side effects of the medication is invaluable to mark progress, and family can be enlisted (and taught how) to assist the person with behavioral and cognitive interventions to manage symptoms. Families are likely to be experiencing a heavy stress burden themselves because of the symptoms, and need support and respite to maintain their own mental well-being.

EVALUATION AND TREATMENT OUTCOMES

Several methods can be used to measure the response to treatment, including nursing observations, patient self-reports and changes in YBOC scores or other rating scales, remission of presenting symptoms, and the ability to complete activities of daily living. The individual should be able to participate in social or group activities, with a degree of comfort and without self-harm or aggressive

intent. They should also be able to demonstrate common knowledge of OCD by describing its symptoms, biologic basis, and treatments.

Continuum of Care

The symptoms of OCD can become debilitating. The symptoms wax and wane throughout treatment. As the focus of treatment shifts from inpatient to outpatient environments, individuals must be assessed continually to ensure favorable outcomes through early intervention if symptoms resurface.

Emergency Care

Individuals with OCD frequently use medical services long before they seek specialized psychiatric treatment. Therefore, early recognition of symptoms and referral are important concerns for nurses working in primary care and other medical settings. After individuals are referred, most psychiatric treatment of OCD occurs on an outpatient basis. Individuals with severe OCD and/or self-harming thoughts and behaviors are hospitalized for their own safety. In these settings, medications are the primary interventions.

Inpatient-Focused Care

In an inpatient setting, the presence of a person with severe OCD may present a nursing management challenge. These individuals require a significant amount of staff time. They may monopolize bathrooms or showers or have disruptive rituals involving eating. Nurses play an integral role in treating the person with OCD. The nurse should help the individual perform activities of daily living to ensure that they are completed. Monitoring medication effects, teaching psychoeducation groups, ensuring adequate caloric intake, and providing individual patient counseling are additional inpatient interventions.

Community Care

Partial hospitalization programs and day treatment programs help individuals in their quest for recovery. These programs can support independence, while individuals begin medications and behavioral therapies. Some patients require outpatient treatment daily when symptoms increase. Maintenance outpatient therapy may be scheduled weekly or biweekly for several weeks until the symptoms are well controlled. Community agency visits are recommended to monitor medication.

Virtual Mental Health Care

Virtual approaches in the assessment and treatment of OCD and related disorders range from online individual and group psychotherapy (well established) to virtual assessment, online peer-support, and (hypothesized) computerized programs designed to break neurocognitive habits (digital behavior change interventions). As the nation quarantines, virtual mental health care can help individuals cope with mental health issues while staying home. Communication with health professionals via text, audio, or video messaging is available, and there are now easy-to-navigate mental health apps. See [Box 28.7](#) for the expectations of virtual mental health care.

Virtual Assessment and Treatment for Obsessive-Compulsive Disorder (e-OCD)

There are several types of technology-enabled psychotherapy programs available. With increasing demand and an expanding role, evidence about them has been accumulating. Technology programs vary by platform (internet, computerized) type of therapy and the level of clinician involvement (Aboujaoude, 2018.). Computerized cognitive-behavioral therapy, internet-based CBT are proving to be the most effective (Aboujaoude, 2018 with or without an SSRI (Hirschtritt et al., 2017). Less-studied programs such as virtual reality exposure therapy and mobile therapy are also showing promise (Aboujaoude, 2018). Virtual access to therapy has obvious benefits for consumers and may

help reduce stigma as some patients who can't leave their homes can still get treatment. For younger generations who are accustomed to interacting via technology, online models may help normalize mental health care and make the process easier.

BOX 28.7

Expectations for Virtual Service Providers

- Maintain/Update privacy protections for personal health information (PHI).
- Control access without patient's written permission.
- Encrypt patient data in transit and in storage.
- Protect display screens and audio transmissions from 'incidental' viewing or eavesdropping.
- Exchange information with only those who need to access PHI.
- Document rules, policies, and procedures about safeguarding PHI.
- Train all staff and document compliance.
- Negotiate HIPAA compliant business associate agreement (BAA) with cloud hosts.

Online and Virtual Groups for OCD

Virtual support for OCD has been available for many years. Generally, these are peer support groups that offer advice and support for those living with OCD and related disorders and their families/friends and supporters. CBT or a similarly oriented model ERP are typically the types of therapy offered electronically. Online training for qualified, licensed mental health professionals is available to attain certification and training for the skills they wish to develop in their practices. A caution is called for—training sites found on the internet should be thoroughly investigated and demonstrated as reputable (such as training attained from the National Alliance on Mental Illness) before signing up or paying for the program.

Emerging Technologies

Profound changes are on the horizon for the assessment and management of OCD, which will help tailor treatment, define diagnostic procedures, and improve moment-to-moment condition monitoring for actional outcomes

(Ferrerri et al., 2019). Some new devices and digital measurement tools are already available, like a smartphone application to log the frequency of compulsive activity, or wearable products like a wrist band that monitors compulsions and minimizes observer influence. More exciting still is the possibility of programs (digital behavior change interventions) that can modify cognitive behavior. Computerized models of habit alteration (to differentiate habits from goal-directed behavior) with the potential to alter behavior have already been developed (Pinder et al., 2018), and one study using a digital strategy was able to determine that all symptoms dimensions (except hoarding) were associated with bias toward habits at the expense of goal-directed behavior (Snorrason et al., 2016). What this all means and how it impacts the practices of licensed and advance practice psychiatric nurses are yet to be determined, but it may change education, challenge beliefs, and ethics and even alter the professional culture of nursing.

Integration with Primary Care

Effective treatment for those with OCD requires a continuum of preventive and restorative mental health and addiction services, according to changing needs over time and across different levels of the health care system. A team-based approach for individuals and families with OCD and related disorders is best when mental health care and general medical care are offered in the same setting. Currently, there is little articulation between behavioral health and primary care systems. As virtual therapies and treatments become popular, it may be even more difficult to coordinate and integrate care. The goals of primary care in promoting self-care and the recovery and resilient orientation of behavioral health are highly compatible (NCBH, 2020). Policies to promote better integration and collaboration between behavioral health and primary care should be a priority for mental health advocates, like nurses.

OTHER RELATED OBSESSIVE-COMPULSIVE DISORDERS

The other related obsessive-compulsive disorders are grouped together in the

Diagnostic and Statistical Manual (DSM-5) because evidence has accumulated to show a relationship, such as symptom similarity, presentation, frequent co-occurrence, genetic risks, and other common threads (APA, 2013). Grouping disorders together also allows for more discriminating research, which can improve screening, assessment, and earlier treatment. Trichotillomania, excoriation disorder, BDD, and hoarding disorder are briefly described here.

Trichotillomania and Excoriation Disorder

Trichotillomania is chronic self-destructive hair pulling that results in noticeable hair loss, usually in the crown, occipital, or parietal areas of the head, although sometimes also involves the eyebrows and eyelashes. The individual has an increase in tension immediately before pulling out the hair or while attempting to resist the behavior. After the hair has been pulled, the person feels a sense of relief. Some would classify this disorder as one of self-mutilation. It becomes a problem when accompanied by significant distress or impairment in other areas of function. A hair-pulling session can last several hours, and the individual may either ritualistically eat the hairs or discard them. Hair ingestion may result in the development of a hair ball, which can lead to anorexia, stomach pain, anemia, intestinal obstruction, and peritonitis. Other medical complications include infection at the hair-pulling site. Hair pulling is usually done alone and persons may deny it; for some there is little conscious awareness, and for others active pulling may regulate negative feelings (Lochner et al., 2019).

Clinical Course

The onset of trichotillomania occurs among children before the age of 5 years and in adolescents. For the young child, distraction or redirection may successfully eliminate the behavior. The behavior in adolescents may begin a chronic course that may last well into adulthood.

Diagnostic Criteria

Trichotillomania is diagnosed when recurrent pulling out of hair with hair loss

occurs. The individual is unable to reduce or stop such hair pulling, which causes considerable distress (APA, 2013).

Etiology and Treatment

This disorder is poorly understood. An etiologic relationship to OCD has not been established, but support is present for a familial connection (Lochner et al., 2019). The prevalence of trichotillomania is estimated at 1% to 2% of the population (APA, 2013). No particular medication class demonstrates effectiveness in treatment. Studies of individual medications, including olanzapine (antipsychotic) and clomipramine (tricyclic antidepressant), show treatment effectiveness (Baczynski & Sharma, 2020). CBT and habit reversal training, a behavioral intervention, can improve the symptoms.

Evidenced-Based Nursing Care of Persons with Trichotillomania

The assessment includes a review of current problems, developmental history (especially school conflicts and learning difficulties), family and social history, identification of support systems, previous psychiatric treatment, and general health history. The cultural context in which the trichotillomania occurs must be taken into consideration because in some cultures, this behavior may be viewed as socially acceptable. The hair-pulling history and pattern are also used to determine the duration and severity of the disorder. Within the therapeutic relationship, a cognitive-behavioral approach can be used to help the person identify when hair pulling occurs, the precipitating events, and the details of the episode.

Individuals with trichotillomania report that anxiety, loneliness, anger, fatigue, guilt, frustration, and boredom can all trigger the hair-pulling behavior. Persons with chronic hair pulling typically avoid social activities and events. In addition, the economic impact of trichotillomania can be significant in relation to lost work or school days. Teaching about the disorder will help affected individuals understand that they are not alone and that others have also had this problem. The goal of treatment is to help the individual learn to substitute positive

behaviors for the hair-pulling behavior through self-monitoring of events that precipitate the episodes.

Excoriation (Skin-Picking) Disorder

Repetitive and compulsive picking of skin causing tissue damage characterizes **excoriation or skin-picking disorder** (APA, 2013). Although face, arms, or hands are the most common sites for picking, it can occur at other body sites. Most affected people pick with their fingers, but tweezers or pins are also sometimes used. Similar to other disorders, skin picking causes significant distress to individuals. Prevalence is estimated at 1.4% to 5%; it occurs more frequently in persons with OCD. Treatment data are limited but include behavioral and pharmacologic interventions. CBT and ACT are highly recommended. SSRIs, topiramate, and N-acetylcysteine are sometimes prescribed for symptom reduction. Antihistamines can be used to reduce pruritus (itch or an unpleasant sensation of the skin that provokes the urge to scratch). It is a characteristic feature of many skin diseases and an unusual sign of some systemic diseases. Nursing care is similar to caring for a person with trichotillomania. Cold compresses or cremes (antibiotics and corticosteroids) can also be applied. These disorders can carry a significant amount of shame and embarrassment, and individuals frequently try to camouflage skin lesions that could be detected. Possible medical sequela, such as infections, lesions, scarring, and even severe physical disfigurement, can result (Torales et al., 2020).

Body Dysmorphic Disorder

Individuals with BDD focus on real (but slight) or imagined defects in appearance, such as a large nose, thinning hair, or small genitals. Preoccupation with the perceived defect causes significant distress and interferes with their ability to function socially. They feel so self-conscious that they avoid work or public situations. Some fear that their “ugly” body part will malfunction. Surgical correction of the problem by a plastic surgeon or a dermatologist does not correct their preoccupation and distress. BDD is an extremely debilitating disorder and can significantly impair an individual’s QOL. BDD usually begins in adolescence and continues throughout adulthood. These individuals are not

usually seen in psychiatric settings unless they have a coexisting psychiatric disorder or a family member insists on psychiatric attention (see [Box 28.8](#)).

BOX 28.8 CLINICAL VIGNETTE

Body Dysmorphic Disorder

K, a 16-year-old girl, for about 6 months has believed that her pubic bone is becoming increasingly dislocated and prominent. She believes that everyone stares at it and talks about it. She does not remember a particular event related to the appearance of the symptom but is absolutely convinced that she can be helped only by a surgical correction of her pubic bone.

She was treated recently for anorexia nervosa with marginal success. Although her weight is nearly normal, she continues to be preoccupied with the looks of her body. She spends almost the entire day in her bedroom, wearing excessively large pajamas, and she refuses to leave the house. Once or twice a day, she lowers herself to the ground and measures, with her fingers, the distance between her pelvic girdle and the ground in order to check the position of the pubic bone.

In desperation, her parents called the clinic for help.

The family was referred to a home health agency and a psychiatric home health nurse who arranged for an assessment visit.

What Do You Think?

- How should the nurse approach K? Should an assessment begin immediately?
- From the vignette, identify nursing diagnoses, outcomes, and interventions.

Adapted from Sobanski, E., & Schmidt, M. H. (2000). “Everybody looks at my pubic bone”—a case report of an adolescent patient with body dysmorphic disorder. *Acta Psychiatrica Scandinavica*, 101, 80–82.

BOX 28.9

The Role of Intrusive Imagery in Hoarding Disorder.

Stewart, N. A. J., Brewin, C.R., & Gregory, J. D. (2020). The role of intrusive imagery in hoarding disorder. *Behavior Therapy*, 51(1), 42–53.

THE QUESTION: Do people with hoarding disorder (HD) experience intrusive imagery more frequently, and how does it differ from intrusive imagery experienced by individuals without HD (healthy controls)?

METHODS: A semi-structured interview was used in this investigational study. Opportunity sampling was used to identify and screen participants for two groups. Subjects in one group (HD) met the *DSM-5* criteria for HD, and subjects in the second group (CC) had no mental health problems. Semi-structured interview questions explored the presence and characteristics of intrusive images in everyday and in discarding situations, by having the participant identify the intrusive image (frequency) and ranking its valence on six criteria: emotional tone, vividness, realness (happening now), identification (with image), avoidance of the image, and interference of the image with everyday life. Data (mixed) across groups were compared, and narrative descriptions were coded into themes.

FINDINGS: Both groups (96% for the HD group and 86% for the CC) experienced intrusive imagery. Everyday imagery for the HD group was more frequent and more negative; these images were more likely to interfere with their lives, and they tried to avoid them. No differences in vividness or that the images reflected their identity was found. The themes of the HD group (everyday imagery) reflected illness or death to others and negative interpersonal memories, whereas the CC group has themes that were more neutral. During the discarding scenarios, there were significant differences with the HD group reporting more frequent intrusive imagery when discarding low (subjective) value episodes, and (unexpectedly) more positive imagery when discarding (or trying to discard) high-value objects. The authors conclude that mental events have an important role in maintaining HD and that this is the first study of this kind that links imagery to compulsive hoarding.

IMPLICATIONS FOR NURSING: This study highlights the importance of trauma history screening and the unsuspected aftermaths of traumatic events. It also provides nurses with a better understanding of how mental imagery contributes to the inability to discard possessions in HD, which has heretofore

remained inexplicable. Better understanding of why discarding objects is so difficult for those with HD may help families address hoarding with more empathy. This study alerts nurses to the need to explore images around discarding possessions and begins to give some direction about how nurses can better help patients with HD rescript the images that keep them living in cluttered, unsafe, and unhealthy environments.

This disorder occurs in men and women, with a prevalence of 2.4% in the United States (APA, 2013). The risk of depression, suicide ideation, and suicide is high. The suicide risk in BDD is increased by the presence of other disorders such as substance use disorder, major depressive disorder, eating, and personality disorders. People with comorbid OCD-BDD have high morbidity, a decrease in insight, and poor psychosocial functions (Eskander et al., 2020). No single theory explains the cause of BDD. Unrealistic cultural expectations and genetic predisposition most likely underlie this disorder.

Hoarding Disorder

Difficulty parting with or discarding possessions, regardless of actual value, characterize hoarding disorder. Individuals with this disorder have a need to save items and experience distress if their items are discarded. Most affected individuals with hoarding disorder also exhibit excessive acquisition (excessive purchasing of items or collecting free items).

The prevalence of this disorder is estimated at 2% to 6% (APA, 2013). Hoarding may begin in childhood with an increase in severity throughout a life span. This disorder tends to be familial and present in different generations. Over 50% of the individuals have co-occurring depression or chronic anxiety. See [Box 28.9](#). Treatment includes pharmacologic agents and CBT. There is some evidence that peer-led groups may be effective (Mathews et al., 2018).

Hoarding poses public health and safety risks for individuals, families, and communities. Excessive collection of items not only clutters living areas but can also lead to being trapped in an inaccessible environment and one that is at high risk for fire. Home health nurses are often the first health care providers that recognize the problem and so are a valuable resource in determining the safety hazards and helping the individual become aware of the problem and seek treatment. Currently, treatment includes CBT and medication for co-occurring

mental disorders (Mathews et al., 2016).

SUMMARY OF KEY POINTS

- Obsessions are excessive, intrusive, or unwanted thoughts. Compulsions are repetitive behaviors performed in a ritualistic manner.
- The most common obsession is the fear of contamination.
- Compulsions relieve anxiety and should not be interrupted unless the behavior jeopardizes the safety of the person or others. Interrupting compulsive behavior increases the person's anxiety.
- OCD is characterized by obsessions, compulsion, or both. OCD can occur in children and adults.
- Medications and CBT can help affected individuals to get through episodes and reduce the compulsive behavior.
- Nursing care focuses on motivating the person for change, administering and monitoring medication, providing psychoeducation, and supporting positive new behaviors.
- The primary characteristics of trichotillomania and excoriation disorders are compulsive behaviors that damage the hair or skin. Compulsive behaviors of both disorders cause significant distress to the person who cannot stop or decrease the behaviors. Medications and psychotherapy can reduce these behaviors.
- BDD involves excessive focus on slight or imagined defects in appearance. The person with these extremely distressing defects seeks treatment by plastic surgeons or dermatologists. Correction

does not relieve the patient's preoccupation, which continues to interfere with their QOL. These individuals are at high risk for depression and suicide.

- Hoarding disorder can begin in childhood and last a lifetime. Individuals with this disorder need to save things and become very upset if items are removed. When excessive collection leads to extreme clutter, it becomes a safety issue.

CRITICAL THINKING CHALLENGES

1. Differentiate an obsession from a compulsion.
2. List common obsession-compulsion dimensions and their consequences to the individual and family.
3. Jane, a 35-year-old single mother, has been unable to go to work because she fears her apartment will burn down. She is constantly checking the stove and furnace. Her family convinced her to be admitted to a mental health unit. Discuss how you would prioritize her assessment and develop a plan of care.
4. Jon, a 25-year-old man, is admitted to an inpatient unit for depression and extreme anxiety. He was diagnosed with OCD as a child and had been able to function with medication. He recently married and decided to stop taking his medication. When his symptoms recurred, his wife tried to prevent Jon's compulsive behaviors by removing the knobs from the stove. He became more anxious. As Jon's nurse, develop a teaching plan about OCD for his wife.
5. Explain how nurses contribute to treatment using CBT and behavioral strategies.
6. Identify patient teaching strategies for children and adults with OCD, including milieu modifications.

7. Explain the behaviors associated with trichotillomania, excoriation disorder, BDD, and hoarding disorder. What are the similarities and differences?

Movie Viewing Guides

Aviator: 2004. The movie starring Leonardo DiCaprio depicts the earlier years of film producer, industrialist, and aviator Howard Hughes who suffered from OCD. Hughes' perfectionism in his film making and his need for order related to his food and cleanliness eventually contributed to his functional decline. Several scenes illustrate his obsession and compulsion. Hughes' symptoms eventually take over his life, and he retreats to a self-imposed solitary confinement.

Viewing Points: How does his early life contribute to the development of his OCD symptoms? Identify his obsessions and compulsions. If Howard Hughes were your patient, what nursing diagnoses and interventions would you want to implement? Identify teaching needs related to medication and the obsessions and compulsions.

Trauma- and Stressor-Related Disorders

Nursing Care of Persons with Posttraumatic Stress and Other Trauma-Related Disorders

Boyd Mary Ann

KEYCONCEPTS

- resilience
- psychological trauma
- traumatic event

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of psychological trauma in mental disorders.
2. Discuss the importance of resilience in prevention of mental disorders.
3. Delineate clinical symptoms and course of posttraumatic stress disorder.
4. Analyze the primary theories related to posttraumatic stress disorder.
5. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with posttraumatic stress disorder.

6. Apply nursing persons-centered, recovery-oriented nursing process for persons with posttraumatic stress disorder.
7. Identify medications used to treat people with posttraumatic stress disorder.
8. Develop wellness strategies for persons with posttraumatic stress disorder.
9. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
10. Discuss the importance of integrated health care.
11. Describe dissociation and dissociative disorders.

KEY TERMS

- Complex posttraumatic stress disorder (CPTSD)
- Depersonalization
- Derealization
- Dissociation
- Emotional reactions
- Hyperarousal
- Hypervigilance
- Intrusion
- Numbing
- Posttraumatic stress disorder (PTSD)
- Trauma-informed care

Case Study

Thirty-year-old Susan is admitted to an inpatient mental health unit following a suicide attempt. Her relationship with her husband has deteriorated since she returned from Iraq 6 months ago. She is overwhelmed by her responsibilities as a parent and wife. She has been diagnosed with posttraumatic stress disorder.

INTRODUCTION

All of us experience stress in our daily lives, but our responses vary from person to person. One person may develop a severe **emotional reaction** (strong agitation of feelings), and another resilient individual is hardly aware of a traumatic event. While most stressful events do not lead to mental disorders, sometimes, emotional problems and mental disorders develop as the response to trauma. This chapter explains the role of resilience in buffering the mental health consequences of psychological trauma and the nursing care for those who develop trauma- and stressor-related disorders. **Posttraumatic stress disorder (PTSD)** is highlighted in this chapter.

TRAUMA AND RESILIENCE

Trauma can be viewed from several different perspectives. Physical trauma may result from bodily injury resulting from an accident, self-inflicted damage, or violence perpetrated by others. Falls are a leading cause of accidents in the home. Automobile accidents are a major threat to adolescents. Self-inflicted physical trauma is often associated with mental disorders. Physical abuse of intimate partners and elder abuse are nationwide health problems. Rape and sexual abuse are physically traumatic and produce psychological trauma.

KEYCONCEPT **Psychological trauma** is an emotional injury caused by an overwhelmingly stressful event that threatens one's survival and sense of security.

Harassment, embarrassment, child abuse, sexual abuse, employment discrimination, police brutality, bullying, and domestic violence are examples of events that can lead to psychological trauma. Family violence, loss of family members, acts of terrorism, and natural disasters are all traumatic events. Exposure to war, natural disasters, and witnessing catastrophic events also may cause psychological trauma.

Not everyone who experiences a traumatic event will be emotionally injured. One explanation for the variability in experiencing psychological trauma is resilience.

Resilience reduces the impact of risk factors and enhances the ability to

“bounce back” and recover from stressful experiences. The stronger the resilience, the less likely the individual will experience reactions that lead to maladaptive behaviors and outcomes (Naifeh et al., 2019). An important mental health promotion nursing strategy is enhancing resilience, especially for persons with mental and/or substance abuse problems (see Box 29.1).

BOX 29.1

Resilience

Joe, a 22-year-old college student, was a victim of an armed robbery. His companion was shot and killed when Joe refused to give the robbers his money. After the incident, he was preoccupied with thoughts of the murder and felt personally responsible for his friend’s death.

Joe sought psychological help from the college counseling center. During weekly counseling sessions, Joe was able to reframe his experience. Although he still has brief periods of sadness, he no longer blames himself for his friend’s death. He is now resuming his normal activities and is no longer having intrusive thoughts.

Resilience develops in association with a positive self-concept and self-worth, a feeling of being in control one’s life, and a feeling of power. Resilience is acquired over time, beginning in early childhood, as positive problem-solving, communication, and coping skills are learned. Some children seem more resilient to trauma and are able to cope quite well with traumatic events (Mitra & Hodes, 2019). Positive family and community support also play a role in developing resilience.

KEYCONCEPT Resilience is the capacity to withstand stress and catastrophe. It develops over time and is the culmination of multiple internal and external factors.

TRAUMA- AND STRESSOR-RELATED DISORDERS OVERVIEW

Exposure to a traumatic or otherwise stressful event can lead to a trauma- and

stressor-related disorder such as reactive attachment disorder, disinhibited social engagement disorder, PTSD, acute stress disorder, and adjustment disorder.

Trauma- and Stressor-Related Disorders Across the Lifespan

Trauma- and stressor-related disorders can develop at any time throughout a lifespan. In children, exposure to trauma can cause enduring emotional problems that lead to any one of these disorders. One of the most traumatic losses for children is an unexpected death of a loved one, which can lead to multiple psychiatric disorders (see [Chapter 16](#)) (Atwoli et al., 2017).

Childhood psychological and physical abuse including sexual abuse can lead to a lifelong struggle with a trauma- and stressor-related disorder. Adverse childhood experiences are categorized by the CDC-Kaiser Permanente Adverse Childhood Experiences (ACE) Study into three groups: abuse (emotional, physical, sexual); household challenges (mother treated violently, household substance abuse, mental illness in household, parental separation or divorce, criminal household member); and neglect (emotional, physical). In this study of 8,667 adult members of a health maintenance organization childhood physical and sexual abuse, as well as witnessing of maternal battering, was common. More than one third of the members experienced more than one type of maltreatment. The more frequent and severe the abuse as a child, the greater the PTSD symptoms as an adult (Chang et al., 2019; Oral et al., 2016).

Military violence is responsible for lifelong effects for deployed service members. There are many reports of older adults who served in World War II developing symptoms of PTSD in later life. There is a growing number of research studies that demonstrate the traumatic impact on children during military deployment and reintegration of their parents (Williamson et al., 2018).

When an older adult experiences trauma, memories of a lifetime of previous traumas and abuse influence the current experience. Loss of partners, friends, and family members through death, marriage, or relocation can add to the trauma. Elder abuse is discussed in [Chapter 31](#).

POSTTRAUMATIC STRESS DISORDER

PTSD occurs following exposure to an actual or threatened traumatic event such as death, serious injury, or sexual violence (American Psychiatric Association [APA], 2013). Traumatic events include those that are directly experienced, witnessed, learned about from others, or repeated exposure to aversive events. Examples of traumatic events are violent personal assault, rape, military combat, natural disasters, terrorist attacks, being taken hostage, incarceration as a prisoner of war, torture, an automobile accident, or being diagnosed with a life-threatening illness.

KEYCONCEPT **Traumatic events** include those that are directly experienced, witnessed, learned about from others, or repeated exposure to adverse events.

Clinical Course

Most people who experience a traumatic event do not develop PTSD. However, for those who do, the symptoms often develop within several days of the event and must persist for a minimum of 30 days in order for the criteria of the diagnosis to be met. In some cases, the symptoms may initially occur substantially after the event, sometimes up to 6 months later. This is known as delayed-onset PTSD (APA, 2013). About one third of the persons diagnosed with PTSD develop chronic symptoms. For these individuals, symptoms fluctuate in intensity with time and usually are worse during periods of stress. Children with PTSD may react differently than adults (see Box 29.2).

BOX 29.2

Posttraumatic Stress Disorder Symptoms in Children and Adolescents

PTSD Symptoms in Children

- Bedwetting, after they had learned how to use a toilet
- Forgetting how or being unable to talk
- Acting out the scary event during playtime
 - Being unusually clingy with a parent or other adult

PTSD Symptoms in Adolescents

- May show symptoms similar to adult
- Develop disruptive, disrespectful, or destructive behaviors

- Feel guilty for not preventing injury or death

Thoughts of revenge. (Source: U.S. Department of Health & Human Services. www.nimh.nih.gov.)

Diagnostic Criteria

PTSD is diagnosed following exposure to a traumatic event when symptoms in four general areas appear: (1) intrusive symptoms, avoidance of person(s), places, or objects that are a reminder of the traumatic event; (2) negative mood and cognitions or negative thoughts associated with the event; (3) **hyperarousal** characterized by aggressive, reckless, or self-destructive behavior; and (4) sleep disturbances or **hypervigilance** for at least 1 month (APA, 2013).

Intrusion

In PTSD, **intrusion** is defined as involuntary appearance of thoughts, memories, or dreams of traumatic events that cause psychological and sometimes physiologic distress. Often the intrusive thoughts are associated with cues that symbolize or resemble the original event. Sometimes, the traumatic images, thoughts, or perceptions are reexperienced, known as flashbacks. Nightmares are common. Intrusive symptoms also include dissociative reactions (i.e., feeling or acting as if the event is reoccurring). Sleeping is difficult. Terrifying flashbacks and nightmares often include fragments of traumatic events exactly as they happened. Many stimuli (e.g., loud noises, odors) associated with the trauma cause flashbacks and dreams. Consequently, affected individuals avoid such stimuli (Brooks et al., 2019).

In children, older than 6, repetitive play may occur that expresses the themes or aspects of the traumatic events. They may reenact the specific trauma. Nightmares of these children may not have content (APA, 2013).

Remember Susan?

She suffers from flashbacks of exploding helicopters when she hears loud noises. Her husband tells her she screams while sleeping. She reports frightening nightmares.

Avoidance and Numbing (Dissociative Symptoms)

Individuals with PTSD avoid reminders of the event including people, places, or activities associated with the event (e.g., fireworks may bring back memories of war). Many persons suffering with this disorder escape situations by altering their state of consciousness or **numbing** by dissociating. **Dissociation** is a disruption in the normally occurring linkages among subjective awareness, feelings, thoughts, behavior, and memories (APA, 2013). A person who dissociates is making themselves “disappear.” That is, the person has the feeling of leaving their body and observing what happens to them from a distance. During trauma, dissociation enables a person to observe the event while experiencing no pain or only limited pain and to protect themselves from awareness of the full impact of the traumatic event (see Box 29.3). Examples of dissociation include (1) **derealization** (feelings of unreality) and **depersonalization** (the experience of self or the environment as strange or unreal); (2) periods of disengagement from the immediate environment during stress, such as “spacing out”; (3) alterations in bodily perceptions; (4) emotional numbing; (5) out-of-body experiences; and (6) amnesia about abuse-related memories.

Mood and Cognition

After a traumatic event, moods often become more irritable with episodes of explosive anger, fear, guilt, or shame. Individuals with PTSD often have difficulty experiencing positive emotions such as happiness or love. Consequently, they become estranged from loved ones who become frustrated with their family member’s unpredictable moods and lack of emotional connection. In PTSD, the thought process becomes distorted with exaggerated negative beliefs or expectations about oneself, others, and the world. They may believe that no one can be trusted or that they are terrible people (APA, 2013).

Hyperarousal and Hypervigilance

After a traumatic experience, the stress system seems to go on permanent alert,

as if the danger might return at any time. In this state of physiologic hyperarousal, the traumatized person is hypervigilant for signs of danger, startles easily, reacts irritably to small annoyances, and sleeps poorly. They are looking for physical danger, a repeat of a trauma, or something wrong in a relationship. The state of hyperarousal causes other problems for family members. The affected individual is irritable and overreacts to others, which cause others to avoid the person who in turn maintains a state of continual arousal (Marshall et al., 2019).

BOX 29.3

Dissociation

Carol, a 14-year-old high school student, was brutally raped by an older man. When the accused man was arrested, Carol could not recall any part of the attack. Her last memory was walking home after school and seeing a strange man parked on the street.

Sleep Disturbance

Sleep disturbance is one of the most commonly reported symptoms of PTSD. The disruptions fall into two categories—insomnia (persistent difficulty falling asleep or staying asleep) and nightmares. Many people with PTSD experience both. Sleep disturbances prior to the trauma is believed to be a risk factor for PTSD and insomnia immediately after the trauma is predictive of PTSD developing within 1 year. Improvement in sleep quality is associated with reduction of PTSD symptoms (Maguire et al., 2020).

Susan and Her Family

Susan feels she does not fit into the family and no longer believes she has a role as a wife and mother. She is extremely irritable and argues with her husband constantly. She is suspicious of her neighbors and fearful that her children will be kidnapped.

Complex Posttraumatic Stress Disorder

Complex posttraumatic stress disorder (CPTSD) is a subgroup of PTSD that occurs with severe chronic, repetitive trauma that continues for months or years. While PTSD focuses on the threats and avoidance of harm, CPTSD is understood as a betrayal of trust and occurs in extreme childhood neglect, repeated sexual or physical abuse, domestic abuse, and human trafficking. These traumas result in fundamental damage to one's sense of self, personality changes, and significant impairment in personal, family, social, education, and occupational functioning (Ford, 2019).

This diagnosis is not specified in the *DSM-5* but is accepted by several international organizations. For example, the WHO's *International Classification of Diseases* (ICD-11) differentiates CPTSD from PTSD by symptoms. PTSD core symptoms are intrusion, avoidance, and hyperarousal. CPTSD symptoms include the core PTSD symptoms plus emphasis on symptoms of affective dysregulation, negative self-concept, and interpersonal problems (Böttche et al., 2018; Jowett et al., 2020).

Posttraumatic Stress Disorder Across the Lifespan

Children

In children 6 years and younger, exposure to actual or threatened death, serious injury, or sexual violence may result in PTSD. The symptoms include recurrent, involuntary, and intrusive distressing memories of the events. These memories may not appear distressing and may be expressed as play. The child may not be able to explain or remember the content of the distressing dreams related to the event. For a child 6 years and under to be diagnosed with PTSD, one of the following symptoms must be present for at least 1 month and not related to physiologic changes caused by medication or illness: avoidance of stimuli or negative cognitions/mood associated with the traumatic event, irritable behavior and angry outbursts after the event with little or no provocation, or clinically significant distress (APA, 2013).

Older Adults

PTSD in older adults can occur following a new trauma or to an event that happened in several years earlier. Since there are multiple possible traumas that can precipitate PTSD, longevity increases the possibility of experiencing a traumatic event. There are many well-published accounts of World War II veterans who first experienced PTSD symptoms when they were in the 1970s. Older adults are also exposed to other traumas associated with physical health issues such as cardiovascular and musculoskeletal conditions, pain, loss of partners, changes in residences, and consequences of the COVID-19 pandemic (González-Sanguino et al., 2020; Pietrzak et al., 2021; Sommer et al., 2021).

Epidemiology and Risk Factors

The lifetime prevalence of PTSD ranges from 6.1% to 9.2% in the United States and Canada. The type of trauma a person experiences is related to the probability of PTSD occurring. For example, in sexual relationship violence, there is a 33% probability that PTSD will occur compared to exposure to organized violence, such as a civilian in a war zone, of 3% (Gradus, 2020).

Risk factors for PTSD include a prior diagnosis of acute stress disorder; the extent, duration, and intensity of trauma involved; and environmental factors. High levels of anxiety, low self-esteem, and existing personality difficulties may increase the likelihood that PTSD will develop (Sareen et al., 2020). COVID-19 health care workers working in high-risk units are high risk for PTSD related to the perception of risk of infection, job-related stress, direct contact with affected patients, being quarantined, being infected, lack of confidence in equipment and protective measures (Preti et al., 2020).

Gender Differences

PTSD varies among all genders. Women are approximately twice as likely as men to experience PTSD; the median time from onset to remission for women is 4 years compared with 1 year for men. Several factors may contribute to these differences. People experience different types of traumatic events. As reported by Mota, men report exposure to events such as fires or disasters, life-threatening accidents, physical assault, combat, being threatened with a weapon, and being held captive. Women report anxiety and depressive disorders, child

abuse, sexual molestation, sexual assault, and traumatic events before the age of 18 years (Mota et al., 2019).

Consider This

Susan was exposed to exploding improvised explosive devices (IEDs) while serving in Iraq. Between the ages of 6 to 9 years old, she was sexually abused by an uncle. She never told anyone.

PTSD symptoms in women who are sexually assaulted may vary based on their age at the time of the first sexual assault. The younger the assault, the more severe the symptoms (Angelone et al., 2018). In a landmark study, childhood cancer survivors have been found to have four times the risk of developing PTSD as their siblings (Oral et al., 2016). Similarly, high rates of PTSD have been reported among patients with alcohol and drug dependence who have experienced childhood abuse (Fitzpatrick et al., 2020).

Box 29.4

PTSD and Risky Sexual Behavior

Weiss, M. H., et al. (2019). *A longitudinal examination of posttraumatic stress disorder symptoms and risky sexual behavior: Evaluating emotion dysregulation dimensions as mediators*. *Archives of Sexual Behavior*. <https://doi.org/10.1007/s10508-019-1392-y>

THE QUESTION: Are PTSD symptoms a predictor of risky sexual behavior among trauma-exposed community women? Is emotional dysregulation a factor in risky sexual behavior?

METHODS: A convenience sample of 491 women 18 to 25 recruited from four sites in the southern and midwestern United States completed 5 assessments every 4 months for a 16-month period. The assessments included (1) traumatic exposure, (2) PTSD symptoms, (3) emotion dysregulation (inability to accept negative emotion [“When upset, I become angry at self for feeling that way”], difficulties engaging in goal-directed behaviors when distressed, difficulties controlling impulsive behaviors, limited strategies to regulate emotion, lack of emotional awareness and clarity), and (4) risky sexual behavior (number of different vaginal sexual partners, number of instances of condomless sex, number of instance of risky/impulsive sexual behavior such as sex in exchange for money, drugs).

FINDINGS: Women who were unable to accept their own negative feelings (i.e., they felt they should not be angry or upset) were more likely to be distressed and engaged in risky sexual behavior to reduce the negative affect of the emotion and PTSD symptoms. Women who experienced difficulties controlling impulsive behavior would be more likely to engage in risky sexual behavior.

IMPLICATIONS FOR NURSING: Early intervention in primary care and school settings for girls and women who are victims of sexual assault may prevent future revictimization and PTSD.

High rates of PTSD in veterans returning from Iraq and Afghanistan are unprecedented in modern times. PTSD prevalence estimates range from 0% to 48% in males and from 2% to 68% in women (Maguen et al., 2020). PTSD is more prevalent in the Army, among enlisted personnel when compared to officers, and more common among health care occupations, combat specialists, and service and supply personnel. PTSD in veterans is associated with postdeployment violence and alcohol misuse (Kennedy, 2020). Suicide attempts are predicted by pre-deployment history of minor traumatic brain injury (TBI), frequent mental health treatment visits, young age, female, and indicators of relationship difficulties (low relationship quality, previously married, not dating) (Zuromski et al., 2019) (see [Chapter 40](#)).

Ethnicity and Culture

Discrimination is associated with higher rates of PTSD in minority groups. African American individuals experience higher rates of PTSD than White individuals and are more likely to develop PTSD following trauma exposure. Research shows that discrimination contributes to the disparate rates of PTSD experienced by African Americans (Brooks Holliday et al., 2020). Increasing discrimination since the terrorist attacks (9/11) and the discriminatory climate of the Trump administration are associated with more severe PTSD symptoms experienced by Muslim Americans (Lowe et al., 2019). Asian Americans experienced increased stress and PTSD during the COVID-19 pandemic because of heightened discrimination related to the initial source of the coronavirus (Liu et al., 2020). Violent victimization of African American and Puerto Rican adolescents contributes to emerging increase in PTSD and comorbid psychiatric disorders (Pahl et al., 2020).

Etiology

A growing body of research postulates that biologic factors, including neurobiology and genetics, interact with environmental factors, such as childhood experiences, and the severity and extent of the traumatic exposure, to affect susceptibility to PTSD. The amygdala and hippocampus appear to be important players in fear conditioning along with the thalamus, locus coeruleus, and sensory cortex. Interaction between the cortex and the amygdala may be necessary for specific stimuli to elicit traumatic memories (Lori et al., 2019).

Several neurochemical systems are involved in regulating fear conditioning, including norepinephrine, dopamine, opiate, and corticotropin-releasing systems. Hyperarousal symptoms are characteristic of increased noradrenergic function, particularly in the locus coeruleus and in the limbic system (hypothalamus, hippocampus, and amygdala), and of increased dopamine activity, particularly in the prefrontal–cortical systems (Malikowska-Racia & Salat, 2019).

Behavioral sensitization may be one mechanism underlying the hyperarousal seen in PTSD. The sensitized person reacts with a magnified stress response to later, milder stressors. Research shows that traumatic exposure can alter neurotransmitter connectivity in the frontal areas resulting in severe reaction to a minor stressor. This finding would account for the fact that some individuals with PTSD experience intense fear, anxiety, and panic in response to minor stimuli. One example of behavioral sensitization is that PTSD after combat exposure is more likely to develop in veterans who are survivors of childhood abuse than in those who have not experienced prior trauma (Young et al., 2020).

RECOVERY-ORIENTED CARE FOR PERSONS WITH PTSD

Recovery from PTSD takes time and involves support and patience from the family and friends, as well as a team of health care providers. **Trauma-informed care** is important in supporting recovery and includes an understanding of trauma and an awareness of the impact it can have across settings, services, and populations. Early recognition of the symptoms and treatment lead to a more successful outcomes with less likelihood of major complications. It is important to understand that there are several paths to recovery (see [Chapter 2](#)).

Teamwork and Collaboration: Working Toward Recovery

Major approaches to the treatment of PTSD include pharmacotherapy and psychotherapy. The selection of treatment is guided by practice guidelines that recommend various interventions based on medical and functional status, preexisting psychiatric and medical conditions, and current mental health assessment. The treatment guidelines, developed by the Department of Veterans Affairs and Department of Defense with the support of the Institute of Medicine, recommend education, brief psychotherapy sessions, and acute symptom management (sleep disturbance, hyperarousal, pain) for an acute reaction. During an acute reaction, psychological debriefing is not recommended. For treatment of more chronic symptoms, trauma-focused therapy and stress management are recommended along with medication (Department of VA & DOD, 2017).

Psychotherapeutic approaches to the treatment of patients with PTSD include psychodynamic psychotherapy; cognitive behavioral therapy (CBT); and eye movement, desensitization, and reprocessing. *Psychodynamic psychotherapy* focuses on different factors that may influence current PTSD symptoms such as early childhood experience and current relationships. There is emphasis on the unconscious mind. *CBTs* focus on the evaluation of situations, thoughts, feelings, and the problematic ways these evaluations cause a person to act (see Box 29.5).

BOX 29.5

Cognitive Behavioral Therapies

Therapy	Purpose
Exposure therapy	Helps people face and control their fear by exposing them to the trauma in a safe way. Strategies are mental imagery, writing, or visits to the place where the event happened.
Cognitive restructuring	Helps people make sense of the bad memories by reframing their experiences in a more realistic way. They may feel guilt or shame about what is not their fault.
Cognitive processing therapy	Helps people understand why recovery from traumatic events has been difficult and how symptoms of PTSD affect daily life. Focus is on identifying how traumatic experiences changed thoughts and beliefs and influenced current feelings and behaviors.

Stress inoculation training

Teaches a person how to reduce anxiety. Like cognitive restructuring, this treatment helps people look at their memories in a healthy way.

Eye Movement Desensitization and Reprocessing therapy is a process of reviewing and visualizing disturbing memories of traumatic or distressing experiences to reduce the long-term impact of the events. The patient is guided through images of the trauma, allowing for progressive desensitization. Under deep relaxation, the patient maintains an image of the traumatic event while focusing on the lateral movement of the clinician's finger. This recent approach has been successful in minimizing the fear response and avoidance pattern of those with PTSD (Every-Palmer et al., 2019). Virtual Reality Exposure Therapy, the use of a virtual environment to facilitate emotional process of memories related to the trauma, is being used in some treatment settings. It can be used as a part of exposure therapy (Bourassa et al., 2020).

Group therapy and family therapy should also be considered in the treatment of those with PTSD. Sharing the traumatic experiences with family or with others who have experienced trauma can be both supportive and therapeutic. PTSD disrupts both the life of the patient and their significant others. Social support is a protective factor in the development of the disorder, and patients who have PTSD can benefit from tangible social support they receive from spouses, family, and friends (Ahmad et al., 2020).

Safety Issues

PTSD is associated with an increased risk of suicide, suicide attempts, aggression, and substance abuse (Fox et al., 2020; Kehle-Forbes et al., 2019; Miles et al., 2020). The first contact the nurse often has with the patient is after a suicide attempt or an aggressive episode. A careful assessment should include determination of the risk for self-injury or aggression toward others. These individuals are in high risk for substance abuse and suicide, so that a suicide risk assessment should be included in the nursing assessment. Safety measures such as suicide precautions may be needed, particularly if the person is hospitalized.

EVIDENCE-BASED NURSING CARE OF THE PERSON WITH POSTTRAUMATIC STRESS

DISORDER

Patients with PTSD receive nursing services in a variety of settings throughout the continuum of care. Many will access care through a primary care setting, and others will seek out services in a mental health or primary health clinic. In many instances, the patient is reluctant to disclose information and has a difficult time trusting others. Distrust is especially common in persons whose trauma is associated with a violation of trust such as a rape. Gaining the patient's trust through a warm, empathic interaction, for example, offering the patient the opportunity to talk about the trauma without pressing them on the details, can lead to a meaningful therapeutic relationship.

Mental Health Nursing Assessment

After the physical health needs are met and suicidal/aggressive safety measures are established, the mental health nursing assessment targets specific areas. These include identification of the original trauma, specific physical symptoms, and the emotional and behavioral consequences of the patient's PTSD. The nursing assessment is best conducted through an interview to identify the impact of the trauma and the individual's physical and psychological strengths. The full assessment may need to take place over the course of one or more meetings, depending on the patient's capacity to discuss the traumatic events and sequelae without emotionally reexperiencing the trauma (retraumatization).

Trauma

Identifying the original trauma establishes the nature of the trauma and the length of time that the patient's PTSD has been present. However, if the person does not want to talk about the details of the trauma, the nurse should not pursue the topic. The meaning of the trauma to the individual is much more important than what happened. The survivor of trauma may be seeking help for the consequences of the trauma and is unable to discuss the original trauma. If the person wants to share information related to the traumatic experience, the following questions can be used in the assessment:

- In what ways has your life been different since the trauma?

- What does the trauma mean to you?
- Do you feel that you are the same person now as you were before the trauma? How are you the same? How are you different?
- Did anyone help you? Who are the supportive people in your life?
- Were you a survivor of trauma or abuse prior to the trauma associated with PTSD?

Physical Health Assessment

The assessment should focus not only on the physical problems but also on healthy aspects. For example, nutrition, exercise, and self-care, such as hobbies and leisure activities, may be the individual's strengths. The assessment process should be similar to the one described in [Chapter 10](#).

Physical Health

Sleep: In PTSD, sleep is often disrupted or practically nonexistent. Disturbing nightmares are common. The nurse should compare sleep patterns before and after the trauma. Insomnia is typically characterized by difficulty falling asleep, fragmented sleep, or panic like awakenings. The nurse should also assess for nightmares including frequency and intensity. Family members may be able to provide detailed information that is out of the patient's awareness.

Pain: The original trauma may result in chronic pain. For example, physical abuse or wartime injury may result in long-term physical treatment and pain. Prescribed pain medication is often used for reasons other than those for which it was prescribed. For example, a co-occurring traumatic brain injury may be present.

Other Somatic Responses: Patients with PTSD often have multiple unexplained physical problems (e.g., gastrointestinal, cardiovascular, neurologic, and musculoskeletal symptoms). Sometimes, the patient is reluctant to admit a trauma such as a rape or domestic assault and instead seeks out medical care for physical problems. Obtaining a trauma history becomes very important when multiple physical symptoms are present.

Nutrition

The nutritional status of a person with PTSD can be severely compromised by a poor diet following a traumatic event. Over time, a poor diet can increase the risk of other chronic diseases. The unhealthy eating habits usually appear shortly after the trauma. The nurse should assess for changes in diet.

Medication

Taking regularly prescribed medication is often difficult following a trauma. The nurse should determine the medications, vitamins, and herbal supplements the patient was taking prior to the trauma. If the person has been unable to maintain a recommended medication regimen, medication adherence can be addressed when goals are established.

Substance Use

Substance Use: Commonly, individuals with PTSD self-medicate to relieve the discomfort, anxiety, or pain caused by the trauma. The use of alcohol or other drugs is common. Assessment of the use of substances and the frequency will give direction for interventions.

Consider This

Susan started drinking alcohol regularly in Iraq. After returning home, she continued to drink six to eight cans of beer every day.

Psychosocial Assessment

The focus of the psychosocial assessment is identifying the severity of the PTSD

symptoms, the disruptions that these symptoms cause the affected individual and family and current coping approaches. The patient should be asked about intrusive thoughts, irritable moods, negative thoughts, avoidance behaviors, and arousal behaviors, and what impact they have on their daily lives.

Behavioral Responses

Avoidance and isolation are common responses to trauma. The nurse should determine if the person is avoiding others, situations, or environmental reminders of the trauma. Other responses associated with PTSD are agitation and aggression after the event or events. The nurse would want to determine if these behaviors are interfering with functioning and interpersonal relationships.

The nurse should assess for hyperarousal and hypervigilance such as checking surroundings and difficulty focusing on conversations. The person may be easily startled or distracted and overreacts to things happening in the environment.

Self-Concept

In PTSD, guilt, shame, and depression are often present. Guilt may relate to feeling responsible for the events that led up to the trauma. Survivor guilt occurs when one person survives a traumatic event when others do not (see Box 29.6). Assessing self-esteem and self-concept will provide clues to the patient's resilience (see [Chapter 10](#)).

BOX 29.6

Survivor Guilt

A 92-year-old survivor of World War II concentration camps has suffered from depression most of his adult life. When admitted to a long-term care facility, his daughter told the nurse that her dad often had bouts of depression where he would bemoan the fact that he had lived, and his parents and siblings had not. He often told his daughter that he felt guilty because he had survived the Holocaust.

Stress and Coping Patterns

The amount of daily stress can impact the ability of the person to manage PTSD

symptoms. The individual may notice that the PTSD symptoms are worse on certain days or during certain circumstances. For example, one nurse noticed her hypervigilance was worse after working the night shift for several days. These stresses should be linked to the person's current coping skills, which may be positive (meditation, relaxation) or negative (use of substances).

As the nurse and patient identify and evaluate to the effectiveness of coping skills, the nurse should determine if the patient is resilient in dealing with stress. Some coping skills may be effective immediately but have negative consequences such as the use of substances. Developing new coping skills may be important in order to enhance resilience and positive consequences.

Functional Status

An important assessment component is determining the impact of the PTSD symptoms on daily functioning. Is the person able to maintain activities of daily living, shopping, and maintaining a household? Are there difficulties in school or work performance? If there are problems in these areas, the nurse will be able to address them during the recovery planning.

Social Network and Systems

A family assessment focusing on any changes in family dynamics that has occurred since the traumatic event should also be included. The availability of a support network should be determined and built into the recovery plan.

Quality of Life

Quality of life is an overall measure of the culmination and impact of these previously discussed changes. The impact of the trauma and PTSD symptoms on overall quality of life should be examined. For example, a rape can leave a person despondent and unable to function. Nightmares and flashbacks impede sleep and physical health.

Strength Assessment

Throughout the assessment, the nurse should be listening for evidence of individual physical and psychosocial strengths. Was the patient physically healthy before the traumatic event occurred? How does the patient cope with the stress of the trauma? Does the patient have family or friends who can support the individual? Is the patient motivated to deal with PTSD symptoms, develop new coping strategies, and engage in a collaborative, therapeutic relationship? Are there financial or social resources available? This information can be used in helping patient develop a safety and recovery plan.

CLINICAL JUDGMENT

The first priority is safety. If there is a risk for suicide, the nurse and patient should first begin to address these ideations and behaviors. For someone who has been traumatized and, as a result, developed PTSD, the nurse and patient can establish a recovery plan that addresses areas that interfere with coping and functioning such as feelings of anxiety, hopelessness, and powerlessness. For some individuals, a loss of impulse control that results in angry outbursts or aggressive behavior characterizes their difficulty with their quality of life and well-being.

THERAPEUTIC RELATIONSHIP

Establishing a trusting relationship with a person with PTSD is the basis of nurse–patient collaboration. Needs and safety are defined by the survivor who chooses the help that is wanted. Developing a relationship may take time because many survivors have had their trust violated during the traumatic event (see Box 29.7). Trauma can have a lasting effect on the ability to trust others and form intimate relationships. Coping behaviors may be misinterpreted as being “noncompliant” and can lead to negative reactions by health care providers.

BOX 29.7 • THERAPEUTIC DIALOGUE: BORDERLINE PERSONALITY DISORDER

Susan did not want to be admitted to the inpatient unit and reported that she did not want to live. Her husband wants Susan to forget about Iraq and return to her former self. When she arrived on the unit, she was asked several assessment questions. She did not want to tell her story again to the nurse. The nurse needed to complete the admission assessment.

INEFFECTIVE APPROACH

Nurse: Susan, I need to ask you some questions.

Susan: Can't it wait?

Nurse: Oh—unfortunately I have to ask questions.

Susan: I am tired of talking. Everyone is asking the same questions. For the record, I do not have a problem, I do not drink too much, and I wish my husband would go away.

Nurse: Your husband is a nice guy and is only trying to help.

Susan: You do not know what you are talking about. He wants to control me.

Nurse: If you just answer some questions, I can finish my assessment.

Susan: Not now. Go away.

EFFECTIVE APPROACH

Nurse: Hi Susan, my name is Jane, and I am your nurse today.

Susan: What do you want? I don't need a nurse.

Nurse: Well, we can just talk. What brought you here?

Susan: I am tired of talking. Everyone is asking the same questions. For the record, I do not have a problem, I do not drink too much, and I wish my husband would go away.

Nurse: Talking can be tiring. What questions have you been asked?

Susan: My whole life story—where I grew up, when I got married,

how do I get along with my husband and children, what happened in Iraq?

Nurse: You have had a lot of questions since you have been here. How were you able to answer all those questions?

Susan: The worst questions were about abuse and Iraq. I don't think I can talk about that yet.

Nurse: Why don't we stick to the easier ones for now?

Susan: OK, I can try.

CRITICAL THINKING CHALLENGE

- What ineffective techniques did the nurse use in the first scenario? Whose needs was the nurse meeting?
- What effective techniques did the nurse use in the second scenario?

MENTAL HEALTH NURSING INTERVENTIONS

Trauma is linked to health challenges over the lifespan. Trauma-informed care considers the events and circumstances causing the trauma, the person's experience of these events, and the effects of the trauma (SAMHSA, 2014). Adverse childhood experiences can lead to physiologic changes that lead to long-term health and social problems. When caring for an individual with PTSD, the impact of the trauma should be considered. Survivors of trauma may respond to the present through the lenses of their past.

Establishing Recovery and Wellness Goals

The nurse needs to guide the patient in prioritizing goals. It is unrealistic to expect the patient to work on all goals at a time. Trauma can leave people feeling powerless. For example, one place to start is with reestablishing reasonable eating and sleeping patterns. By introducing small changes, the patient will be able to determine which interventions are likely to be effective.

Physical Care

Many of the same nursing interventions discussed in [Chapter 18](#) are used with the person with PTSD. Proper nutrition and regular exercise can help fortify the resilience.

Sleep Enhancement

Sleep hygiene is also an important strategy because sleep disruption is common in PTSD. Early life adversity and PTSD severity are associated with fewer hours of resting and sleeping when compared to those who had lower early life adversity (see [Chapter 28](#)) (Gavrieli et al., 2015). Nurses should collaborate with the patient in finding a strategy that will help the person sleep and manage nightmares. For example, the individual may want to sleep with the lights on because of the nightmares. However, light interferes with nighttime sleep for some people. It may be possible to go to sleep with the lights on but ask a family member to turn off the lights later. Some persons with PTSD find that they cannot sleep in their bed but can sleep in a chair. Some of the following strategies may be helpful:

- Establish and maintain a regular bedtime and rising time.
- Avoid naps.
- Abstain from alcohol. Although alcohol may assist with sleep onset, an alerting effect occurs when it wears off.
- Refrain from caffeine after midafternoon. Avoid nicotine before bedtime and during the night. Caffeine and nicotine are strong stimulants and cause fragmented sleep.
- Avoid exercising 3 hours before bedtime.

Exercise and Yoga

Severe PTSD symptoms are associated with poor physical performance and decreased physical functioning (van den Berk-Clark et al., 2018). Yet, we know that exercise is associated with reduced PTSD symptoms (Hall et al., 2020). Nurses need to encourage patients with PTSD to engage in regular exercise, not only for health promotion but also to reduce symptoms. Practicing yoga may motivate people with PTSD to increase physical activity along with enhancing

self-efficacy. Simple stretching and breathing have shown to reduce abnormal cortisol levels and can be taught in many practice settings (Niles et al., 2018).

Nutrition Interventions

PTSD and early life adversity are associated with risk of obesity, diabetes, and cardiovascular disease. The greater the symptoms, the higher the body weight and blood pressure and lower the insulin sensitivity (Kidman et al., 2020). Poor diet quality including the consumption of *trans* fatty acids can be a major health issue with these individuals. Monitoring body weight and blood pressure should be included in the patient's plan of care. If these health issues are present, nurses should encourage patients to make different food choices and to choose healthy foods. Referral to a dietitian may be necessary.

Smoking Cessation

Individuals with PTSD have higher smoking rates than others, and fewer have quit than the general population. Smoking serves as a way of coping with the symptoms of PTSD. Smoking often co-occurs with alcohol use disorders and cannabis use. Nurses should discuss the health risks associated with these behaviors and encourage the patient to reduce their use. Smoking cessation programs are readily available in most communities (Homish et al., 2019).

Medication Interventions

The selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors, atypical antipsychotics, and mood stabilizers may be effective in reducing the symptoms of PTSD (see Chapters 12 and 25). Two SSRI antidepressants, sertraline (Zoloft) and paroxetine (Paxil), are approved for PTSD and are used to treat symptoms such as sadness, worry, anger, and feeling numb inside (see Box 29.8). Benzodiazepines are not recommended for persons with PTSD. Recently, off-label use of prazosin, an α_1 inhibitor, has been shown to be effective in treating nightmares and improving sleep in PTSD (Ehret, 2019). When prescribed in conjunction with psychotherapy, pharmacotherapy can minimize the excessive fear and anxiety of PTSD (Grasser

& Javanbakht, 2019).

Box 29.3

Drug Profile: Sertraline (Zoloft)

DRUG CLASS: Antidepressant (SSRI)

RECEPTOR AFFINITY: Blocks the reuptake of serotonin

INDICATIONS: Major depressive disorder, obsessive–compulsive disorder, panic disorder, PTSD, premenstrual dysphoric disorder, social anxiety disorder

ROUTES AND DOSAGES: Available in 25-mg, 50-mg, 100-mg rts, 20 mg/mL

Adults: 50 to 200 mg PO once daily; start 50 mg PO once daily, may increase by 50 mg/day

HALF-LIFE (PEAK EFFECT): 62 to 104 hours

SELECTED ADVERSE REACTIONS: Nausea, headache, insomnia, diarrhea, dry mouth, ejaculatory dysfunction, somnolence, weakness, lack of energy, tremor, dyspepsia, anorexia, constipation, decrease in libido, nervousness, anxiety, rash, visual disturbance

WARNINGS: Increase suicidality risk in children, adolescents, and young adults with major depressive or other psychiatric disorders. Contradicted in persons being treated with monoamine oxidase inhibitors and pimozide, an antipsychotic. Risk for serotonin syndrome.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Take exactly as prescribed.
- Can be taken with or without food.
- If a dose is missed, take missed dose as soon as patient remembers unless time for next dose; then skip missed dose.
- Can cause sleepiness or may affect ability to make decisions, think clearly or react quickly.
- Do not drive, operate heavy machinery until patient knows how medication will affect them.
- Do not drink alcohol while taking medication.
- Report any signs and symptoms of adverse reactions, suicidal thoughts, or actions.
- Notify your health care provider if severe agitation, hallucinations, coordination problems, muscle twitching, racing heartbeat, high or low blood pressure, muscle rigidity, sweating or fever, nausea, vomiting, diarrhea occur.

Because the person with PTSD may take many different types of medication, the nurse needs to monitor for any drug interactions and teach the person about all the medications including expected therapeutic effect(s) and side effects. These individuals often take prescribed or over-the-counter pain medications that may interact with mood stabilizers, antidepressants, antianxiety agents, or antipsychotic agents.

Management of Complications

Substance Abuse Interventions: If the person has been using substances to dull the feelings associated with the trauma, the nurse should educate the individual about the addiction and make a referral to a substance abuse treatment team. It is important for the nurse to use a nonjudgmental approach, recognizing the person is suffering from the trauma and is trying to cope with intrusive thoughts and pain. The nurse should emphasize that there are more effective coping mechanisms and offer hope that the person can find other means of alleviating the PTSD symptoms.

Psychosocial Interventions and Trauma-Informed Care

Many of the same psychosocial interventions discussed in [Chapter 27](#) can be used for persons with PTSD. Relaxation strategies and stress reduction techniques are particularly helpful for these individuals. Encouraging the person to participate in a support group can decrease the isolation that may be present and learn how others deal with their symptoms. Service and companion dogs are also helpful in helping the person address the stress of PTSD.

Therapeutic Interactions

One of the greatest treatment challenges is avoiding secondary trauma. When caring for persons with PTSD, we should assume that they have a history of traumatic stress. Extreme stress occurs when shocking or unexpected events overwhelm a person's ability to cope. The nurse should respect how and when a person chooses to talk about the trauma. Healing from trauma requires finding and maintaining a sense of safety, gaining a sense of control over one's life and environment.

The focus of the interactions should be on understanding "what happened," not on what is wrong with the person. The nurse seeks to understand the meaning of the experience to the individual. Similar events have different meanings to different people. When patients are describing traumatic events, it is important for the nurse to avoid responding in shock, dismay, or disgust. A welcoming approach creates a safe environment for the person to discuss the

trauma. Within a collaborative relationship, coping strategies, not symptoms, are the focus. In a safe environment, the person can develop positive coping skills and make sense of who they are.

Enhancing Cognitive Functioning

There are several approaches to managing the intrusive thoughts, dissociative experiences, and hypervigilance that the person may be experiencing. The intrusive thoughts could be addressed through distraction, thought stopping, meditation, or relaxation. Deep breathing or reframing the situation may reduce the hypervigilance and refocusing may reduce the dissociation. The specific approach will depend on the ability of the person to use the techniques.

Psychoeducation

Teaching About Symptoms

PTSD impacts every aspect of a person's life. Trauma, genetic predisposition, brain changes, risk for multiple health problems, and risk for addiction are a part of PTSD. Education about the disorder, its consequences, health risks, and treatment become key topics for patient and family education. Psychoeducation should be individualized to the person's specific issues. There are general psychoeducation topics that should be considered for patient teaching (see Box 29.9).

BOX 29.9

Posttraumatic Stress Disorder

When caring for a person with a PTSD, be sure to include the following topic areas in the teaching plan:

- Identification of individual triggers and cues that lead to reexperiencing trauma
- Safety plans for stressful periods
- Recovery plans that focus on personal strengths
- Risk factors for reoccurrence of symptoms
- Various treatment options: if one does not help, others exist
- Avoid substances such as alcohol and drugs
- Nutrition

- Exercise
- Sleep hygiene
- Follow-up appointments
- Community services

Wellness Strategies

Many of the wellness strategies are interventions to treatment of the symptoms of PTSD. For example, sleep hygiene is important for those with sleep problems. Managing stress is very important for a person with this disorder. Practicing healthy stress management techniques are critical for handling the events related to hyperarousal. An innocent loud noise may be misinterpreted as a gunshot causing an aggressive response. Exercise helps reduce stress and supports healthy functioning.

Providing Family Education

Families need support as they learn to cope with their family member with PTSD. Family members often feel hopeless in trying to understand the changes that their loved one is undergoing. In many instances, the member with PTSD is unable to share information about the trauma and the symptoms. If alcohol or other drugs are used to self-medicate, the family has additional challenges in dealing with the substance use. Support groups, education about PTSD, and family therapy are helpful.

Promoting Safety

Hospitalization provides a measure of safety for the patient. During hospitalization, the nurse should continue with suicide risk screening as needed and protection from triggering events such as loud noises or stimulating activities. A safety plan should be developed if the patient has had thoughts of dying by suicide (see [Chapter 22](#)).

Evaluation and Treatment Outcomes

The treatment of PTSD may last several years with changing goals. Early in treatment, the goals may be to reduce the intrusive thoughts and regulate sleep; later goals may include being able to establish a trusting relationship with a partner. The evaluation will be modified as the goals and interventions change.

Continuum of Care

The person with PTSD is primarily treated in the community rather than a medical facility as an inpatient. Short-term hospitalization for safety may be needed if suicidal or homicidal thoughts are strong or for an adjustment of medication.

Emergency Care !

When individuals with PTSD need emergency care, they are usually having suicidal ideation or thoughts to hurt others. Safety interventions should be implemented. It is important for the nurse to know the nature of the trauma to be able to approach the patient. For example, a person previously exposed to combat may be sensitive to loud noises and is more likely to become aggressive when doors slam, whereas a woman who has been raped may not tolerate anyone touching her.

Inpatient-Focused Care

Inpatient settings can provide a safe environment for the person who is tormented with frequent flashbacks, has become depressed and potentially suicidal, or is harboring thoughts about hurting others. Medications may be initiated or adjusted. However, hospitalization and restrictive treatment can also retraumatize the patient. Being locked in a mental health unit or being restrained can be extremely traumatizing to the person who has already been traumatized. See the Nursing Care Plan 29.1, which sets forth a plan of care for Susan, the case study patient in this chapter.

NURSING CARE PLAN 29.1

The Person with Posttraumatic Stress Disorder

Susan is a 30-year-old woman admitted to an acute mental health unit after a suicide attempt with an overdose of benzodiazepines and alcohol. She was discharged from the Army 6 months ago and returned home to her husband and two children, age 6 and 8. She was sexually assaulted by an uncle when she was 6 years old. While in Iraq, she was exposed to combat and was sexually assaulted by another soldier. She has been drinking alcohol heavily after her return home. She and her husband have been arguing since her return and are now discussing divorce. She decided to end it all.

Setting: Acute Mental Health Unit

Baseline Assessment: Susan is dressed in hospital scrubs following medical treatment of overdose. She is oriented X3. She is gazing downward, with flat affect, shoulders slightly hunched, soft voice. She reports she is no longer having suicidal thoughts but feels very depressed. “I don’t know what to do. I don’t feel close to my kids and my husband wants a divorce.” She reports that she began taking her mother’s benzodiazepines to help her sleep. She is having constant thoughts about the killings she saw in Iraq, cannot sleep, often has nightmares when she does sleep, does not want sexual relations with husband, and sleeps on a couch close to the front door. She drinks six to eight beers a day. She has not worked since returning from Iraq. She is 5'5"

tall, weighs 140 lbs (BMI 23.3), has BP 120/70; P70, R16. Her goal is to have a normal life.

Strengths: Husband states he does not want a divorce and wants to stay married and is willing to engage in counseling. Mother is very supportive. She has work skills.

Associated Psychiatric Diagnosis	Medications
Posttraumatic Stress Disorder Lorazepam 1 mg every 4 to 6 hours as needed Zolpidem 5 mg PO HS as needed	Sertraline, 25 mg every morning for 1 week, then 50 mg PO every day.

Priority of Nursing Care: Post-Trauma Behaviors

Important Characteristics	Associated Considerations
Depression Flashbacks Intrusive thoughts	Abuse, witnessing violent death Rape Substance abuse

Outcomes

Initial	Long Term
<ul style="list-style-type: none">• Motivate patient to reduce use of alcohol and abuse of benzodiazepines for stress reduction.• Discuss original trauma and the more recent trauma in Iraq.• Increase quality of sleep.• Practice stress reduction techniques.	<ul style="list-style-type: none">• Engage in psychotherapy to reduce impact of trauma.• Develop positive healthy strategies for managing stress.

Interventions

Interventions	Rationale	Ongoing Assessment
<ul style="list-style-type: none"> Initiate a nurse–patient relationship by using an accepting, nonjudgmental approach. 	<p>A relationship with a therapist will provide an opportunity for Susan to discuss her trauma and strengths.</p>	<p>Determine the extent to which Susan is willing to trust and engage in a therapeutic relationship.</p>
<ul style="list-style-type: none"> Encourage Susan to identify symptoms of PTSD. 	<p>By identifying symptoms, Susan will be able to recognize that the intrusive thoughts, insomnia, and other symptoms are related to her traumatic experience.</p>	<p>Assess Susan’s recognition of her symptoms and her level of understanding of the symptoms’ relationship to her current distress.</p>
<ul style="list-style-type: none"> Help Susan develop a plan to address her current marital problems such as counseling or therapy after discharge. 	<p>Her marital problems may be related to her sexual assaults and exposure to combat.</p>	<p>Determine Susan’s willingness to develop a plan.</p>
<ul style="list-style-type: none"> Administer sertraline 50 mg as prescribed. Observe for target effect and side effects. Begin teaching about the medication and the importance of taking the medication as prescribed, avoiding consuming alcohol, and reporting any side effects. 	<p>Sertraline is an SSRI that blocks the reuptake of serotonin and is indicated for PTSD.</p>	<p>Make sure that Susan takes her medication. Monitor for improvement in PTSD symptoms and side effects such as nervousness, nausea, and any others.</p>
<ul style="list-style-type: none"> Monitor sleep patterns and teach improved sleep hygiene. 	<p>Disturbed sleep is common in</p>	<p>If Susan continues to have disturbed</p>

Administer zolpidem as prescribed.	association with PTSD.	sleep or experience side effects from zolpidem therapy, notify the primary care prescriber.
<ul style="list-style-type: none">Support development of resilience by examining Susan's strengths (e.g., social support, nutrition, exercise).	Resilience is important in reducing the impact of previous trauma. Positive social support, nutrition, and exercise help support resilience.	Determine Susan's social support, nutrition, and exercise regimen.

Priority of Nursing Care: Difficulty in Assuming Parenting Responsibilities

Important Characteristics	Associated Considerations
Decreased capacity to parent Inadequate coping to stresses of parenting	Substance use Stress Conflict with husband

Outcomes

Initial	Long Term
<ul style="list-style-type: none">Resume parenting role.Decrease conflict with husband.Reduce use of substances.	<ul style="list-style-type: none">Serve as role model to children.Develop positive relationship with husband.Eliminate the use of substances as a stress reliever.

Evaluation

Interventions	Rationales	Ongoing Assessment
---------------	------------	--------------------

<ul style="list-style-type: none"> • Collaborate with Susan in identifying her current role perceptions. 	Recovery-oriented nursing care engages the patient in decision-making.	Validate whether her current role perceptions accord with reality.
<ul style="list-style-type: none"> • Identify the changes that she would like to make in her parenting role. 	Relationship rebuilding starts with self-awareness of personal goals.	Determine if she needs referral to community resources that can help her with her relationship and role issues.
<ul style="list-style-type: none"> • Discuss her goals for her marriage. 		
<ul style="list-style-type: none"> • Discuss strategies for reducing substance use for stress reduction. 	Substance use for stress reduction has negative outcomes with high risk of addiction.	Determine whether strategies are useful to Susan. May need referral to substance abuse counselor if necessary.
<ul style="list-style-type: none"> • Offer relaxation, meditation, or imagery for stress reduction. 		

Community Care

Treatment mostly occurs in the community with the individual attending group therapy, support groups, individual therapy, and medication management. Most appointments will occur after working hours. Nursing care can be delivered in all settings. The community setting is an excellent opportunity for patient and family education.

Virtual Mental Health Care

Virtual strategies are beneficial for the care of individuals with PTSD. Remote access to providers and treatment apps are readily available on cell phones and computers. More sophisticated virtual reality technology is also being used. For

example, imagery tasks are used to create safe spaces through the use of Google or Microsoft applications (Frewen et al., 2020).

Integration of Primary Care

The persons with PTSD may first seek help from a primary care provider. For example, sleep problems in adults and behavior problems of children are often treated in a nonmental health environment. Conversely, when mental health clinicians care for persons with PTSD, they must address the physical problems as well as their psychological problems. Because there is no one medication indicated for PTSD, there is a risk of multiple medications being prescribed to treat various physical and mental health problems. Ideally, individuals with PTSD should be treated in an integrated setting where close monitoring of all treatments is possible.

OTHER TRAUMA- AND STRESSOR-RELATED DISORDERS

Acute stress disorder is similar to PTSD except that it is resolved within 1 month of the traumatic event. Acute stress disorder can develop into PTSD if the symptoms last longer than 1 month. Two trauma- and stressor-related disorders typically occurring in childhood are reactive attachment disorder and disinhibited social engagement disorder. *Reactive attachment disorder* is characterized by inhibited, emotionally withdrawn behavior toward an adult caregiver. These children rarely seek or respond to comfort when distressed. This disorder usually occurs when the primary caregiver frequently changes. In *disinhibited social engagement disorder*, the child is overly familiar with others in ways uncharacteristic of cultural norms. For instance, the child does not hesitate to go somewhere with an unfamiliar adult.

One of the most common diagnoses for hospitalized persons is adjustment disorder (APA, 2013). These disorders occur within 3 months of the stressor. Affected individuals experience distress that seems out of proportion to the severity of the stressor and may be unable to function socially. After the situation is resolved, the symptoms subside.

Dissociative Disorders

Dissociative disorders are thought to be responses to extreme external or internal events or stressors where dissociation, or a splitting from the self, occurs as a way of coping with severe anxiety. Prevalence is higher among people who experience childhood physical or sexual abuse than among others. The onset of these disorders may be sudden or may occur gradually; the course of each may be long term or transient. Dissociative disorders include *dissociative amnesia*, the inability to recall important yet stressful information; *depersonalization/derealization disorder*, the feeling of being detached from one's mental processes; and *dissociative identity disorder* (DID) (formerly called multiple personality disorder), presence of at least two distinct personality or identity states.

The essential feature of these disorders involves a failure to integrate identity, memory, and consciousness. That is, unwanted intrusive thoughts disrupt one's contact with the here and now, or memories that are normally accessible are lost. These disorders are closely related to the trauma- and stressor-related disorders but are categorized separately. Persons with dissociative disorders may also have comorbid substance abuse, mood disorders, personality disorders, or PTSD (APA, 2013).

DID has long been a controversial diagnosis, with many skeptics challenging the legitimacy of this disorder. Recent empirical evidence supports DID as a complex, posttraumatic developmental disorder. Once believed to be relatively rare, prevalence rates are reported at approximately 1.1% to 1.5% of community samples. The highest prevalence is found in groups highly exposed to trauma or cultural oppression (Brand et al., 2016). There is also emerging evidence that there are structural brain changes in persons with this disorder (Reinders et al., 2018).

Treatment options include the use of antidepressants to treat the patient's underlying mood and anxiety. Psychotherapy options include CBT and psychodynamic psychotherapy to determine the triggers that lead to heightened anxiety and dissociation.

SUMMARY OF KEY POINTS

- The development of psychological trauma depends on the meaning of the event and the resilience of the individual. The stronger the resilience, the more likely the individual will be able to withstand the negative impact of a potentially traumatic event.
- Resilience develops over time when there are a positive self-concept and measured self-worth, and when problem-solving, communication, and coping skills have been learned.
- PTSD occurs after a traumatic event and is characterized by involuntary intrusive thoughts, avoidance and numbing, negative moods and thoughts, and hyperarousal. CPTSD develops when there is betrayal of trust and chronic repetitive trauma over months or year.
- Women are twice as likely as men to experience PTSD. Service members returning from Iraq and Afghanistan have high rates of PTSD.
- There are several approaches to the treatment of PTSD including CBT, traditional psychotherapy, and medications.
- Nursing care focuses on assessing symptoms of PTSD, building strengths, enhancing resilience, and collaborating with the patient in counseling interventions, administration of medication, psychoeducation, and family support.

CRITICAL THINKING CHALLENGES

1. What are the various traumatic events that can lead to PTSD? Why do some people develop PTSD and others, who have experienced the same trauma, do not?

2. Identify strategies the nurse can use to support the development of resilience.
3. Differentiate intrusive thoughts from dissociative symptoms.
4. Give examples of derealization and depersonalization.
5. Compare trauma- and stressor-related disorders with dissociative disorders.
How are they similar? How are they different?
6. How should a nurse approach a military veteran who is having intrusive thoughts, is having nightmares, and is unable to sleep?

Movie Viewing Guides

The Dry Land: (2010). James (Ryan O’Nan), an Iraq war veteran, returns to his small-town life in Texas. His family quickly realizes that he has changed and has PTSD. He is irritable, anxious, and considers suicide. He keeps a gun at his bedside. He drinks with his friends and is easily provoked into fights. His family cannot truly understand the pain he feels. An award-winning movie, it depicts a veteran’s struggle with regaining his life.

Viewing Points: Identify the behaviors that are characteristic of PTSD. Identify the strengths that he demonstrated that represented resilience. Develop a plan of care that includes his family, friends, and community support.

Personality and Impulse-Control Disorders

Nursing Care of Persons with Personality and Impulse-Control Disorders

Hansen, Mary Ann Boyd Kimberlee

KEYCONCEPTS

- antisocial personality disorder (ASPD)
- borderline personality disorder (BPD)
- difficult temperament
- emotional dysregulation
- impulse-control disorders
- personality
- personality disorder
- self-harm
- temperament

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

- l. Discuss the role of a personality in personality disorders.

2. Delineate the clinical symptoms of borderline personality disorder and antisocial personality disorder, with emphasis on emotional dysregulation, self-harm, temperament, and impulsivity.
3. Analyze the theories explaining personality disorders.
4. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with borderline personality disorder.
5. Apply a person-centered, recovery-oriented nursing process for persons with borderline personality disorder.
6. Identify the role medications play in treating people with borderline and antisocial personality disorders and discuss their effectiveness.
7. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
8. Develop wellness strategies for persons with borderline personality disorder.
9. Discuss the importance of integrated health care for persons with borderline personality disorder.
10. Describe other personality disorders and relevant nursing care for persons with these disorders.
11. Compare and contrast disruptive impulse-control disorders.

KEY TERMS

- Affective instability
- Avoidant personality disorder
- Cognitive schemata
- Dependent personality disorder
- Dialectical behavior therapy (DBT)
- Dichotomous thinking
- Dissociation
- Histrionic personality disorder
- Identity diffusion
- Inhibited grieving
- Intermittent explosive disorder

- Invalidating environment
 - Kleptomania
 - Mentalization-based therapy (MBT)
 - Mentalizing
 - Narcissistic personality
 - Obsessive-compulsive personality disorder
 - Paranoid personality disorder
 - Parasuicidal behavior
 - Personality traits
 - Projective identification
 - Pyromania
 - Schizoid personality disorder
 - Schizotypy
 - Schizotypal personality disorder
 - Separation-individuation
 - Splitting
-

Case Study: Rebecca

Rebecca is a 23-year-old single female who lives alone. She has few friends but does attend regular psychotherapy sessions that help her understand her emotions and behaviors. She becomes very upset when her therapist leaves town for a planned vacation. Her family wants to help but is frustrated with Rebecca's inability to deal with everyday stresses.

Case Study: Danny

Danny is a 55-year-old man admitted to the inpatient mental health

unit from the county jail after threatening suicide with a plan to hang himself. He was arrested after physically assaulting his girlfriend with whom he lives.

INTRODUCTION

The concept of personality seems deceptively simple but instead is very complex. Historically, the term *personality* was derived from the Greek word *persona*, the theatrical mask used by dramatic players that had the connotation of a projected pretense or allusion. With time, the connotation changed from being an external surface representation to the internal traits of the individual

KEYCONCEPT **Personality** is a complex pattern of characteristics, largely outside of the person's awareness, which comprise the individual's distinctive pattern of perceiving, feeling, thinking, coping, and behaving.

Personality traits are prominent aspects of personality that are exhibited in a wide range of social and personal contexts. Intrinsic and pervasive, personality traits emerge from a complicated interaction of biologic dispositions, psychological experiences, and environmental situations that ultimately comprise a distinctive personality.

No sharp division exists between normal and abnormal personality functioning. Instead, personalities are viewed on a continuum from normal at one end to abnormal at the other. Many of the same processes involved in the development of a “normal” personality are responsible for the development of a personality disorder.

This chapter provides an overview of personality disorders with borderline personality disorder (BPD) explained in detail and antisocial personality disorder (ASPD) emphasized. Disruptive impulse-control disorders, a closely related group of disorders, are also discussed. Oppositional defiant disorder and conduct disorder, which are childhood diagnoses, are discussed in [Chapter 37](#).

PERSONALITY DISORDERS OVERVIEW

A personality disorder is “an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment” (American Psychiatric Association [APA], 2013, p. 646).

Historically there has always been the question of the cause of personality disorders. Is it “bad genes” and/or “bad environment”? There appears to be a general agreement that the main etiological factors for personality disorder are heritably heightened affect states (excessive fear, anger, detachment) and adverse environmental factors (substandard parenting, childhood psychological trauma), acting singly or in concert (Svrakic & Divac-Jovanovic, 2019).

KEYCONCEPT A **personality disorder** diagnosis is based on abnormally inflexible behavior patterns of long duration—traced to adolescence or early adulthood—that deviates from acceptable cultural norms.

Consider Christine

Danny explains that rules are made to be broken.

The prevalence rate of any personality disorder in the adult population is estimated at 12.16% (Volkert et al., 2018). These rates are of public health significance because of the extreme social dysfunction and high health care use of persons with personality disorders. Many others do not seek treatment for the distress or impairment related to their personality disorder because they do not

perceive themselves as having a problem. However, they frequently seek help for concurrent medical or mental health disorders.

At present, 10 personality disorders are recognized in the *DSM-5* within three clusters. Cluster A disorders are characterized by odd or eccentric behavior, Cluster B disorders are characterized by dramatic, emotional, or erratic behavior, and in Cluster C disorders, individuals appear anxious or fearful (APA, 2013).

CLUSTER A DISORDERS: PARANOID, SCHIZOID, AND SCHIZOTYPAL PERSONALITY DISORDERS

Paranoid Personality Disorder

Clinical Course and Diagnostic Criteria

Paranoid personality disorder is characterized by a long-standing suspiciousness and mistrust of people in general. Individuals with these traits refuse to assume personal responsibility for their own feelings, assign responsibility to others, and avoid relationships in which they are not in control or power. These individuals are suspicious, guarded, and hostile. They are consistently mistrustful of others' motives, even those of relatives and close friends. Actions of others are often misinterpreted as deception, deprecation, and betrayal, especially regarding loyalty or trustworthiness of friends and associates (APA, 2013).

People with paranoid personality disorder are unforgiving and hold grudges; their typical emotional responses are anger and hostility. They distance themselves from others and are outwardly argumentative and abrasive; internally, they feel powerless, fearful, and vulnerable. Other hallmark features of paranoid personality disorder are persistent ideas of self-importance and the tendency to be rigid and controlling. Blind to their own unattractive behaviors and characteristics, they often attribute these same traits to others. Their outward demeanor often seems cold, sullen, and humorless. They want to appear controlled and objective, yet often they react emotionally, displaying signs of nervousness, anger, envy, and jealousy. Orderly by nature, they are hypervigilant to any environmental changes that may loosen their control of the world.

Occupational problems are common. In clinical populations, paranoid personality disorder is one of the strongest predictors of aggressive behavior, often associated with violence and stalking. People with this disorder do not seek mental health care until they have symptoms of comorbid disorders (Lee, 2017).

Epidemiology and Risk Factors

The prevalence estimates for paranoid personality range from 1.2% to 4.4%. Paranoid personality disorder is the second-most prevalent personality disorder after **obsessive-compulsive personality disorder** (OCPD; Lee, 2017).

Etiology

The etiologic factors of paranoid personality remain unclear, but a genetic predisposition for an irregular maturation may be involved. As children, these individuals tend to be active and intrusive, difficult to manage, hyperactive, and irritable and have frequent outbursts of temper.

Evidence-Based Nursing Care of Persons with Paranoid Personality Disorder

Nurses most likely see these patients about other health problems but formulate nursing approaches based on the patient's underlying paranoia. Assessment of these individuals reveals disturbed or illogical thoughts that demonstrate misinterpretation of environmental stimuli. For example, a man was convinced that his wife was having an affair with the neighbor because his wife and the neighbor left their homes for work at the same time each morning. Although the man's beliefs were illogical, he never once considered that he was wrong. He frequently followed them but never caught them together. He continued to believe they were having an affair.

Because of their inability to develop relationships, these patients are often socially isolated and lack social support systems.

Mental health nursing interventions based on the establishment of a

therapeutic relationship are difficult to implement because of the patient's mistrust. If a trusting relationship is established, the nurse helps the patient identify problematic areas, such as getting along with others or keeping a job. Through therapeutic techniques such as acceptance, confrontation, and reflection, the nurse and patient examine a problematic area to gain another view of the situation. Changing thought patterns takes time. Patient outcomes are evaluated in terms of small changes in thinking and behavior.

Continuum of Care

Individuals with paranoid personalities are unlikely to participate in treatment or recovery plans. If they have other comorbid disorders and are forced to seek treatment (through loss of their job or being ordered by a court in connection with an offense of a chargeable nature), they may seek help for depression or psychosis.

Schizoid Personality Disorder

Clinical Course and Diagnostic Criteria

People with **schizoid personality disorder** are characterized as being seclusive, isolated, and inept at forming relationships (Fariba & Gupta, 2020). They tend to be unable to experience the joyful and pleasurable aspects of life. They are introverted, reclusive, and clinically seem distant, aloof, apathetic, and emotionally detached. Typically, life-long loners, they have difficulty making friends, seem uninterested in social activities, and appear to gain little satisfaction in personal relationships. In fact, they appear to be incapable of forming social relationships. Their interests are directed at objects, things, and abstractions. They may do well at solitary jobs other people might find difficult to tolerate. Often people with schizoid personality disorders may daydream excessively and become attached to animals, and they frequently do not marry or even form long-lasting romantic relationships. As children, they engage primarily in solitary activities, such as stamp collecting, computer games, electronic equipment, or academic pursuits such as mathematics or engineering. In addition, they seem to have a cognitive deficit characterized by obscure

thought processes, particularly about social matters. Communication with others is confused and lacks focus. These individuals reveal minimum introspection and self-awareness, and interpersonal experiences are described in a very mechanical way.

Epidemiology and Risk Factors

Schizoid personality disorder is rarely diagnosed in clinical settings. It is estimated that the prevalence is 3.1% (APA, 2013).

Etiology

The etiologic processes are speculative. There may be neuroanatomical or neurotransmitter changes associated with schizoid disorder (Fariba & Gupta, 2020). The defects of this personality may stem from an adrenergic–cholinergic imbalance in which the parasympathetic division of the autonomic nervous system is functionally dominant. Excesses or deficiencies in acetylcholine and norepinephrine may result in the proliferation and scattering of neural impulses that may be responsible for the cognitive “slippage” or affective deficits.

Evidence-Based Nursing Care of Persons with Schizoid Personality Disorder

Difficulty with social relations and low self-esteem are typical nursing priorities of patients with schizoid personality disorder. Major treatment goals are to enhance the experience of pleasure, prevent social isolation, and increase emotional responsiveness to others. Because these individuals often lack customary social skills, social skills training is useful in enhancing their ability to relate in interpersonal situations. The primary focus is to increase the patient’s ability to feel pleasure. The nurse balances interventions between encouraging enough social activity to prevent the individual from retreating into a fantasy world and too much social activity that becomes intolerable to the patient.

The nurse may find working with such individuals unrewarding and as a

result, the attending nurses may become frustrated, feel helpless, or become bored during the interactions. It is difficult to establish a therapeutic relationship with these individuals because they tend to shy away from interactions and are rarely motivated about treatment. Evaluation of outcomes should be in terms of increasing the patient's feelings of satisfaction with solitary activities.

Continuum of Care

People with schizoid personalities are rarely hospitalized unless they have a comorbid disorder. Family members may seek treatment for them in an outpatient setting.

Schizotypal Personality Disorder

Clinical Course and Diagnostic Criteria

Schizotypal personality disorder is characterized by a pattern of social and interpersonal deficits. The term **schizotypy** refers to traits that are similar to the symptoms of schizophrenia but are less severe. Cognitive perceptual symptoms are a primary characteristic and include magical beliefs (similar to delusions) and perceptual aberrations (similar to hallucinations). Other common symptoms include referential thinking (interpreting insignificant events as personally relevant) and paranoia (suspicion of others).

Persons with schizotypal personality disorder are more dramatically eccentric than those with schizoid personality disorder who are characteristically flat, colorless, and dull. These individuals are perceived as strikingly odd or strange in both appearance and behavior, even to laypersons. They may have unusual mannerisms, an unkempt manner of dress that does not quite “fit together,” and inattention to usual social conventions (e.g., avoiding eye contact, wearing clothes that are stained or ill fitting, and being unable to join in the give-and-take banter of coworkers). Devoid of any close friends other than first-degree relatives, their mood is constricted or inappropriate, with excessive social anxieties. They usually exhibit an avoidant behavior pattern.

Persons with schizotypal personality disorder may respond to stress with transient psychotic episodes (lasting minutes to hours). Because of their short

duration, the symptoms mirror but fall short of features that would justify the diagnosis of schizophrenia. Many individuals (30% to 50%) with schizotypal personality disorder also have a co-occurring major depressive disorder diagnosis when admitted to a hospital (APA, 2013; Racioppi et al., 2018). Schizotypal personality disorders may be slightly more common in males (APA, 2013).

Epidemiology and Risk Factors

The lifetime prevalence of schizotypal personality disorder is 3.9%, with higher rates among men (4.2%) than women. There are cultural variations of traits across countries and cultures. Persons from some cultures express all of the symptoms of schizotypal personality disorder and others only one or two distinct symptoms (Fonseca-Pedrero et al., 2018).

Etiology

Magnetic resonance imaging studies of individuals with schizotypal personality disorder show smaller gray matter volume, which is correlated with negative symptoms. Studies show changes in temporal gyrus volume asymmetry and in the white matter tracts (Chan et al., 2018). There is also evidence that trauma-exposed individuals have a greater risk of developing schizotypal disorder (Quidé et al., 2018).

Evidence-Based Nursing Care of Personswith Schizotypal Personality Disorder

Depending on the amount of decompensation (i.e., deterioration of functioning and exacerbation of symptoms), the assessment of a patient with a schizotypal personality disorder can generate a range of clinical priorities. If a person has severe symptoms, such as delusional thinking or perceptual disturbances, the nursing priorities are similar to those for a person with schizophrenia (see [Chapter 24](#)). If symptoms are mild, social isolation, coping with stress and daily

living, low self-esteem, and difficult social interactions are the focus of nursing care.

People with schizotypal personality disorder need help in developing recovery-oriented strategies to increase their sense of self-worth and recognize their positive attributes. They can benefit from social skills training and environmental management that increases their psychosocial functioning. Their eccentric thoughts and behaviors alienate them from others. Reinforcing socially appropriate dress and behavior can improve their overall appearance and ability to relate to the environment. Because they have a hard time generalizing from one situation to another, attention to cognitive skills is important.

Continuum of Care

Quality of life for a patient with schizotypal personality disorder can be improved with supportive psychotherapy, but their suspiciousness, lack of trust, or impaired social interactions make it difficult to establish a therapeutic relationship. These individuals do not usually seek treatment unless more serious symptoms appear, such as depression or anxiety. Medications are not generally used unless the individual has coexisting anxiety or depression.

Nursing care is often provided in a home or clinic setting, with the personality disorder being secondary to the purpose of the care. This means that nurses focus on other aspects of patient care and may miss the underlying psychiatric disorder. A psychiatric nursing consult may be needed for these patients to help identify the disorder.

CLUSTER B DISORDERS: BORDERLINE, ANTISOCIAL, HISTRIONIC, AND NARCISSISTIC PERSONALITY DISORDERS

Borderline Personality Disorder

The term *borderline* was first coined by Adolph Stern in 1938 when he identified a “border line group of patients” who “fit frankly neither into the psychotic nor into the psychoneurotic group, and are extremely difficult to handle by any

psychotherapeutic method” (Stern, 1938).

People with BPD have problems regulating their moods, developing a self-identity, maintaining interpersonal relationships, maintaining reality-based thinking, and avoiding impulsive or destructive behavior. The severity and difficulty in treating the disorder lead to enormous public health costs from health care utilization and functional disability (Meuldijk et al., 2017).

KEYCONCEPT **Borderline personality disorder (BPD)** is characterized by a disruptive pattern of instability related to self-identity, interpersonal relationships, and affect, combined with marked impulsivity and destructive behavior. BPD has historically been seen as a lifelong, highly disabling disorder; however, research over the past two decades has challenged that assumption. BPD can be accurately identified in adolescence, and the course of the disorder in adolescence and adulthood is generally similar, with reductions in symptoms over time (Winsper, 2021).

Clinical Course

Individuals with BPD appear more competent than they actually are and often set unrealistically high expectations for themselves. When these expectations are not met, they experience intense shame, self-hate, and self-directed anger. Their lives are like soap operas—one crisis after another. Some of the crises are caused by the individual’s dysfunctional lifestyle or inadequate social milieu, but many are caused by fate—the death of a spouse or a diagnosis of an illness. They react emotionally with minimal coping skills. The intensity of their emotions often frightens them and others. Friends, family members, and coworkers limit their contact with the person, which furthers the sense of aloneness, abandonment, and self-hatred. It also diminishes opportunities for learning self-corrective measures.

Remissions from the acute symptoms (e.g., self-injurious behaviors, suicide attempts, or threats about suicide) are fairly common, and the relapse rate is relatively low compared with other disorders. Overall, the prognosis is good for persons with BPD (Chapman et al., 2020). However, psychosocial functioning does not necessarily improve as symptoms decrease (Shah & Zanarini, 2018).

Diagnostic Criteria

BPD is a “pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and

present in a variety of contexts” (APA, 2013, p. 663). See Key Diagnostic Characteristics 30.1. Individuals with BPD also exhibit related cognitive and behavioral dysfunctions.

KEY DIAGNOSTIC CHARACTERISTICS 30.1 • BORDERLINE PERSONALITY DISORDER 301.83

Diagnostic Criteria

A pervasive pattern of instability of interpersonal relationships, self-image, and diminished affect, and marked impulsivity, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. (**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5.)
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance use, reckless driving, binge eating). (**Note:** Do not include suicidal or self-mutilating behavior covered in Criterion 5.)
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient stress-related paranoid ideation or severe dissociative symptoms.

Associated Behavioral Findings

- Pattern of undermining self at the moment a goal is to be realized
- Possible psychotic like symptoms during times of stress
- Recurrent job losses, interrupted education, and broken marriages
- History of physical and sexual abuse, neglect, hostile conflict, and early parental loss or separation

Unstable Interpersonal Relationships

People with BPD have an extreme fear of abandonment, as well as a history of unstable or insecure attachments (Palihawadana et al., 2019). They suffer from difficulties in emotion regulation, which includes **affective instability**, impulsivity, fear of abandonment, eruptions of rage, feelings of emptiness, unstable interpersonal relationship, chronic dysphoria, or depression, as well as heightened risk-taking behaviors (Grambal et al., 2016). Most have never experienced a consistently secure, nurturing relationship and are constantly seeking reassurance and validation. In an attempt to meet their interpersonal needs, they idealize others and establish intense relationships that violate others' interpersonal boundaries, which leads to rejection. The relationships of individuals with BPD may be chaotic, intense, and marked with difficulties (Grambal et al., 2016). When these relationships do not live up to their expectations, they devalue the person. Continually disappointed in relationships, these individuals, who are already intensely emotional and have a poor sense of self, feel estranged from others and inadequate in the face of perceived social standards. Intense shame and self-hate follow. These feelings often result in self-injurious behaviors, such as wrist cutting, self-burning, or head banging. BPD is associated with high mortality by suicide. There is also a high risk to die prematurely because of impulsive risk-taking, as well as succumbing to violence from others. Even though the characteristics of BPD are easy to identify, the diagnosis is often overlooked. A key reason for this neglect is the perception that the overemotional, sometimes theatrical, and self-injurious behaviors are signs of willfulness and manipulations rather than signs of an illness (Ekselius, 2018).

Consider Rebecca

Rebecca hates being alone, but her behaviors drive others away. When she

feels rejected, anxious, or angry, she cuts her wrists, which decreases her anxiety.

Unstable Self-Image

These patients appear to have no sense of their own identity and direction; this becomes a source of great distress to them and is often manifested by chronic feelings of emptiness and boredom. It is not unusual for people with BPD to direct their actions in accord with the wishes of other people. For example, one woman with BPD describes herself: “I am a singer because my mother wanted me to be. I live in the city because my manager thought that I should. I become whatever anyone tells me to be. Whenever someone recommends a song, I wonder why I didn’t think of that. My boyfriend tells me what to wear.” distress to them and is often manifested by chronic feelings of emptiness and boredom. It is not unusual for people with BPD to direct their actions in accord with the wishes of other people. For example, one woman with BPD describes herself: “I am a singer because my mother wanted me to be. I live in the city because my manager thought that I should. I become whatever anyone tells me to be. Whenever someone recommends a song, I wonder why I didn’t think of that. My boyfriend tells me what to wear.”

Unstable Affect

Affective instability (i.e., rapid and extreme shift in mood) is a core characteristic of BPD and is evidenced by erratic emotional responses to situations and intense sensitivity to criticism or perceived slights. For example, a person may greet a casual acquaintance with intense affection yet later be aloof with the same acquaintance. Friends describe individuals with BPD as moody, irresponsible, or intense. These individuals often fail to recognize their own emotional responses, thoughts, beliefs, and behaviors and have difficulty interpreting the facial effects of others. In this disorder, recognizing emotions in others is altered (Santangelo et al., 2017).

Cognitive Dysfunctions

People with BPD often have **dichotomous thinking** . That is, they evaluate experiences, people, and objects in terms of mutually exclusive categories (e.g., good or bad, success or failure, trustworthy or deceitful). Their interpretation of normally occurring events is usually extremely positive or extremely negative. Sometimes their thinking becomes disorganized with irrelevant, bizarre notions and vague or scattered thought connections, as well as delusions and hallucinations.

Another cognitive dysfunction common in BPD is **dissociation** , or times when thinking, feeling, or behaviors occur outside a person's awareness. It is a coping strategy for avoiding disturbing events. In dissociating, the person does not have to be aware of or remember traumatic events. There is evidence of functional changes in the fronto-limbic regions (amygdala, anterior cingulate, inferior frontal gyrus, medial, and dorsolateral prefrontal cortices) and temporoparietal areas (Krause-Utz & Elzinga, 2018).

Impaired Problem-Solving

In BPD, affected people often fail to engage in active problem-solving. Instead, problem-solving is attempted by soliciting help from others in a helplessly hopeless manner. Suggestions offered are rarely taken up.

Impulsivity

These individuals often have difficulty delaying gratification or thinking through the consequences before acting on their feelings; their actions are often unpredictable. Essentially, they act in the moment and clean up the mess afterward. Gambling, spending money irresponsibly, binge eating, engaging in unsafe sex, and abusing substances are typical of these individuals. They can also be physically or verbally aggressive. Job losses, interrupted education, and unsuccessful relationships are common.

Self-Harm Behaviors

The turmoil and unsuccessful interpersonal relationships and social experiences associated with BPD may lead the person to undermine him- or herself when a goal is about to be reached. The most serious consequences are suicide attempts or parasuicidal behavior (i.e., deliberate self-injury with intent to harm oneself).

KEYCONCEPT **Self-harm** is deliberate self-injurious behavior.

Self-harm behavior can be compulsive (e.g., hair pulling), episodic, or repetitive (e.g., cutting wrists, arms, other body parts) and is more likely to occur when the individual with BPD is depressed; has highly unstable interpersonal relationships, especially problems with intimacy and sociability; and is paranoid, hypervigilant (i.e., alert, watchful), and resentful. It is not unusual for persons with this disorder to self-harm in unusual ways such as swallowing pens, staples, and even razor blades, or banging one's head against a brick wall. All self-harm behaviors should be considered potentially life threatening and taken seriously.

Borderline Personality Disorder Across the Life Span

Many children and adolescents show symptoms similar to those of BPD, such as moodiness, self-destruction, impulsiveness, lack of temper control, and rejection sensitivity. If a family member has BPD, the adolescent should be carefully assessed for this disorder. Because symptoms of BPD begin in adolescence, it makes sense that some children and adolescents would meet the criteria for BPD even though it is not diagnosed before young adulthood. More likely, some personality traits, such as impulsivity and mood instability, in many adolescents should be recognized and treated whether or not BPD eventually develops.

Epidemiology and Risk Factors

The estimated prevalence of BPD is roughly 1.0% in community settings. In clinical settings, the prevalence of BPD is approximately 12% in outpatient mental health clinics and 22% in inpatient psychiatric settings, with a higher proportion of women. Several studies demonstrated that traumatic life events, such as sexual and physical abuse, parental divorce, or illness or parental

psychopathology, are important risk factors for the development of BPD.

Age of Onset and Gender Differences

BPD commonly starts and peaks in early to late adolescence and then largely declines over time (Winsper, 2021). Women are more often diagnosed with BPD, but it is generally believed that it occurs equally in people (Mainali et al., 2020).

One possible explanation for women being diagnosed more often than men is that it is more socially acceptable for women to seek help from the health care system. Another reason is that childhood sexual abuse, which more commonly affects girls, is one of the strongest risk factors for BPD. Still another explanation is that because eating disorders are more common in women with BPD, they have a greater likelihood of also having a mood, anxiety, or posttraumatic stress disorder. Men with BPD are more likely to have a substance use problem and intermittent explosive disorder (IED). Other studies cite parental loss and separation as risk factors. Clearly, more research is needed to identify risk factors for the development of BPD (Ellison et al., 2018).

Ethnicity and Culture

The pattern of behavior seen in BPD has been identified in many settings around the world (Choudhary & Gupta, 2020). Adolescents and young adults with identity problems (especially when accompanied by substance use) may transiently display behaviors that misleadingly give the impression of BPD. Such situations are characterized by emotional instability, “existential” dilemmas, uncertainty, anxiety-provoking choices, conflicts about sexual orientation, and competing social pressures to decide on careers.

Familial Differences

BPD has a clear genetic predisposition, with studies showing over 40% heritability (Amad et al., 2014). BPD has a clear heritability component on self-harm, with estimates ranging from 31% to 41%. There are strong relationships

demonstrated in twin studies that demonstrated heritability of impulsive spending, risk of suicide and injury, and other risk-taking behaviors (Schermer et al., 2020).

Comorbidity

Comorbid psychiatric disorders are extremely common in patients with BPD. Mood disorders, particularly MDD and substance use disorder, anxiety disorder, and eating disorder are more frequently seen in patients with BPD, compared with patients with other personality disorders (Chapman et al., 2020). The coexistence of BPD with other disorders presents clinicians with the difficult choice of which disorder receives treatment priority. Symptoms associated with this disorder often provoke negative reactions on the part of clinicians, which interfere with clinicians' ability to provide effective care (Shah & Zanarini, 2018).

Etiology

Evidence supports a biopsychosocial etiology. Studies suggest that BPD traits are heritable, although the specific genetic factors remain unclear. There is clear evidence of differences in brain functioning between those with and without BPD. There is also clear evidence that psychological and social factors contribute to the development of the disorder (Meehan et al., 2018). The following discussion highlights the leading explanations for BPD.

Biologic Theories

Evidence of central nervous system dysfunction in BPD is now clear, including possible structural changes. Biologic abnormalities are associated with three BPD characteristics: affective instability; transient psychotic episodes; and impulsive, aggressive, and suicidal behavior. Associated brain dysfunction occurs in the limbic system and frontal lobe and increases the behaviors of impulsiveness, parasuicide, and mood disturbance (Perez-Rodriguez et al., 2018).

Psychosocial Theories

Psychosocial Theories

Using psychoanalytic methodology suggests persons with BPD have not achieved the normal and healthy developmental stage of **separation-individuation**, during which a child develops a sense of self, a permanent sense of significant others (object constancy), and integration of seeing both bad and good components of oneself (Stern et al., 2018). Those with BPD lack the ability to separate from the primary caregiver and develop a separate and distinct personality or self-identity. **Projective identification**, a defense mechanism by which people with BPD protect their fragile self-image, is believed to play an important role in the development of BPD. For example, when overwhelmed by anxiety or anger at being disregarded by another, they defend against the intensity of these feelings by unconsciously blaming others for what happens to them. They project their feelings onto a significant other with the unconscious hope that that person knows how to deal with it. Projective identification becomes a defensive way of interacting with the world, which leads to more rejection.

Maladaptive Cognitive Processes

Cognitive schemata are patterns of thought that determine how a person interprets events. Each person's cognitive schemata screen, code, and evaluate incoming stimuli. In personality disorders, maladaptive cognitive schemata cause misinterpretation of other people's actions or reactions and of events that result in dysfunctional ways of responding. Cognitive schemata are important in understanding BPD (and ASPD as well).

Individuals with BPD develop dysfunctional beliefs and maladaptive schemata early in life, leading them to misinterpret environmental stimuli continuously, which, in turn, leads to rigid and inflexible behavior patterns in response to new situations and people (Esmaeilian et al., 2019). Because those with BPD have been conditioned to anticipate rejection and disappointment in the past, they become entrenched in a pattern of fear and anxiety regarding encountering new people or situations. They have fears that disaster is going to strike at any minute. The work of cognitive therapists is to challenge distortions

in thinking patterns and replace them with realistic ones.

Remember Rebecca?

Rebecca does not see herself as contributing to her problem but believes her misfortunes are caused by others. For example, when she encounters new people, she shares too much personal information and is disappointed when they do not respond with the same intensity. She interprets their response as rejection.

Social Theories: Biosocial Theories

The biosocial viewpoint proposed by Marsha Linehan and colleagues sees BPD as a multifaceted problem, a combination of innate emotional vulnerability (sensitivity and reactivity to environmental stress), emotional dysregulation (inability to control emotions in social interactions), and the environment (Linehan, 1993) ([Box 30.1](#)).

BOX 30.1

Behavioral Patterns in Borderline Personality Disorder

1. *Emotional vulnerability.* Person experiences a pattern of pervasive difficulties in regulating negative emotions, including high sensitivity to negative emotional stimuli, high emotional intensity, and slow return to emotional baseline.

2. *Self-invalidation*. Person fails to recognize one's own emotional responses, thoughts, beliefs, and behaviors and sets unrealistically high standards and expectations for self. May include intense shame, self-hate, and self-directed anger. Person has no personal awareness and tends to blame social environment for unrealistic expectations and demands.
 3. *Unrelenting crises*. Person experiences pattern of frequent, stressful, negative environmental events, disruptions, and roadblocks—some caused by the individual's dysfunctional lifestyle, others by an inadequate social milieu, and many by fate or chance.
 4. *Inhibited grieving*. Person tries to inhibit and overcontrol negative emotional responses, especially those associated with grief and loss, including sadness, anger, guilt, shame, anxiety, and panic.
 5. *Active passivity*. Person fails to engage actively in solving of own life problems but will actively seek problem-solving from others in the environment, learned helplessness, hopelessness.
 6. *Apparent competence*. Tendency for the individual to appear deceptively more competent than they actually are, usually because of failure of competencies to generalize across expected moods, situations, and time. Person fails to display adequate nonverbal cues of emotional distress.
- Adapted from Linehan, M. (1993). *Cognitive-behavioral treatment of borderline personality disorder* (p. 10). Guilford Press.

KEYCONCEPT Emotional dysregulation is the inability to control emotions in social interactions and includes an instability of mood, marked shifts to or from depression, stress-related and transient mood crashes, rejection sensitivity, and inappropriate and intense outbursts of anger.

The emotional dysregulation and aggressive impulsivity entail both social learning and biologic regulation. Much of the neurobiologic research is directed at corticolimbic function and other cerebral functions (Perez-Rodriguez et al., 2018). In fact, restoring balance in these systems permits more consistent neural firing between the limbic system and the frontal and prefrontal cortices. When these circuits are functional, the person has a greater capacity to think about their emotions and modulate behavior more responsibly.

The ability to control emotion is partly learned from private experiences and encounters with the social environment. BPD is believed to develop when emotionally vulnerable individuals interact with an **invalidating environment**, a social situation that negates private emotional responses and communication. When core emotional responses and communications are continuously dismissed, trivialized, devalued, punished, and discredited (invalidated) by respected or valued persons, the vulnerable individual becomes unsure about their feelings. A minor example of an invalidating environment or response follows: The parents of Emily, a 4-year-old girl, tell her that the family is going to grandmother's house for a family meal. The child responds, "I am not going to Grandma's. I hate Stevie (her cousin)." The parents reply, "You don't hate Stevie. He is a wonderful child. He is your cousin, and only a spoiled and selfish little girl would say such a thing." The parents have devalued Emily's feelings

and discredited her comments, thereby invalidating her feelings and sense of personal worth.

The most severe form of invalidation occurs in situations of child sexual abuse. Often, the abusing adult has told the child that this is a “special secret” between them. The child experiences feelings of fear, pain, and sadness, yet this trusted adult continuously dismisses the child’s true feelings and tells the child what they should feel.

Family Response to Borderline Personality Disorder

Individuals with BPD are typically part of a chaotic family system, but their behavior adds to the chaos. Family members often feel captive to these patients. Family members are afraid to disagree with them or refuse to meet their multiple needs, fearing that self-destructive behavior will follow. During the course of the disorder, family members often get “burned out” and withdraw from the patient, only adding to the patient’s fear of abandonment (Kay et al., 2018).

RECOVERY-ORIENTED CARE FOR PERSONS WITH BORDERLINE PERSONALITY DISORDER

Teamwork and Collaboration: Working Toward Recovery

Treatment of BPD requires the collaboration of the entire mental health care team. Because persons with BPD view the world in absolutes, nurses and other treatment team members are alternately categorized as all good or all bad. This defense is called **splitting** and presents clinicians with a challenge to work openly with each other as well as the patient until the issue can be resolved through team meetings and clinical supervision.

People with BPD are inadvertently highly stigmatized by many clinicians. Much of the stigma occurs when clinicians encounter these patients in crisis settings, such as the emergency department, crisis clinics, and general psychiatric inpatient wards. As these are not the settings in which treatment occurs, clinicians develop a biased perspective on these patients. Few clinicians have the opportunity to see these patients improve over time in specialized treatment clinics; nonetheless, these patients improve and are treatable. Staff

often accuse these individuals of “manipulation” to get attention and say so in a very derogatory manner. In reality, all of us want attention from significant people in our lives. Most of us have the necessary skills to successfully meet our need for closeness and attention without alienating the very people who are important to us. People with BPD are unsuccessful in developing long-term meaningful relationships or getting what they want because their approach alienates others. Their need for attention and closeness to others is very normal: It is how they seek attention that is problematic.

Psychotherapy is needed to help the individual with BPD manage the dysfunctional moods, impulsive behaviors, and self-injurious behaviors. Specially trained therapists who are comfortable with the many demands of these patients are needed. These therapists represent a variety of mental health disciplines, including psychology, social work, and advanced practice nursing. This disorder requires ongoing treatment as the individual copes with multiple interpersonal crises. Several types of medications are usually needed, including mood stabilizers, antidepressants, and anxiolytics; careful medication monitoring is necessary.

Dialectical behavior therapy (DBT) combines cognitive and behavior therapy strategies with acceptance-based practice drawn from Zen and humanistic approaches; it was developed for persons with BPD. Core interventions include problem-solving, exposure techniques (i.e., gradual exposure to cues that set off aversive emotions), skills training, contingency management (i.e., reinforcement of positive behavior), and cognitive modification. Skills groups are an integral part of DBT and are taught in group settings in which patients practice emotional regulation, interpersonal effectiveness, distress tolerance, core mindfulness, and self-management skills. Weekly individual therapy sessions focus on enhancing motivation and improving competence (DeCou et al., 2019).

Mentalization-based therapy (MBT) is a psychodynamic psychotherapy that is used in both individual and group formats. In MBT, borderline personality symptoms are viewed as a result of distortion or reduction in **mentalizing**, which is the ability to understand the mental states of oneself and others, including thoughts and feelings, that lead to actions. The goal of MBT is to improve patients’ capacity to accurately understand others’ actions and develop self-awareness skills through a therapeutic relationship (Levy et al., 2018).

Safety Issues

Persons with BPD can be extremely volatile emotionally. Because they experience emotions so intensely, they are at high risk for self-harm and suicide. Self-harm threats should be taken very seriously.

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH BORDERLINE PERSONALITY DISORDER

Persons with BPD may enter the mental health system early (during young adulthood or even before) because of their chaotic lifestyles. Behavior includes unstable moods, problems with interpersonal relationships, low self-esteem, and self-identity issues. Thinking and behavior are dysregulated (Box 30.2). They have problems in daily living, including maintaining intimate relationships, keeping a job, and living within the law (Box 30.3). Nursing Care Plan 30.1—which sets forth a plan of care for Rebecca, the case study patient in this chapter—is available at <http://thepoint.lww.com/Boyd7e>.

Mental Health Nursing Assessment

Physical Health

People with BPD are usually able to maintain personal hygiene and physical functioning. Because of the comorbidity of BPD and eating disorders and substance use, however, a nutritional assessment may be needed. The patient should be queried about physiologic responses of emotion. Sleep patterns also should be assessed because sleep alterations may suggest coexisting depression or mania.

Physical Indicators of Self-Injurious Behaviors

Patients with BPD should be assessed for self-injurious behavior or suicide

attempts. It is important to ask the patient about specific self-abusive behaviors, such as cutting, scratching, or swallowing foreign objects. The patient may wear long sleeves to hide injury to the arms. Specifically, asking about thoughts of hurting oneself when experiencing a major upset provides an opportunity for prevention and for coaching the patient toward alternative self-soothing measures.

BOX 30.2

Response Patterns of Persons with Borderline Personality Disorder

- Affective (mood) dysregulation
- Mood lability
- Problems with anger
- Interpersonal dysregulation
- Chaotic relationships
- Fears of abandonment
- Self-dysregulation
- Difficulties with sense of self
- Sense of emptiness
- Behavioral dysregulation
- Parasuicidal behavior or threats
- Impulsive behavior
- Cognitive dysregulation
- Dissociative responses
- Paranoid ideation

BOX 30.3 CLINICAL VIGNETTE

Borderline Personality Disorder

Joanne is a 22-year-old single woman who was recently fired from her job as a data entry clerk. She lives with her mother and stepfather, who brought her to the emergency department after finding her crouched in a fetal position in the bathroom, her wrists bleeding. She seemed to be in a daze. This is her first psychiatric admission although her mother and stepfather have suspected that she has “needed help” for a long time. In high school, she received brief treatment for a potential eating disorder. She remains very thin but is able to eat at least one meal per day. During periods of stress, she will go for

days without eating. Joanne is the second of three children. Her parents divorced when she was 3 years old. She has not seen her father since he left. Although she has pleasant memories of her father, her mother has told her that he beat Joanne and her sisters when he was drinking. When Joanne was 6 years old, her older sister died as a result of an automobile accident. Joanne was in the car but was uninjured. As a child, Joanne was seen as a potential singing star. Her natural musical talent attracted her teachers' support, which encouraged her to develop her talent. She took singing lessons and entered statewide competitions in high school. Although she enjoyed the attention, she was never really comfortable in the limelight and felt "guilty" about having a talent that she sometimes resented. She was able to make friends but found that she was unable to keep them. They described her as "too intense" and emotional. She had one boyfriend in high school, but she was very uncomfortable with any physical closeness. After ending the relationship with the boyfriend, she concentrated on dieting to have a "perfect body." When her dieting attracted her parents' attention, she vowed to eat just enough to keep them "off her back about it." She spent much of her leisure time with her grandmother. She attended college briefly but was unable to concentrate. It was during college and after her grandmother's death that Joanne began cutting her wrists during periods of stress. It seemed to calm her.

After leaving college, Joanne returned home. She had several jobs and short-lived friendships. She was usually fired from her job because of "moodiness," and it took her several months before she would again find another. She spent days in her room listening to music. Her recent episode occurred after she was fired from work and spent 3 days in her bedroom.

What Do You Think?

- How would you describe Joanne's mood?
- Are Joanne's losses of her father and sister really severe enough to affect her ability to relate to others now? Do the losses seem to relate to the self-injury?
- What behaviors indicate problems with self-esteem and self-identity are present?

NURSING CARE PLAN 30.1

The Patient with Borderline Personality Disorder

Rebecca is a 23-year-old woman admitted voluntarily to the inpatient mental health unit after cutting her wrists and arriving in the emergency department with blood-soaked towels wrapped around her wrists. She lives alone and has no close friends. Her relationships are intense, which drives people away. She often reveals too much personal information to strangers. Her therapist left town and she believes that she will not return. This admission is one of multiple past admissions.

Setting: Inpatient Psychiatric Unit in a General Hospital

Baseline Assessment: Rebecca's wrists have several fresh lacerations and many older cuts in various stages of healing. She also has several scars from self-harming incidents in the past. Before harming herself, Rebecca reports feeling angry, anxious, numb, empty, or feeling detached from her body. She states that after she cuts herself she feels a sense of relief. She has a poor self-concept and low self-esteem. She says she does not understand why everyone is so mean to her. She has a history of being sexually abused as a child by her uncle following the death of her mother at age 4. BP is 120/70, P72, R 15, Ht. 5'4", Wt. 130, BMI 22.3.

Psychiatric Diagnosis	Medications
Borderline personality disorder	Sertraline (Zoloft) 150 mg daily for anxiety and depression

Priority of Care: Self-Injury

Important Characteristics

Cuts and scratches on body
Self-inflicted wounds

Associated Considerations

Fears of abandonment secondary to therapist's vacation

Inability to handle stress

Outcomes

Initial

Remain safe and not harm herself.

Identify feelings before and after cutting herself.

Agree not to harm herself over the next 24 hours.

Identify ways of dealing with self-harming impulses if they return.

Discharge

Verbalize alternate thinking with more realistic expectations of others.

Identify community resources to provide structure and support while therapist is away.

Interventions

Interventions

Rationale

Ongoing Assessment

Monitor patient for changes in mood or behavior that might lead to self-injurious behavior.

Discuss with patient need for close observation and rationale to keep her safe.

Administer medication as prescribed and evaluate medication

Close observation establishes safety and protection of patient from self-harm and impulsive behaviors. Explanation to patient for purpose of nursing interventions helps her cooperate with the nursing activity. Allows for adjustment of medication dosage based on target behaviors and outcomes.

Permits patient time to return to more thoughtful ways of responding rather than her previous reactive response. Also permits her to save face and avoid embarrassment of

Document according to facility policy.

Continue to observe for mood and behavior changes.

Assess her response to increasing level of observation.

nursing staff.	

Evaluation

Outcomes (at 3 Days)	Revised Outcomes	Interventions
Outcomes	Revised Outcomes	Interventions
Remained safe without further harming self. Identified fears of abandonment before cutting herself and relief of anxiety afterward.	Use hotlines or call friends if fears to harm self- return.	Give patient hotline number and ask her to record friends' numbers in an accessible place.
She identified friends to call when fears return and hotlines to use if necessary.		
Agreed to not harm herself over the next 3 days.	Does not harm self for 3 days.	Remind her to call someone if urges return.
Enrolled in a day hospital program for 4 weeks.	Attend day hospital program.	Follow-up on enrollment.

Priority of Care: Feeling Abandoned

Important Characteristics Associated Considerations

Frequent feelings of abandonment Therapist's absence

Outcomes

Initial

1. Discuss being lonely.
2. Identify previous ways of coping with loneliness.

Discharge

3. Identify strategies to deal with loneliness while therapist is away.

Interventions

Interventions

Rationale

Ongoing Assessment

Develop a therapeutic relationship.

People with BPD are able to examine loneliness within the structure of a therapeutic relationship.

Assess her ability to relate and nurse's response to the relationship.

Discuss past experience with therapist being gone with emphasis on how she was able to survive it.

She has survived therapist's absences before. By identifying the strategies she used, she can build on those strengths.

Assess her ability to assume any responsibility for "living through it." This will

		become a strength.
Acknowledge that it is normal to feel angry when the therapist is gone, but there are other strategies that may help the patient deal with the loneliness besides cutting.	Acknowledging feelings is important. Helping patient focus on the possibility of other strategies for dealing with the anger helps her regain a sense of control over her behavior.	Assess whether she is willing to acknowledge that there are other behavioral strategies to manage her anger.
Begin immediate disposition planning with focus on day hospitalization or day treatment for skills training and management of loneliness.	While patient is in the hospital, she is out of the stressful environment in which she can learn more effective behaviors and use the therapy. Moving out of the hospital and back into outpatient therapy decreases possibility of regression and lost learning (Linehan, 1993).	Assess her willingness to learn new skills within a day treatment setting.
Teach her about stress management techniques. Assign her to anger management group while she is in the hospital.	Learning about ways of dealing with feelings and stressful situations helps the patient with BPD choose positive strategies rather than self-destructive ones.	Monitor whether she actually attends the groups. She should be encouraged to attend.

Evaluation

Outcomes	Revised Outcomes	Interventions
Rebecca was able to verbalize her anger	None	

about her therapist's absence and fears of abandonment. The last two times her therapist went on vacation, the patient became self-injurious and was hospitalized for 2 weeks.

Rebecca was willing to be discharged the next day if she could attend day treatment while her therapist was gone.	Identify other strategies of dealing with her therapist's vacation besides cutting herself.	Attend stress management, communication, and self-comforting classes.
---	---	---

Medication

Patients with BPD may be taking several medications. As mood dysregulation is a primary symptom, treatment with mood stabilizers (e.g., Lithium, Valproate, or Lamotrigene) and/or a low-to-moderate dose of an atypical antipsychotic (e.g., aripiprazole or quetiapine) are common (Svrakic & Dvac-Jovanovic, 2019). Depressive symptoms are frequently treated with SSRIs, SNRIs, or TCA and may be augmented with atypical antipsychotics and/or lamotrigene. Benzodiazepines should be avoided for anxiety due to habituation and that they are not meant for long-term use. Buspar is considered a safer option for treating anxiety in patients with BPD. Initially, patients may be reluctant to disclose all the medications they are taking because, for many of them, trial and error has led to repeated prescription. They are fearful of having medication taken away from them. Development of rapport with special attention to a nonjudgmental approach is especially important when eliciting current medication practices. The effectiveness of the medication in relieving the target symptom needs to be determined.

Nutrition

A nutritional assessment is important if the person is using food for self-soothing and anxiety control. In some instances, excessive food intake may indicate self-injury or impulse eating may occur. The assessment should also include the use of caffeinated beverages (e.g., coffee, tea, cola, energy drinks). Since there is often a co-morbidity with anorexia nervosa and bulimia nervosa, an assessment focusing on eating patterns and food intake is important. In patients who engage in bingeing or purging, assessment should include examining the teeth for pitting and discoloration, as well as the hands and fingers for redness and calluses caused by inducing vomiting. See [Chapter 32](#).

Substance Use

Since individuals with BPD are at risk for substance use, use of alcohol, OTC medications, and street drugs should be carefully assessed (Rosenström et al., 2020). Use of benzodiazepines (i.e., Xanax, Ativan, or Valium) is contraindicated due to the risk of habituation and abuse. Impulsiveness in patients with BPD must be considered. Alcohol can lower inhibition and lead to high-risk behaviors (e.g., suicide and parasuicide gestures or accidental overdosing).

Psychosocial Assessment

People with BPD have usually experienced significant losses in their lives that shape their view of the world. They experience **inhibited grieving**, “a pattern of repetitive, significant trauma and loss, together with an inability to fully experience and personally integrate or resolve these events” (Linehan, 1993). They have unresolved grief that can last for years and will avoid situations that evoke those feelings of separation and loss. During the assessment, the nurse can identify the losses (real or perceived) and explore the patient’s experience during these losses, paying particular attention to whether the patient has reached resolution. A history of physical or sexual abuse and early separation from significant caregivers may provide important clues to the severity of the disturbances.

Mood fluctuations are common and can be assessed by any number of the depression and anxiety screening scales or by asking the following questions:

- What things or events bother you and make you feel sad or angry?
- Do these things or events trouble you more than they trouble other people?
- Do friends and family tell you that you are moody?
- Do you get angry easily?
- Do you have trouble with your temper?
- Do you think you were born with these feelings or did something happen to make you feel this way?

Mental Status and Appearance

Appearance and activity level generally reflect the person's mood and psychomotor activity. Many of those with BPD have been physically or sexually abused and thus should be assessed for depression. A disheveled appearance can reflect depression or an agitated state. When feeling good, these patients can be very engaging; they tend to be dramatic in their style of dress and attract attention, such as by wearing an unusual hairstyle or heavy makeup. Because physical appearance reflects identity, patients may experiment with their appearance and seek affirmation and acceptance from others. Body piercing, tattoos, and other perceived adornments provide a mechanism to define self.

Rebecca's Assessment

Rebecca loves to project a dramatic appearance when she is feeling good. When she is in a good mood, she projects as an overly confident, engaging person. She has several body piercings. She refuses to discuss any childhood trauma or sexual abuse.

Cognitive Disturbances

The mental status examination of those with BPD usually reveals normal thought processes that are not disorganized or confused except during periods of stress. Those with BPD usually exhibit dichotomous thinking, or a tendency to view things as absolute, either black or white, good or bad, with no perception of compromise. Dichotomous thinking can be assessed by asking patients how they view other people. Evidence of dichotomous thinking is indicated with responses of “good” or “bad,” “wonderful” or “terrible.”

Self-Concept and Identity Disturbance

Unstable self-image is often manifested as an identity disturbance or identity diffusion, a loss of the capacity for self-definition and commitment to values, goals, or relationships. There is not a consistent sense of self, and the process of identity formation is impaired. They have difficulties differentiating themselves from others and defining psychological boundaries. The nurse can recognize identity diffusion if the patient reports an ongoing “emptiness” or contradictory behavior. “I know I should not have gone out with him, but he wanted to see me.” The person’s thoughts and behavior will seem fragmented and superficial (Bozzatello et al., 2019).

Dissociation and Transient Psychotic Episodes

With BPD, periods of dissociation and transient psychotic episodes may occur.

Dissociation can be assessed by asking if there is ever a time when the patient does not remember events or has the feeling of being separate from their body. Some patients refer to this as “spacing out.” By asking specific information about how often, how long, and when dissociation first was used, the nurse can get an idea of how important dissociation is as a coping skill. It is important to ask the person what happens in the environment when dissociation occurs. Frequent dissociation indicates a highly habitual coping mechanism that is difficult to change. Because transient psychotic states occur, it is also important to elicit data regarding the presence of hallucinations or delusions and their frequency and circumstances.

Impulsivity

Impulsivity can be identified by asking the patient whether they do things impulsively or at the spur of the moment. For example: “Have there been times when you were hurt by your actions or were sorry later that you acted in the way you did?” Direct questions about gambling, choices in sexual partners, sexual activities, fights, arguments, arrests, and habits related to consumption of alcohol can also help in identifying areas of impulsive behavior.

From a neurophysiologic perspective, impulsively acting before thinking seems to be mediated by rapid nerve firing in the mesolimbic area. This activates psychomotor responses before pathways reach the prefrontal cortex (Perez-Rodriguez et al., 2018). Teaching the patient strategies to slow down automatic responses (e.g., deep breathing, counting to 10) buys time to think before acting.

Interpersonal Skills

Assessment of the person’s ability to relate to others is important because interpersonal problems are linked to dissociation and self-injurious behavior. Information about friendships, frequency of contact, and intimate relationships provide data about the person’s ability to relate to others. Patients with BPD often are sexually active and may have numerous sexual partners. Their need for closeness clouds their judgment about sexual partners, so it is not unusual to find these patients in abusive, destructive relationships with people with ASPD.

Stress and Coping Skills

Coping with stressful situations is one of the major problems of people with BPD. Assessment of their coping skills and their ability to deal with stressful situations is important. Self-esteem is closely related to identifying with health care workers. Patients with BPD perceive their families and friends as being weary of their numerous crises and their seeming unwillingness to break the vicious self-destructive cycle. Feeling rejected by their natural support system, these individuals create one within the health system. During periods of crisis, especially during the late evening, early morning, or on weekends, they may call or visit various psychiatric units asking to speak to specific personnel who formerly cared for them. They even know different nurses' scheduled days off and make the rounds to several hospitals and clinics. Sometimes they bring gifts to nurses or call them at home. Because their newly created social support system cannot provide the support that is needed, the patient continues to feel rejected. One of the treatment goals is to help the individual establish a more natural support network.

Functional Status

Some individuals with BPD can function very well except during periods when symptoms erupt. They hold jobs, are active in communities, and can perform well. During periods of stress, symptoms often appear. Conversely, some individuals with severe BPD function poorly; they seem to be always in a crisis, which often they have created.

Social Support Systems

Identification of social supports (e.g., family, friends, religious organizations) is the purpose of assessing resources. Knowing how the patient obtains social support is important in understanding the quality of interpersonal relationships. For example, some patients consider as their "best friends" nurses, physicians, and other health care personnel. Because these are false friendships (i.e., not

reciprocated), they inevitably lead to frustration and disappointment. However, helping the patient find ways to meet other people and encouraging the patient's efforts are more realistic.

Risk Assessment: Suicide or Self-Injury

It is critical that patients with BPD be assessed for suicidal and self-damaging behavior, including alcohol and drug use (see [Chapter 22](#)). The assessment should include direct questions, such as asking whether the patient thinks about or engages in self-injurious behaviors. If so, the nurse should continue to explore the behaviors: what is done, how is it done, how frequently is it done, and what are the circumstances surrounding the self-injurious behavior. It is helpful to explain briefly to the patient that sometimes people cut, scratch, or pick at themselves as a way of bringing some relief and comfort. Although the behavior brings temporary relief, it also places the person at risk for infection. Approaching the assessment in this way conveys a sense of understanding and is more likely to invite the patient to disclose honestly.

Quality of Life

An inferior quality of life is associated with all personality disorders, poor health, and significant suffering (Ekselius, 2018). Persons diagnosed with BPD are predisposed to have a substantial degree of functional impairment through a variety of social and occupational domains, including trouble with finding and maintaining adequate work, housing, or relationships. BPD patients have poor social functioning; they are often socially isolated and unemployed or on long-term sick leave. Many patients with BPD do not finish their education or complete at a minimal level. BPD patients often participate in problematic relationships and practice problematic parenting. Job environment can be one of the areas where patients with BPD struggle for maintaining their identity. Conflicts with boss and colleagues are frequent; individuals with BPD mostly fight against assumed injustice and nepotism and accuse the others of incompetence, lack of diligence, and gaining benefits from their bosses. Occupational patterns are characterized by instability, intense preoccupation, the subsequent loss of interest in the job, lack of job satisfaction, and problems in

relationships. Later in life, most of them achieve greater stability in social and work functioning (Grambal et al., 2016).

Strength Assessment

The strength assessment is important because these positive thoughts, skills, and behaviors can be supported as the individuals replace self-defeating behaviors with positive ones. Many of these individuals are extremely resilient despite the trauma that they have often experienced. The person's strength will emerge in the assessment and increase as the nurse gets to know the patient better. Some key questions include the following:

- How do you make yourself feel better?
- How do you resist the urge to hurt yourself?
- How do you make friends?
- What is the most positive thought, skill, or behavior that you have?

CLINICAL JUDGMENT

The first priority in care is safety of the patient. Self-injury and suicide ideation should be considered when establishing recovery goals. If the patient is not experiencing suicidal or self-injury thoughts or behavior, the patient thought processes (dissociation) or ability to cope with everyday stress may emerge as priorities of care, especially if these interfere with daily living. If the individual copes with stressful situations by dissociating or hallucinating, the nurse should begin to help the patient identify other coping strategies. Patients who are very emotional sometimes find that they will be able to cope if they learn emotional regulation strategies. For other patients, identity issues, anxiety, or low self-esteem may become priorities of care.

Identified strengths should be included in the priorities. By including a person's strengths, such as being motivated to manage self-destructive thoughts, the nurse can channel these attributes to deal with specific issues.

THERAPEUTIC RELATIONSHIP

Psychiatric-mental health registered nurses do not function as the patient's primary therapists, but they do need to establish a therapeutic relationship that strengthens the patient's coping skills and self-esteem and also supports individual psychotherapy. The therapeutic relationship helps the patient to experience a model of healthy interaction with consistency, limit setting, caring, and respect (both self-respect and respect for the patient). Patients who have low self-esteem need help in recognizing genuine respect from others and reciprocating with respect for others. In the therapeutic relationship, the nurse models self-respect by observing personal limits, being assertive, and clearly communicating expectations (Box 30.4). The nurse should always avoid using stigmatizing language, such as describing the person's behavior as manipulating instead of reporting or documenting specific behaviors.

BOX 30.4 • THERAPEUTIC DIALOGUE: BORDERLINE PERSONALITY DISORDER

INEFFECTIVE APPROACH

Rebecca: Hey, you know what? You are my favorite nurse. That night nurse sure doesn't understand me the way you do.

Nurse: Oh, I'm glad you are comfortable with me. Which night nurse?

Rebecca: You know, Sue.

Nurse: Did you have problems with her?

Rebecca: She is terrible. She sleeps all night or she is on the telephone.

Nurse: Oh, that doesn't sound very professional to me. Anything else?

Rebecca: Yeah, she said that you didn't know what you were doing. She said that you couldn't nurse your way out of a paper bag (smiling).

Nurse: She did, did she? (Getting angry.) She should talk.

Rebecca: Well, I gotta go to group. Where will you be? I feel so much better if I know where you are. I don't know how I can possibly be discharged tomorrow.

EFFECTIVE APPROACH

Rebecca: Hey, you know what? You are my favorite nurse. That night nurse sure doesn't understand me the way you do.

Nurse: I really like you, Rebecca. Tomorrow you will be discharged, and I'm glad that you will be able to return home.

(Nurse avoided responding to "favorite nurse" statement.

Redirected interaction to impending discharge.)

Rebecca: That night nurse slept all night.

Nurse: What was your night like? (Redirecting the interaction to Sara's experience.)

Rebecca: It was terrible. Couldn't sleep all night. I'm not sure that I'm ready to go home.

Nurse: Oh, so you are not quite sure about discharge? (reflection)

Rebecca: I get so, so lonely. Then, I want to hurt myself.

Nurse: Lonely feelings have started that chain of events that led to cutting, haven't they? (validation)

Rebecca: Yes, I'm very scared. I haven't cut myself for 1 week now.

Nurse: Do you have a plan for dealing with your lonely feelings when they occur?

Rebecca: I'm supposed to start thinking about something that is pleasant—like spring flowers in the meadow.

Nurse: Does that work for you?

Rebecca: Yes, sometimes.

CRITICAL THINKING CHALLENGE

- How did the nurse in the first scenario get sidetracked?
- How was the nurse in the second scenario able to keep the patient focused on herself and her impending discharge?

Nurses should use their own self-awareness skills to examine their personal response to the patient. How the nurse responds to the patient can often be a clue to how others perceive and respond to the person. For example, if the nurse feels irritated or impatient during the interview that is a sign that others respond to this person in the same way; conversely, if the nurse feels empathy or closeness, chances are this patient can evoke these same feelings in others.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

Changing or modifying personality traits is difficult. The person has to want to change cognitive, emotional, and behavioral responses that were established in early childhood. The recovery goals should initially focus on the most problematic areas and will shift as outcomes are achieved. The patient and nurse should establish specific wellness goals, such as reducing food intake or increasing exercise. There should be an agreed-upon plan.

Physical Care

Usually, the person can manage hydration and self-care fairly well. This section focuses on those areas that are more likely to be problematic.

Sleep Hygiene

Disturbed sleep patterns are common in BPD. The nurse can intervene by helping the person establish a regular bedtime routine by teaching sleep hygiene strategies such as avoiding foods and drinks that could interfere with sleep. If relaxation exercises are used, they should be adapted to the tolerance of the

individual. Special consideration must be made for persons who have been physically and sexually abused and who may be unable to put themselves in a vulnerable position (e.g., lying down in a room with other people or closing their eyes). These patients may need additional safeguards to help them sleep, such as a night light or repositioning the furniture in the room to allow a quick exit.

Teaching Nutritional Balance

The nutritional status of the person with BPD can quickly become a priority, particularly if the patient has coexisting eating disorders, mood disorders, or substance dependence. Eating is often a response to stress, so patients can quickly become overweight. This is especially problematic when the patient has also been taking medications that promote weight gain, such as antipsychotics, antidepressants, or mood stabilizers. Helping the patient learn the basics of nutrition, make reasonable choices, and develop other coping strategies than eating are important interventions. If patients are engaging in purging or severe dieting practices, teaching the patient about the dangers of both of these practices is important (see [Chapter 32](#)). Referral to an eating disorders specialist may be needed.

Medication Interventions

Limiting medication is better for people with BPD. Patients should take medications only for target symptoms for a short time (e.g., an antidepressant for a bout with depression) because they may be taking many medications, particularly if they have a comorbid disorder, such as a mood disorder or substance use. Medications are used to control emotional dysregulation, impulsive aggression, cognitive disturbances, and anxiety as an adjunct to psychotherapy. Recent evidence shows some benefits from atypical antipsychotics, but there is little evidence to support the use of mood stabilizers. There is weak evidence to either support or exclude the SSRIs (Hancock-Johnson et al., 2017).

Administering and Monitoring Medications

In inpatient settings, it is relatively easy to control medications; in other settings, however, patients must be aware that it is their responsibility to take their medication and monitor the number and type of drugs being taken. Patients who rely on medication to help them deal with stress and those who are periodically suicidal are at high risk for abuse of medications. Patients who experience unusual side effects are also at high risk for noncompliance. The nurse must determine whether the patient is actually taking medication, whether the medication is being taken as prescribed, its effect on target symptoms, and the use of any OTC drugs (e.g., antihistamines, sleeping pills, or herbal supplements with similar pharmacologic activity).

Monitoring Side Effects

Patients with BPD appear to be sensitive to many medications, so the dosage may need to be adjusted based on the side effects they experience. Listen carefully to the patient's description of the side effects. Any unusual side effects should be accurately documented and reported to the prescriber.

Teaching Points

Patients should be educated about the prescribed medications and their interactions with other drugs and substances, but they should be encouraged to avoid relying on medication alone. Interventions include teaching patients about the medication and how and where it acts in the brain and body, helping establish a routine for taking prescribed medication, reporting side effects, and facilitating the development of positive coping strategies to deal with daily stresses rather than relying on medications. Eliciting the patient's partnership in care improves adherence and thereby outcomes.

Psychosocial Interventions

Therapeutic Interactions

One key to helping patients with BPD is recognizing their fears of both abandonment and intimacy. Informing the patient of the length of the therapeutic relationship as much as possible allows the patient to engage in and prepare for termination with the least pain of abandonment. If the patient's hospitalization is time limited, it is important to acknowledge the limit overtly and remind the patient with each contact how many sessions remain.

In day treatment and outpatient settings, the duration of treatment may be indeterminate, but the nurse may not be available that entire time. The termination process cannot be casual; this would stimulate abandonment fears. However, some patients end prematurely when the nurse informs them of the impending end as a way to leave before being rejected. The best approach is to explore these anticipated feelings with the patient. After careful planning, the nurse and patient discuss how to cope with anticipated feelings, including the wish to run away, review the progress the patient has made, and summarize what the patient has learned from the relationship that can be generalized to future encounters.

Establishing Personal Boundaries and Limitations

Personal boundaries are highly context specific; for example, stroking the hair of a stranger on the bus would be inappropriate, but stroking the hair and face of one's intimate partner while sitting together would be appropriate. Clarifying limits requires making explicit what is usually implicit. This may mean having a standing time during each shift that the nurse will talk with the patient. The nurse should refrain from offering personal information, which is frequently confusing to the person with BPD. At times, the person may present in a somewhat arrogant and seemingly entitled way. It is important for the nurse to recognize such a presentation as reflective of internal confusion and dissonance. Responding in a very neutral manner avoids confrontation and a power struggle, which might also unwittingly reinforce the patient's internal sense of inferiority.

Some additional strategies for establishing the boundaries of the relationship

include the following:

- Documenting in the patient’s chart the agreed-on appointment expectations
- Sharing the treatment plan with the patient
- Confronting violations of the agreement in a nonpunitive way
- Discussing the purpose of limits in the therapeutic relationship and applicability to other relationships

When patients violate boundaries, it is important to respond right away but without taking the behavior personally. For example, if a patient is flirtatious, simply say something like, “Mr. J., I feel uncomfortable with your overly friendly behavior. It seems out of place because we have a professional relationship. That would be more fitting for an intimate relationship that we will never have.”

Enhancing Cognitive Functioning

The nurse can often challenge the patient’s dysfunctional ways of thinking and encourage the person to think about the event in a different way. When a patient engages in catastrophic thinking, the nurse can challenge by asking, “What is the worst that could happen?” and “How likely would that be to occur?” Or in dichotomous thinking, when the patient fixates on one extreme perception or alternates only between the extremes, the nurse should ask the patient to think about any examples of exceptions to the extreme. The point of the challenge is not to debate or argue with the patient but to provide different perspectives to consider. Encouraging patients to keep journals of real interactions to process with the nurse or therapist is another effective way of testing the reality of their thinking and anticipations, affording more choices and flexibility (Box 30.5).

BOX 30.5 CLINICAL VIGNETTE

Challenging Dysfunctional Thinking

Ms. S had worked for the same company for 20 years with a good job record. After an accident, she made some minor mistakes in her work that she quickly corrected. She informed her company nurse that her work was “really slipping” and that she was fearful of her coworkers’ disapproval and of getting fired from her job. The nurse asked her to keep a journal of coworkers’ comments for the next week. At

the next visit, the following dialogue occurred:

Nurse: I noticed that you received several compliments on your work. Even a close friend of your boss expressed appreciation for your work.

Ms. S: It was a light week at work. I really don't believe they meant what they said.

Nurse: I can see how you can believe that one or two comments are not genuine, but how do you account for four and five good reports on your work?

Ms. S: Well, I don't know.

Nurse: It looks like your beliefs are not supported by your journal entries. Now, what makes you think that your boss wants to fire you after 20 years of service?

In problem-solving, the nurse might encourage the patient to debate both sides of the problem and then search for common ground. Practicing communication and negotiation skills through role-playing helps the patient make mistakes and correct them without harm to their self-esteem. The nurse also encourages patients to use these skills in their everyday lives and report back on the results, asking patients how they feel applying the skills and how doing so affects their self-perceptions. Success, even partial success, builds a sense of competence and self-esteem (Table 30.1).

Using Behavioral Interventions

The goal of behavioral interventions is to replace dysfunctional behaviors with positive ones. The nurse has an important role in helping patients control emotions and behaviors by acknowledging and validating desired behaviors and ignoring or confronting undesired behaviors. Patients often test the nurse for a response, so nurses must decide how to respond to particular behaviors. This can be tricky because even negative responses can be viewed as positive reinforcement by the patient. In some instances, if the behavior is irritating but not harmful or demeaning, it is best to ignore, rather than focus, on it. However, grossly inappropriate and disrespectful behaviors require confrontation. If a patient throws a glass of water on an assistant because she is angry at the treatment team for refusing to increase her hospital privileges, an appropriate intervention would include confronting the patient with her behavior and issuing the consequences, such as losing her privileges and apologizing to the assistant.

TABLE 30.1 THOUGHT DISTORTIONS AND CORRECTIVE STATEMENTS

Thought Distortion	Corrective Statement
Catastrophizing	
<i>"This is the most awful thing that has ever happened to me"</i>	<i>"This is a sad thing but not the most awful."</i>
<i>"If I fail this course, my life is over."</i>	<i>"If you fail the course, you can take the course again. You can change your major."</i>
Dichotomizing	
<i>"No one ever listens to me."</i>	<i>"Your husband listened to you last night when you told him ..."</i>
<i>"I never get what I want."</i>	<i>"You didn't get the promotion this year, but you did get a merit raise."</i>
<i>"I can't understand why everyone is so kind at first and then always dumps me when I need them the most."</i>	<i>"It is hard to remember those kind things and times when your friends have stayed with you when you needed them."</i>
Self-Attribution Errors	
<i>"If I had just found the right thing to say, she wouldn't have left me."</i>	<i>"There is not a single right thing to say, and she left you because she chose to."</i>
<i>"If I had not made him mad, he wouldn't have hit me."</i>	<i>"He has a lot of choices in how to respond, and he chose hitting. You are responsible for your feelings and actions."</i>

However, such an incident can be used to help the patient understand why such behavior is inappropriate and how it can be changed. The nurse should explore with the patient what happened, what events led up to the behavior, what the consequences were, and what feelings were aroused. Advanced practice nurses or other therapists explore the origins of the patient's behaviors and responses, but the generalist nurse needs to help the patient explore ways to change behaviors involved in the current situation. The laboriousness of this analytic process may be a sufficient incentive for the patient to abandon the dysfunctional behavior.

Psychoeducation

Patient education within the context of a therapeutic relationship is one of the most important, empowering interventions for the generalist psychiatric–mental health nurse to use. Teaching patients skills to resist parasuicidal urges, improve emotional regulation, enhance interpersonal relationships, tolerate stress, and enhance overall quality of life provides the foundation for long-term behavioral changes. These skills can be taught in any treatment setting as a part of the overall facility program (Box 30.6). If nurses are practicing in a facility where DBT is the treatment model, they can be trained in DBT and can serve as group skills leaders.

Box 30.6

Psychoeducation Checklist: Borderline Personality Disorder

When caring for the patient with borderline personality disorder, be sure to include the following topic areas in the teaching plan:

- Management of medication, if used, including drug action, dosage, frequency, and possible adverse effects
- Regular sleep routines
- Nutrition
- Safety measures
- Functional versus dysfunctional behaviors
- Cognitive strategies (e.g., distraction, communication skills, thought stopping)
- Structure and limit setting
- Social relationships
- Recovery strategies
- Community resources

Teaching Emotional Regulation

A major goal of cognitive therapeutic interventions is emotional regulation—recognizing and controlling the expression of feelings. Patients often fail even to recognize their feelings; instead, they respond quickly without thinking about the consequences. Remember, the time needed for taking action is shorter than the time needed for thinking before acting. Pausing makes up for the momentary lag between the limbic and autonomic response and the prefrontal response.

Another element of emotional regulation is learning to delay gratification. When the patient wants something that is not immediately available, the nurse can teach patients to distract themselves, find alternate ways of meeting the

need, and think about what would happen if they have to wait to meet the need.

Teaching Effective Ways to Communicate

Patients lack interpersonal skills in relating because they often had inadequate modeling and few opportunities to practice. The goals of relationship skill development are to identify problematic behaviors that interfere with relationships and to use appropriate behaviors in improving relationships. The starting point is with communication. The nurse teaches the patient basic communication approaches, such as making “I” statements, paraphrasing what the other party says before responding, checking the accuracy of perceptions with others, compromising and seeking common ground, listening actively, and offering and accepting reactions. Besides modeling the behaviors, the nurse guides patients in practicing a variety of communication approaches for common situations. When role-playing, the nurse needs to discuss not only what the skills are and how to perform them but also the feelings patients have before, during, and after the role-play.

In day treatment and outpatient settings, the nurse can give the patient homework, such as keeping a journal, applying role-playing skills to actual situations, and observing behaviors in others. In the hospital, the patient can experience the same process, where the nurse is available to offer immediate feedback. Whatever the setting or whatever the specific problems addressed, the nurse must keep in mind and remind the patient that change occurs slowly. Thus, working on the problems occurs gradually, with severity of symptoms as the guide to deciding how fast and how much change to expect.

Wellness Strategies

Whole Health is a cutting-edge approach to care that supports a person’s health and well-being. This approach is currently being implemented throughout the U.S. Department of Veterans Affairs. It is a nationally supported, grassroots movement that is bringing about system-wide transformation to health care in VA medical centers across the country. Whole Health centers around **what matters to you**, not what’s the matter with you. The health care team gets to

know you as a person, and then works with you to develop an individual health plan that is based on your values, needs, and goals. Whole Health is wellness-oriented care. It has been found to be extremely effective for patients with all kinds of health care needs and is a great adjunctive care approach for persons with psychiatric disorders. Whole Health programs like meditation, yoga, acupuncture, Tai Chi, nutrition, and cooking classes serve as nonpharmaceutical approaches to health and wellness. Patients with BPD and depression especially have reported enjoying and benefiting from Whole Health programs.

Although some health care providers have implemented some type of wellness education and training in their practices for many years, the Whole Health approach to care is anticipated to be more formally included in all medical practices in the future.

Building Social Skills and Self-Esteem

In the hospital, the nurse can use group therapy to discuss feelings and ways to cope with them. Women with BPD benefit from assertiveness classes and women's health issues classes. Many of the women are involved in abusive relationships and lack the ability to resolve these relationships because of their extreme anxiety regarding separating from those they love and their extreme need to feel connected. These women verbalize desires to do it, but they do not have the strength and self-confidence needed to leave. Exposing them to a different style of interaction as well as validation from other people increases their self-esteem and ability to get away from negative influences.

Providing Family Education

Caring for or living with a person with BPD is challenging. Families and friends experience high levels of anxiety, depression, and grief. They often feel that they are burdened with the person's problems and crises. These feelings are higher in families with a member with this disorder than families of individuals with other severe mental disorders. Psychoeducation programs are currently being studied to support families and friends in their relationship with the affected person and reduce the feelings of grief, depression, anxiety, and burden (Betts et al., 2018).

The awareness of these caregiver issues affords the nurse the opportunity to provide family educations in several areas:

- Educating the family about the diagnosis of BPD
- Educating the caregiver about mental health and support recourses for the person with BPD
- Educating the caregiver and normalizing their feelings that they too need support and care
- Educating the caregiver on access to mental health care for self-care and access to caregiver support resources (e.g., The National Alliance on Mentally Illness.)

Promoting Safety

Patients with BPD are usually admitted to the inpatient setting because of threats of self-harm. Observing for antecedents of self-injurious behavior and intervening before an episode are important safety interventions. Patients can learn to identify situations leading to self-destructive behavior and develop preventive strategies.

Because patients with BPD are impulsive and may respond to stress by harming themselves, observation of the patient's interactions and assessment of mood, level of distress, and agitation are important indicators of impending self-injury. Remembering that self-harm is an effort to self-soothe by activating endogenous endorphins, the nurse can assist the patient to find more productive and enduring ways to find comfort. Linehan (1993) suggests using the Five Senses Exercise:

- Vision (e.g., go outside and look at the stars or flowers or autumn leaves)
- Hearing (e.g., listen to beautiful or invigorating music or the sounds of nature)
- Smell (e.g., light a scented candle, boil a cinnamon stick in water)
- Taste (e.g., drink a soothing, warm, nonalcoholic beverage)
- Touch (e.g., take a hot bubble bath, pet your dog or cat, get a massage)

Evaluation and Treatment Outcomes

Evaluation and treatment outcomes vary depending on the severity of the disorder, the presence of comorbid disorders, and the availability of resources. For a patient with severe symptoms or continual self-injury, keeping the patient safe and alive may be a realistic outcome. Helping the patient resist parasuicidal urges may take years. In contrast, individuals who rarely need hospitalization and have adequate resources can expect to recover from the self-destructive impulses and learn positive interaction skills that promote a high-quality lifestyle. Most patients fall somewhere in between, with periods of symptom exacerbation and remission. In these patients, increasing the symptom-free time may be the best indicator of outcomes.

Continuum of Care

Treatment and recovery involve long-term therapy. Hospitalization is sometimes necessary during acute episodes involving **parasuicidal behavior**, but after this behavior is controlled, patients are discharged. It is important for these individuals to continue with treatment in the outpatient or day treatment setting. Because these individuals often appear more competent and in control than they are, nurses must not be deceived by these outward appearances. These individuals need continued follow-up and long-term therapy, including individual therapy, psychoeducation, and positive role models (see Box 30.7). There is growing evidence that virtual psychosocial applications for persons with BPD are clinically useful (Frías et al., 2020).

Integration with Primary Care

The mental health team should work closely with the primary care providers and explain the behaviors that interfere with receiving care. People with BPD often have multiple medical problems such as diabetes, obesity, and hyperlipidemia. The person may not show up for appointments yet expect the providers to call and remind them. Their interaction style and need for attention may quickly wear out a busy primary care staff, causing the staff to reject the person. Emotional dysfunction may erupt when the person is confronted with a stressful

situation or diagnosis. The mental health team should be available to provide support to the primary care staff and help the patient negotiate the health care system.

ANTISOCIAL PERSONALITY DISORDER

ASPD is defined as “a pervasive pattern of disregard for, and violation of, the rights of others occurring since age 15 years” (APA, 2013, p. 659). This diagnosis is given to individuals 18 years of age or older who fail to follow society’s rules—that is, they do not believe that society’s rules are made for them and so are consistently irresponsible. ASPD has a long history in the psychopathological literature. A condition termed *moral insanity* was first described in the early 19th century. Since then the disorder has also been called psychopathy, and sociopathy (Paris, 1997). The term *psychopath*, or *sociopath*, a person with a tendency toward antisocial and criminal behavior with little regard for others, is often used in describing the behaviors of people with ASPD.

Box 30.7

Research for Best Practice: Brief Admissions During Prolonged Treatment

Helleman, M., Goossens, P. J., Kaasenbrood, A., & van Achterberg, T. (2016). *Brief admissions during prolonged treatment in a case involving borderline personality disorder and posttraumatic stress disorder: Use and functions*. *Journal of the American Psychiatric Nurses Association*, 22(3), 215–224

THE QUESTION: How can brief admissions be used during a long-term treatment process (7 years) for a person suffering from severe symptoms of borderline personality disorder and complex PTSD?

METHODS: A descriptive qualitative case study design explored the usefulness of brief admissions to an acute care setting for a 37-year-old female with borderline personality disorder and PTSD. Multiple sources of data were triangulated to reach convergence on the functions and use of brief admissions across and extended treatment period. Semistructured interviews were conducted with the patient, her husband, psychiatric, community

psychiatric nurse, and a clinical nurse involved in her care. Key concepts in the interview transcripts were identified, coded, and analyzed by two researchers.

FINDINGS: Initially, the main goal of the brief admission was to prevent suicide and self-harm. As treatment progressed, the brief admission served other functions such as prevention of long admissions, prevention of dropout from therapy, opportunities to exercise newly acquired skills, opportunities to expand autonomy and self-care, and to establish preconditions needed to maintain social roles.

IMPLICATIONS FOR NURSING: Brief admission can positively influence the treatment course for a patient with diagnoses of borderline personality disorder and PTSD.

KEYCONCEPT Antisocial personality disorder is characterized by a pervasive pattern of disregard for and violation of the rights of others.

Clinical Course and Diagnostic Criteria

ASPD has a chronic course with antisocial behaviors tending to diminish later in life, particularly after the age of 40 years (APA, 2013). Individuals with ASPD are arrogant and self-centered and feel privileged and entitled. They are self-serving, and they exploit and seek power over others. They can be interpersonally engaging and charming, which is often mistaken for a genuine sense of concern for other people. In reality, they lack empathy; are unable to express human compassion; and tend to be insensitive, callous, and contemptuous of others. Deceit and manipulation for personal profit or pleasure are central features associated with this disorder. They are behaviorally impulsive and interpersonally irresponsible. Many with this disorder repeatedly perform acts that are grounds for arrest (whether they are arrested or not), such as destroying property, harassing others, stealing, or pursuing other illegal occupations. They act hastily and spontaneously, are temperamentally aggressive and shortsighted, and fail to plan ahead or consider alternatives. They fail to adapt to the ethical and social standards of the community. They lack a sense of personal obligation to fulfill social and financial responsibilities, including those involved with being a spouse, parent, employee, friend, or member of the

community. They lack remorse for their transgressions (APA, 2013).

Some of these individuals openly and flagrantly violate laws and end up in jail. But most people with ASPD never come in conflict with the law and instead find a niche in society, such as in business, the military, or politics, which rewards their competitively tough behavior. Although ASPD is characterized by continual antisocial acts, the disorder is not synonymous with criminality. See Key Diagnostic Characteristics 30.2.

Epidemiology and Risk Factors

Twelve-month prevalence rates of ASPD are estimated between 0.2% and 3.3% (APA, 2013). Males with alcohol use disorder and those released from substance abuse clinics, prisons, or other forensic settings have the highest rates. Adverse socioeconomic (i.e., poverty) or sociocultural (i.e., migration) factors also are associated with higher prevalence (APA, 2013). Gender differences also exist in how symptoms are manifest (Key Diagnostic Characteristics 30.2).

Age of Onset

To be diagnosed with ASPD, the individual must be at least 18 years old and must have exhibited one or more childhood behavioral characteristics of conduct disorder before the age of 15 years, such as aggression to people or animals, destruction of property, deceitfulness or theft, or serious violation of rules. The likelihood of developing adult ASPD is increased if onset of conduct disorder is seen before age 10 years as well as an accompanying childhood attention deficit hyperactivity disorder diagnosis (APA, 2013).

KEY CHARACTERISTICS 30.2 • BIPOLAR I DISORDER

301.7

Diagnostic Criteria

- A. A pervasive pattern of disregard for and violation of the rights of others, occurring since age 15 years, as indicated by three (or more) of the following:
 - 1. Failure to conform to social norms with respect to lawful behaviors, as indicated by repeatedly performing acts that are grounds for arrest

2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
 3. Impulsivity or failure to plan ahead
 4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults
 5. Reckless disregard for safety of self or others
 6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
 7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
- B. The individual is at least age 18 years.
- C. There is evidence of conduct disorder with onset before age 15 years.
- D. The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or bipolar disorder.

Associated Findings

- Lacking empathy
- Callous, cynical, and contemptuous of the feelings, rights, and suffering of others
- Inflated and arrogant self-appraisal
- Excessively opinionated, self-assured, or cocky
- Glib, superficial charm; impressive verbal ability
- Irresponsible and exploitative in sexual relationships; history of multiple sexual partners and lack of a sustained monogamous relationship
- Possible dysphoria, including complaints of tension, inability to tolerate boredom, and depressed mood

Comorbidity

ASPD is associated with several other psychiatric disorders, including mood, anxiety, and other personality disorders. ASPD is strongly associated with alcohol and drug abuse (Tielbeek et al., 2018). However, a diagnosis of ASPD is not warranted if the antisocial behavior occurs only in the context of substance use. For example, some people who misuse substances sometimes engage in criminal behavior, such as stealing or prostitution, only when in pursuit of drugs. Therefore, it is crucial to assess whether the person with possible ASPD has engaged in illegal activities at times other than when pursuing or using substances.

Etiology

Biologic Theories

Perhaps more than any other personality disorder, an extensive number of biologically oriented studies explore the genetic bases, neuropsychological factors, and arousal levels among this group of pathologies. Many of these studies show neurobiological changes associated with personality disorders or characteristics, but the evidence lacks that these changes caused the disorder. These studies often overlap with studies of aggression, temperament, and substance use (Kolla et al., 2018; Tielbeek et al., 2017).

Magnetic resonance imaging studies demonstrate difference in the brain regions that are related to impulsivity and irresponsibility (Deming et al., 2020). These findings support the neural basis of fearlessness in these individuals. Impairment in frontotemporal, cerebellar, limbic, and paralimbic regions are associated with poor moral judgment and introspective abilities (Johanson et al., 2020). In adolescence, antisocial behavior is related to increased amygdala reactivity to interpersonal threats, which may lead to anger-related behavior (Dotterer et al., 2017).

Psychosocial Theories

Temperament

Scientists believe temperament is neurobiologically determined, and many believe that it is central to understanding personality disorders. A temperament, the natural predisposition to express feelings and actions, is evident during the first few months of life and remains stable through development. For example, whereas some infants are more relaxed or calm and sleep a lot, others are extremely alert, startled by the slightest noise, cry more, and are sleepless.

Difficult temperaments are common in ASPD and are often on the basis of their aggression and impulsivity.

KEYCONCEPT **difficult temperament** is characterized by withdrawal from stimuli, low adaptability, and intense emotional reactions. Four key behaviors are present in a difficult temperament: aggression, inattention, hyperactivity, and impulsivity.

Temperaments consist of two behavioral dimensions that interact with each other. The activity spectrum varies from intense to passive. The adaptability spectrum varies from having a positive attitude about new stimuli with high flexibility to withdrawal from new stimuli and minimal flexibility in response to change. A strong relationship is found between difficult temperament and ASPD behaviors (Lennox & Dolan, 2014).

Attachment

One of the leading explanations of ASPD is that unsatisfactory attachments in early relationships lead to antisocial behavior in later life. Attachment, attaining and retaining interpersonal connection to a significant person, begins at birth. In a secure attachment, a child feels safe, loved, and valued and develops the self-confidence to interact with the rest of the world. Experiences within the context of secure relationships enable the child to develop trust in others. Strong attachments between parents and child may lower the risk of delinquency, assault, and other offenses that are characteristic of those who develop antisocial behavior (Christian et al., 2017).

In individuals with ASPD, a failure to make or sustain stable attachments in early childhood can lead to avoidance of future attachments. Risk factors for developing dysfunctional attachments include parental abandonment or neglect, loss of a parent or primary caregiver, and physical or sexual abuse. Parents who lacked secure attachment relationships in their own childhoods may be unable to form secure attachment relationships with their own children.

Family Issues

In many cases, individuals with ASPD come from chaotic families in which alcoholism and violence are the norm. Individuals who have been victims of abuse or neglect, live in a foster home, or had several primary caregivers are more likely to be victimized by antisocial behaviors, especially aggression. Child abuse and growing up in a home with domestic violence increase the risk of antisocial behavior (Green & Browne, 2019). It is difficult to separate the influence of social factors on the development of the disorder because the symptoms of ASPD are expressed as social manifestations, including unemployment, multiple divorces and separations, and violence.

Family Response to Antisocial Personality Disorder

If family members are present in a patient's life, they have probably been abused, mistreated, or intimidated by these patients. For example, one patient sold his mother's possessions while she was at work. Another abused his wife after drinking. However, family members may be fiercely loyal to the patient and blame themselves for their shortcomings.

Men who have ASPD often engage in relationships with women who have BPD. This is known as assortive mating. Assortive mating is a pattern and form of sexual selection in which individual with similar phenotypes or observable physical characteristics, including appearance, development, and behavior, mate with one another more frequently than would be expected under a random mating pattern. Individuals with BPD use coercion and manipulation for emotional closeness, whereas those with ASPD use manipulation in the pursuit of physical sex. Individuals with ASPD often mate with BPD because their cold and manipulative behavior feeds into the fears of abandonment of the BPD, resulting in very dramatic and chaotic relationships for both (Munoz Centifanti et al., 2016).

RECOVERY-ORIENTED CARE FOR PERSONS WITH ANTISOCIAL PERSONALITY DISORDER

Nursing Care Plan 30.2 is available at <http://thepoint.lww.com/>

Teamwork and Collaboration: Working Toward Recovery

People rarely seek mental health care for ASPD but rather for treatment of depression, substance use, uncontrolled anger, or forensic-related problems. Patients with psychiatric disorders who are admitted through the courts often have a comorbid diagnosis of ASPD. Patients with ASPD usually present for treatment as a result of an ultimatum. Treatment is often a choice between losing a job, being expelled from school, ending a marriage or relationship with children, or giving up on a chance at probation and psychological treatment.

Under these circumstances, treatment is usually forced on them. Other times people with ASPD who find themselves in trouble with the law will seek out psychiatric care on their own in an attempt to “prove” to the court they are seeking help for their offenses, when they are actually only manipulating the justice system through deception. Most prisons and other correctional facilities require inmates to attend psychotherapy sessions. In either case, working with people with ASPD is likely to be a frustrating and exasperating experience for the nurse due to the patient’s clear lack of insight and/or motivation to change. Treatment is difficult and involves helping the patient alter their cognitive schemata.

Safety Issues

Although they can be interpersonally charming, these patients can become verbally and physically abusive if their expectations are not met. Protection of other patients and staff is a priority.

EVIDENCE-BASED NURSING CARE OF PERSONS WITH ANTISOCIAL PERSONALITY DISORDER

Mental Health Nursing Assessment

Physical Health and Functioning

ASPD does not significantly impair physical functioning except in the presence of coexisting substance use disorder or another psychiatric diagnosis involved. Because substance use is a major problem with this population, the physical effects of chronic use of addictive substances must be considered. If admitted inpatient, the nurse needs to keenly observe for possible withdrawal symptoms from substance use. Conversely, someone who has health problems secondary to chronic substance misuse should also be assessed for concurrent personality disorders. Substance use and ASPD are not mutually exclusive. Some people with substance use disorders are not antisocial but may commit crimes (e.g.,

selling drugs, robbery, theft) in the context of obtaining drugs for their personal use.

Psychosocial Assessment

Eliciting psychosocial data from persons with ASPD may be difficult because of their basic mistrust of authority figures. Many patients with ASPD are committed to mental health care by the court system. They may not give an accurate history or may embellish aspects to project themselves in a more positive light. They often deny any criminal activity even if they are admitted to police custody.

Behavioral Responses

Key areas of assessment are determining the quality of relationships, impulsivity, and the extent of aggression. These individuals do not assume responsibility for their own actions and often blame others for their misfortune. Their disregard for others is manifested in their interactions. For example, one patient with human immunodeficiency virus was engaging in unprotected sex with several different women because he wanted to “have fun as long as I can.” He was completely unconcerned about the possibility of transmitting the virus. These individuals often make good first impressions. Self-awareness is especially important for the nurse because of the initial charming quality of many of these individuals. When these patients realize that the nurse cannot be used or manipulated, they lose interest in the nurse and revert to their normal, egocentric behaviors.

Support Network

Social support for these individuals is often minimal, just as it is for individuals with BPD, but the reasons are different. These individuals have often taken advantage of friends and relatives who, in turn, no longer trust them. Helping the patient build a new support system after new skills are learned is usually the only option. For these individuals to develop friends and re-engage family members, they must learn to interact in new ways, develop empathy, and risk an attachment. For many, this never truly becomes a reality.

Clinical Judgment

People with ASPD are often admitted to psychiatric units following a violent incident, such as a physical confrontation or a suicide attempt. As with any patient, safety is a priority. One of the first priorities is to establish a safe environment for the patient and staff. After safety is established, other mutually agreed-upon priorities can be considered, such as improving interpersonal communication with family members or addressing anger issues.

Outcomes should be short-term and relevant to a specific problem. For example, if a patient has been chronically unemployed, a reasonable short-term outcome is for the patient to set up job interviews rather than obtain a job.

THERAPEUTIC RELATIONSHIP

Therapeutic relationships are difficult to establish because these individuals do not attach themselves to others and are often unable to use a relationship to change behavior. The goal of the therapeutic relationship is to identify dysfunctional thinking patterns and develop new problem-solving behaviors. After the first few meetings with these patients, the nurse may believe that the relationship has a good start, but in reality, a superficial alliance is usually formed. Additional sessions reveal the lack of patient commitment to the relationship. These patients begin to revisit topics discussed in previous sessions or lose interest in trying to work on problems. By using self-awareness skills and accessing supervision regularly, the nurse can identify blocks in the development of a therapeutic relationship (or lack of) and their response to the relationship.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

Recovery involves changing interpersonal and lifestyle behaviors. The overall treatment goals are to develop a nurturing sense of attachment and empathy for other people and situations and to live within the norms of society. Several

current treatment modalities may be helpful in establishing these goals. Harm reduction is a pragmatic approach for managing high-risk behaviors such as substance use or high-risk sexual behaviors that are often characteristic of persons with ASPD. For example, the harm reduction approach recognizes that the reduction of substance use from 7 to 3 days per week is progress. Reducing the harm of substance use is celebrated and built upon for further success. See [Chapter 31](#). Motivational interviewing can help the person explore and resolve ambivalence to change. MBT, discussed earlier in this chapter, can also be for persons with ASPD.

Physical Care

In instances in which there are comorbid disorders, the patient with ASPD may actually interfere with interventions aimed at improving physical functioning. For example, a patient with substance use disorder and ASPD may not develop enough trust within a relationship to examine their delusional thoughts or other aspects of dysfunction, such as alcohol or drug abuse.

In instances in which there are concurrent diagnoses, such as a patient with ASPD with a co-occurring substance use disorder, may actually interfere with interventions aimed at improving his physical functioning. For example, a patient with ASPD who develops a case of pancreatitis may refuse to refrain from abusing alcohol. As a result, he may be hospitalized for multiple episodes of pancreatitis.

Wellness Challenges

Enhancing self-awareness (i.e., exploring and understanding personal thoughts, feelings, motivation, and behaviors) is another nursing intervention that is helpful in developing an understanding about relating peacefully to the rest of the world. Encouraging patients to recognize and discuss their thoughts and feelings helps the nurse understand how the patient views the world. Some evidence indicates that substance misuse can be improved through cognitive-behavioral treatment, but there is little evidence that the core problems of this disorder (aggression, reconviction, global functioning, and social functioning) are improved with psychological interventions (Brazil et al., 2018).

Medication Interventions

There are no medications to treat ASPD, only treatment for symptoms they may experience. For example, impulsive aggression may benefit from the use of lithium, SSRIs, atypical antipsychotics, gamma-aminobutyric acid enhancers, beta-blockers, MAOIs, or buprenorphine (Svrakic & Dvac-Jovanovic, 2019).

Psychosocial Interventions

Facilitating self-responsibility (i.e., encouraging a patient to assume more responsibility for personal behavior) is an important intervention. The nursing activities that are particularly helpful include holding the patient responsible for the behavior, monitoring the extent that self-responsibility is assumed, and discussing the consequences of not dealing with responsibilities. The nurse needs to refrain from arguing or bargaining about the unit rules, such as time for meals, use of the television room, and smoking. Instead, positive feedback is given to the patient for accepting additional responsibility or changing behavior.

Psychoeducation

Patient education efforts have to be creative and thought provoking. In teaching a person with ASPD, a direct approach is best, but the nurse must avoid “lecturing,” which the patient will resent. In teaching the patient about positive health care practices, impulse control, and anger management, the best approach is to engage the patient in a discussion about the issue and then direct the topic to the major teaching points. These patients often take great delight in arguing or showing how the rules of life do not apply to them. A sense of humor is important, as are clear teaching goals and avoiding being sidetracked (see Boxes 30.8, 30.9).

Providing Family Education

Family members of patients with ASPD usually need help in establishing boundaries. Because there is a long-term pattern of interaction in which family

members feel responsible for the patient's antisocial behavior, these patterns need to be stopped. Families need help in recognizing the patient's responsibility for their own actions.

Promoting Safety

Aggressive behavior is often a problem for these individuals and their family members. Similar to patients with BPD, people with ASPD tend to be impulsive. Instead of self-injury, these individuals are more likely to strike out at those who are perceived to be interfering with their immediate gratification. Anger control assistance (helping to express anger in an adaptive, nonviolent manner) becomes a priority intervention. Because the expression of anger and aggression develops during a lifetime, these individuals can benefit from anger management techniques.

BOX 30.8 • THERAPEUTIC DIALOGUE: ANTISOCIAL PERSONALITY DISORDER

INEFFECTIVE APPROACH

Danny: Hey, I need a light for my cigarette.

Nurse: Really? You know the rules—no smoking on the unit.

Danny: I'm not going to smoke here. I just need a light so that I can have a cigarette when I leave here.

Nurse: I also need your cigarettes. Cigarettes are contraband.

Danny: You are terrible—just like the bitch who kicked me out. Who do you think you are anyway?

Nurse: You need to quiet down.

Danny: Yeah, says who?

Nurse: I will call security if you don't quiet down.

Danny: Call them, I don't care.

EFFECTIVE APPROACH

Danny: Hey, I need a light for my cigarette.

Nurse: A light? I don't have a light.

Danny: I need a light so that I can smoke later.

Nurse: Oh, I see. Did you have a lighter when you were admitted?

Danny: Yea, they took everything away including my belt and shoelaces.

Nurse: The reason for storing everything is for the safety of everyone. When you are discharged, you can retrieve everything. I also need to store any cigarettes you have.

Danny: What makes you think I have any cigarettes?

Nurse: Well, you asked for a light. Many patients manage to bring cigarettes into the unit. I need to put them with your things. You can retrieve them when you are discharged.

Danny: This place is something.

Nurse: I will put your cigarettes in a bag with your name on them.

Danny: This sucks. But here they are.

CRITICAL THINKING CHALLENGE

- How did the nurse in the first scenario get sidetracked?
- How was the nurse in the second scenario able to convince Danny to give up his cigarettes without escalating his anger?

Box 30.9

Psychoeducation Checklist: Antisocial Personality Disorder

When caring for the patient with ASPD, be sure to include the following topic areas in the teaching plan:

- Positive health care practices, including substance use control
- Effective communication and interaction skills
- Impulse control
- Anger management
- Group experience to help develop self-awareness and impact of behavior on others
- Analyzing an issue from the other person's viewpoint

- Maintenance of employment
- Interpersonal relationships and social interactions

Group Interventions

Group interventions are more effective than individual modalities because other patients and staff can validate or challenge the patient's view of a situation. Problem-solving groups that focus on identifying a problem and developing a variety of alternative solutions are particularly helpful because patient self-responsibility is reinforced when patients remind each other of better alternatives. Patients are likely to confront each other with dysfunctional schemata or thinking patterns. Teaching patients with ASPD the same communication techniques as those with BPD will also encourage self-responsibility. These patients often attend groups that focus on the development of empathy.

Implementing Milieu Therapy

Milieu interventions, such as providing a structured environment with rules that are consistently applied to patients who are responsible for their own behavior, are important. While living in close proximity to others, the individual with ASPD will demonstrate dysfunctional social patterns that can be identified and targeted for correction. For example, these patients often violate ward rules, such as no smoking or limitations on the number of visitors, and may bring contraband, such as illegal drugs, into the unit.

In an inpatient unit, interventions can be more intense and focus on helping the patient develop positive interaction skills and experience a consistent environment. For example, the focus of nursing interventions may be the patient's continual disregard of the rights of others. On one unit, a patient continually placed orders for pizzas in the name of another patient who had limited intelligence and was genuinely afraid of the person with ASPD. The victimized patient always paid for the pizza. When the nursing staff realized what was happening, they confronted the patient with ASPD about the behavior and revoked his unit privileges.

Evaluation and Treatment Outcomes

The outcomes for patients with ASPD are evaluated in terms of managing specific problems, such as maintaining employment or developing a meaningful interpersonal relationship. The nurse will most likely see these patients for other health care problems, so adherence to treatment recommendations and development of health care practices (e.g., reducing smoking and alcohol consumption) can also be factored into the evaluation of outcomes.

Continuum of Care

People with ASPD rarely seek mental health care unless there is a co-morbid condition, such as depression. Nurses are most likely to see these patients in medical–surgical settings for comorbid conditions. Consistency in interventions is necessary for treating the patient throughout the continuum of care.

OTHER CLUSTER B PERSONALITY DISORDERS

Histrionic Personality Disorder

Clinical Course and Diagnostic Criteria

Attention seeking, *excitable*, and *emotional* are terms used to describe people with **histrionic personality disorder** (HPD). Histrionic personality disorder is one of the most ambiguous diagnostic categories in psychiatry. HPD made its first official appearance in the *Diagnostic and Statistical Manual of Mental Disorders II (DSM II)* and since its revisions through *DSM-V*. HPD is the only modern category in diagnostic classifications that conserved a derivative of the old concept of Hysteria. Several psychiatric disorders are derived from the original term *hysteria* such as the *conversion disorder*, the *somatization disorder*, *somatoform disorders*, *phobic anxiety*, the term *mass hysteria*, and finally the *HPD*. The word *hysteria* is derived from the Greek term *hystera*, meaning the womb or uterus. It has been used since ancient times and appears in text of the Egyptians, Greeks, and Romans. In the Old Rome, the word *Histrione* was already used to define the actors that represented coarse farces representing

those who are false and theatrical (Novais et al., 2015).

HPD is more likely in women. Affected individuals are lively and dramatic and draw attention to themselves by their enthusiasm, dress, and apparent openness. They are the “life of the party” and, on the surface, seem interested in others. Their insatiable need for attention and approval quickly becomes obvious. Their need to be “center stage” arises in two ways: (1) their interests and topics of conversation focus on their own desires and activities and (2) their behavior, including their speech pattern, continually calls attention to themselves. These needs are inflexible and persistent even after others attempt to meet them. Persons with HPDs are quick to form new friendships and just as quick to become demanding. Because they are trusting and easily influenced by other opinions, their behavior often appears inconsistent. Their strong dependency need makes them overly trusting and gullible. They are moody and often experience a sense of helplessness when others are uninterested in them. They are sexually seductive in their attempts to gain attention and often are uncomfortable within a single relationship. Their appearance is provocative and their speech dramatic. They express strong opinions without supporting facts. Loyalty and fidelity are lacking (Hamlat et al., 2019).

Gender influences the manifestations of this disorder. Women dress seductively, may express dependency on selected men, and may “play” a submissive role. Men may dress in a very masculine manner and seek attention by bragging about athletic skills or successes in their jobs. Individuals with this disorder have difficulty achieving any true intimacy in interpersonal relationships. They seem to possess an innate sensitivity to the moods and thoughts of those they wish to please. This hyperalertness enables them to maneuver quickly to gain their attention. They then attempt to control relationships by their seductiveness at one level but become extremely dependent on their friends at another level. Their demand for constant attention quickly alienates their friends. They become depressed when they are not the center of attention.

Epidemiology and Risk Factors

The prevalence of HPD is estimated at 1.8% of the general population of the United States (Grant et al., 2004). No gender differences arise in the occurrence of this disorder; however, this diagnosis is seen more frequently in women than

men clinically. Risk of occurrence of this disorder is greater among African Americans than Whites. Low-income groups and less educated persons are also at higher risk for occurrence of HPD. Widowed, separated, divorced, or people who never married are at greater risk than married ones. This disorder occurs concurrently with other mental disorders; anxiety disorder, obsessive-compulsive syndromes, somatic symptom disorder, substance use disorder, and mood disorders, in which they overplay their feelings of dysthymia by expressing them through dramatic and eye-catching gestures (French & Shrestha, 2020).

Etiology

Research related to this personality disorder is minimal. Some speculate that there is a biologic component and that heredity may play a role but that the biologic influence is less than in some of the previously discussed personality problems. In infancy and early childhood, these individuals are extremely alert and emotionally responsive. The tendencies for sensory alertness may be traced to responses of the limbic and reticular systems. They demonstrate a high degree of dependence on others and a type of dissociation in which they have reduced awareness of their behavior in relation to others (French & Shrestha, 2020).

It is believed that these highly alert and responsive infants seek more gratification from external stimulation during their first few months of life. Depending on the responsiveness of caregivers to them, they develop behavior patterns in response to their caregivers. It is believed that these children experience brief, highly charged, and irregular reinforcement from multiple caregivers (parents, siblings, grandparents, foster parents) who are unable to provide consistent experiences.

Parental behavior and role modeling are also believed to contribute to the development of HPD. Many of the women with this disorder reported that they are just like their mother, who is emotionally labile, bored with the routines of home life, flirtatious with men, and clever in dealing with people. It is believed that through role modeling, these children learn and mimic the behaviors observed in caregivers or adults (French & Shrestha, 2020).

Evidence-Based Nursing Care of Persons with

Histrionic Personality Disorder

The ultimate treatment goal for patients with HPD is to correct the tendency to expect others to fulfill all of their needs. When these individuals seek mental health care, they have usually experienced a period of social disapproval or deprivation. Their hope is that the mental health providers will help fulfill their needs. Specific goals are needed to protect the person from becoming dependent on a mental health system. In the nursing assessment, the nurse focuses on the quality of the individual's interpersonal relationships. It is common that the person is dissatisfied with their partner, and sexual relations may be nonexistent.

During the assessment, the patient will make statements that indicate low self-esteem. Because these individuals believe that they are incapable of handling life's demands and have been waiting for a truly competent person to take care of them, they have not developed a positive self-concept or adequate problem-solving abilities.

Priority of care areas for persons with this disorder include focusing on self-esteem and coping patterns. Outcomes focus on helping the patient develop autonomy, a positive self-concept, and mature problem-solving skills.

A variety of interventions support the outcomes. A nurse-patient relationship that allows the patient to explore positive personality characteristics and develop independent decision-making skills forms the basis of the interventions. Reinforcing personal strengths, conveying confidence in the patient's ability to handle situations, and examining the patient's negative perceptions of him- or herself can be done within the therapeutic relationship. Encouraging the patient to act autonomously can also improve the individual's sense of self-worth. Attending assertiveness groups can help increase the individual's self-confidence and improve self-esteem.

Continuum of Care

Patients with HPD do not seek mental health care unless they have a coexisting medical or mental disorder. They are likely to be treated within the community for most of their lives, with the exception of short hospitalizations for nonpsychiatric problems.

Narcissistic Personality Disorder

Clinical Course and Diagnostic Criteria

People with **narcissistic personality disorder** are grandiose, have an inexhaustible need for admiration, and lack empathy. Beginning in childhood, these individuals believe that they are superior, special, or unique and that others should recognize them in this way (Hamlat et al., 2019). They are often preoccupied with fantasies of unlimited success, power, beauty, or ideal love. They overvalue their personal worth, direct their affections toward themselves, and expect others to hold them in high esteem. They define the world through their own self-centered view. Their sense of entitlement is striking. People with narcissistic personality disorder are benignly arrogant and feel themselves above the conventions of their cultural group. They handle criticism poorly and may become enraged if someone dares to criticize them or else they may appear totally indifferent to criticism. They believe they are entitled to be served and that it is their inalienable right to receive special considerations. People with this disorder want to have their own way and are frequently ambitious for fame and fortune. These individuals are often successful in their jobs but may alienate their significant others, who grow tired of their narcissism. They cannot show empathy, and they feign sympathy only for their own benefit to achieve their selfish ends. Clinically, those with narcissistic personality disorder show overlapping characteristics of BPD and ASPD.

Epidemiology and Risk Factors

The prevalence of narcissistic personality disorder is 6.2% of the U.S. general population with rates greater for men (7.7%) than for women (4.8%) according to a recent national epidemiologic survey (Stinson et al., 2008). Narcissistic personality disorder can be found in professionals who are highly respected, such as those in law, medicine, and science and those associated with celebrity status. Persons with this disorder may impart an unrealistic sense of omnipotence, grandiosity, beauty, and talent to their children; therefore, children of parents with a narcissistic personality disorder have a higher than usual risk of developing the disorder themselves. It also commonly occurs in only children

and among first-born boys in cultural groups in which males have special privileges (Mitra & Fluyau, 2020).

Etiology

Limited evidence suggests biologic factors contribute to the development of this disorder. One notion about its development is that it is the result of parents' overvaluation and overindulgence of a child. These children are overly pampered and indulged, with every whim catered to. They learn to view themselves as special beings and to expect special treatment and subservience from others. They do not learn how to cooperate, share, or consider others' desires and interests. An alternate explanation is that the child never truly separated emotionally from their primary caregiver and therefore cannot envision functioning independently. According to another set of theories, these individuals try to avoid or reduce intense feelings of shame and engage in diverse strategies to gain attention for themselves (Roepke & Vater, 2014).

Evidence-Based Nursing Care for Persons with Narcissistic Personality Disorder

The nurse usually encounters persons with narcissism in medical settings and in psychiatric settings with a coexisting psychiatric disorder. They are difficult patients who often appear snobbish, condescending, and patronizing in their attitudes. It is unlikely that these individuals are motivated to develop sensitivity to others and socially cooperative attitudes and behaviors. Building a therapeutic relationship is a slow process because these patients avoid self-reflection and often reject the clinician's approaches. It is important not to engage in power struggles with the patient. Nurses need to use their self-awareness skills in interacting with these patients and help the person identify concrete, realistic, and measurable treatment goals that the patient identifies as their own (Weinberg & Ronningstam, 2020).

Continuum of Care

Similar to patients with histrionic disorder, those with narcissistic personality disorder do not seek mental health care unless they have a coexisting medical or mental disorder. They are likely to be treated within the community for most of their lives, with the exception of short hospitalizations for nonpsychiatric problems.

CLUSTER C DISORDERS: AVOIDANT, DEPENDENT, AND OBSESSIVE-COMPULSIVE PERSONALITY DISORDERS

Avoidant Personality Disorder

Clinical Course and Diagnostic Criteria

Avoidant personality disorder (AVPD) is characterized by extensive avoidance of social interaction driven by fears of rejection and feelings of personal inadequacy (Lampe & Malhi, 2018). Individuals with this disorder stay out of social situations in which interpersonal contact with others may be expected. Individuals appear timid, shy, and hesitant; they also fear criticism and feel inadequate. These individuals are extremely sensitive to negative comments and disapproval and appraise situations more negatively than others do. They perceive themselves as unwanted and isolated from others. This behavior becomes problematic when it restricts their social activities and work opportunities because of their extreme fear of rejection. In comparison to other personality disorders, AVPD is associated with the highest level of impairment in daily functioning (Weinbrecht et al., 2016).

Chronic depression is associated with AVPD in persons who have experienced childhood abuse and trauma (Klein et al., 2015). Anxious and avoidant attachments with early caregivers have been shown to contribute to the development of AVPD. Fear, expectations of being shamed, and overuse of cognitive and behavioral avoidance contribute to the vicious cycles of maintenance in AVPD (Lampe & Malhi, 2018).

In childhood, persons with AVPD are shy, but instead of growing out of the shyness, it becomes worse in adulthood. They perceive themselves as socially inept, inadequate, and inferior, which, in turn, justifies their isolation and rejection by others. Vocationally, people with AVPD often take jobs on the sidelines, rarely obtaining personal advancement or exercising much authority, but to employers, they seem shy and eager to please. They are reluctant to enter relationships unless they are given strong assurance of uncritical acceptances, so they consequently often have no close friends or confidants (Fariba & Sapra, 2020).

Epidemiology and Risk Factors

The prevalence of AVPD is 2.4% in the general population (APA, 2013), but it has been reported in 10% of outpatients in mental health clinics (Grant et al., 2004). The problem with examining the epidemiology of AVPD is its potential overlap with social anxiety disorder. Several studies found that a significant portion of the patients with diagnoses of social anxiety disorder also met criteria for AVPD (Carter & Wu, 2010; Cox et al., 2009). More research is needed to clarify the relationship between avoidant personality and anxiety disorders. In light of prevalence rates, societal costs, and the current state of research, it needs to be stated that AVPD qualifies as a neglected disorder. Up to now, the available research has primarily focused on the delineation of social anxiety disorder and AVPD (Weinbrecht et al., 2016).

Etiology

Experts speculate that individuals with AVPD experience aversive stimuli more intensely and more frequently than others do because they may possess an overabundance of neurons in the aversive center of the limbic system (Fariba & Sapra, 2020).

Evidence-Based Nursing Care of Personswith

Avoidant Personality Disorder

Assessment of these individuals reveals a lack of social contacts, a fear of being criticized, and evidence of chronic low self-esteem. The focus of nursing care is on increasing self-esteem and decreasing social isolation. The establishment of a therapeutic relationship is necessary to be able to help these individuals meet their treatment outcomes. The development of the nurse–patient relationship is a slow process and requires an extreme amount of patience on the part of the nurse. These individuals may not have had positive interpersonal relationships and need time to be able to be sure that the nurse will not criticize and demean them. Interventions should focus on refraining from any negative criticism, assisting the patient to identify positive responses from others, exploring previous achievements of success, and exploring reasons for self-criticism. The patient's social dimension should be examined for activities that increase self-esteem and interventions focused on increasing these self-esteem-enhancing activities. Social skills training may help reduce symptoms.

Continuum of Care

Long-term therapy is ideal for patients with AVPD because it takes time to make changes in one's behavior. Mental health nurses may initially see these individuals for other health problems. Encouraging the patient to continue with therapy and contacting the therapist when necessary are important in maintaining continuity of care. These patients are hospitalized only for a coexisting disorder.

Dependent Personality Disorder

Clinical Course and Diagnostic Criteria

People with **dependent personality disorder** cling to others in a desperate attempt to keep them close. Their need to be taken care of is so great that it leads to doing anything to maintain the closeness, including total submission and disregard for themselves.

Decision-making is difficult or nonexistent. They adapt their behavior to please those to whom they are attached. They lean on others to guide their lives.

They ingratiate themselves with others and denigrate themselves and their accomplishments. Their self-esteem is determined by others. Behaviorally, they withdraw from adult responsibilities by acting helpless and seeking nurturance from others. In interpersonal relationships, they need excessive advice and reassurance. They are compliant, conciliatory, and placating. They rarely disagree with others and are easily persuaded. Friends describe them as gullible. They are warm, tender, and noncompetitive. They timidly avoid social tension and interpersonal conflicts (Hamlat et al., 2019).

Epidemiology and Risk Factors

A recent study estimates the prevalence at 0.49% (APA, 2013). The diagnosis is made more frequently in women than in men. This gender difference may represent a sex bias by clinicians because when standardized instruments are used, men and women receive diagnoses at equal rates. The risk of dependent personality disorder is greater for the least educated and for widowed, divorced, separated, and never-married women (Disney, 2013).

Etiology

It is likely that a biologic predisposition exists to develop the dependency attachments of this disorder. However, no research studies support a biologic hypothesis. Dependent personality disorder is most often explained as a result of parents' genuine affection, extreme attachment, and overprotection. Children then learn to rely on others to meet their basic needs and do not learn the necessary skills for autonomous behavior. Persons with chronic physical illnesses in childhood may be prone to developing this disorder.

Evidence-Based Nursing Care of Personswith Dependent Personality Disorder

Nurses can determine the extent of dependency by assessment of self-worth, interpersonal relationships, and social behavior. They should determine whether

there is currently someone on whom the person relies (parent, spouse) or whether there has been a separation from a significant relationship by death or divorce.

Priorities of care that are usually identified include low self-esteem, difficulties in social situations, and coping with stresses of everyday life. Home management skills may be a priority if the patient does not have these skills and has to make decisions related to finances, shopping, cooking, and cleaning. The challenge of caring for these patients is to help them recognize their dependent patterns; motivate them to want to change; and teach them adult skills that have not been developed, such as balancing a checkbook, planning a weekly menu, and paying bills when they are due. Occasionally, if a patient is extremely fatigued, lethargic, or anxious, the disorder interferes with efforts at developing greater independence; antidepressants or antianxiety agents may be used in therapy.

These patients readily engage in a nurse–patient relationship and initially look to the nurse to make all decisions. The nurse can support patients to make their own decisions by resisting the urge to tell them what to do. Ideally, these patients are in individual psychotherapy and working toward long-term personality changes. The nurse can encourage patients to stay in therapy and to practice the new skills that are being learned. Assertiveness training is helpful.

Continuum of Care

Individuals with dependent personality disorder readily seek out therapy and are likely to spend years seeking therapy. Hospitalization occurs for comorbid conditions such as depression.

Obsessive-Compulsive Personality Disorder

Clinical Course and Diagnostic Criteria

OCPD stands out because it bears close resemblance to obsessive-compulsive disorder (OCD). Although these disorders have similar names, the clinical manifestations are quite different. A distinguishing difference is that those with OCD tend to use obsessive thoughts and compulsions when anxious but less so

when anxiety decreases. Persons with OCPD do not demonstrate obsessions and compulsions but rather a pervasive pattern of preoccupation with orderliness, perfectionism, and control. They also have the capacity to delay rewards, whereas those with OCD do not (Pinto et al., 2013). Individuals with this disorder attempt to maintain control by careful attention to rules, trivial details, procedures, and lists (Thamby & Khanna, 2019). They may be completely devoted to work, which typically has a rigid character, such as maintaining financial records or tracking inventory. They are uncomfortable with unstructured leisure time, especially vacations. Their leisure activities are likely to be formalized (e.g., season tickets to sports, organized tour groups). Hobbies are approached seriously.

Behaviorally, individuals with OCPD are perfectionists, maintaining a regulated, highly structured, strictly organized life. A need to control others and situations is common in their personal and work lives. They are prone to repetition and have difficulty making decisions and completing tasks because they become so involved in the details. They can be overly conscientious about morality and ethics and value polite, formal, and correct interpersonal relationships. They also tend to be rigid, stubborn, and indecisive and are unable to accept new ideas and customs. Their mood is tense and joyless. Warm feelings are restrained, and they tightly control the expression of emotions (APA, 2013).

Epidemiology and Risk Factors

OCPD is one of the most prevalent personality disorders in the general population, with estimated prevalence ranging from 2.1% to 7.9% (APA, 2013). This disorder is associated with higher education, employment, and marriage. Subjects with the disorder had a higher income than did those without the disorder.

Etiology

As with some other personality disorders, evidence for a biologic formulation is scant. The basis of the compulsive patterns that characterize OCPD is parental overcontrol and overprotection that is consistently restrictive and sets distinct

limits on the child's behavior. Parents teach these children a deep sense of responsibility to others and to feel guilty when these responsibilities are not met. Play is viewed as shameful, sinful, and irresponsible, leading to dire consequences. They are encouraged to resist the natural inclinations toward play and impulse gratification, and parents try to impose guilt on the child to control behavior.

Nursing Care

These individuals seek mental health care when they have attacks of anxiety, spells of immobilization, sexual impotence, and excessive fatigue. The nursing assessment focuses on the patient's physical symptoms (sleep, eating, sexual), interpersonal relationships, and social problems. There may be multiple nursing care priorities such as anxiety, loneliness, decision-making, sexual problems, insomnia, and interpersonal relationships. People with OCPD realize that they can improve their quality of life, but they find it extremely anxiety provoking to make the necessary changes. To change the compulsive pattern, psychotherapy is needed. There may be short-term pharmacologic intervention with an antidepressant or anxiolytic as an adjunct may take place. A supportive nurse-patient relationship based on acceptance of the patient's need for order and rigidity will help the person have enough confidence to try new behaviors. Examining the patient's belief that underlies the dysfunctional behaviors can set the stage for challenging the childhood thinking. Because the compulsive pattern was established in childhood, it will take a long time to modify the behavior.

Continuum of Care

People with OCPD are treated primarily in the community. If there is a coexisting disorder or the person experiences periods of depression is present, hospitalization may be useful for a short period of time.

DISRUPTIVE, IMPULSE-CONTROL, AND

CONDUCT DISORDERS

Disruptive, impulse-control, and conduct disorders are a group of mental conditions that have the essential feature of irresistible impulsivity. Behaviors associated with these disorders violate the rights of others and/or are in conflict with societal norms (APA, 2013). Disorders discussed include IED, kleptomania, and **pyromania**.

KEYCONCEPT Impulsivity, acting without considering consequences or alternative actions, results when neurobiologic overactivity is stimulated by psychological, personality, or social factors related to personal needs of the individual (Tansey, 2010).

KEYCONCEPT Impulse-control disorders often coexist with other disorders and are characterized by an inability to resist an impulse or temptation to complete an activity that is considered harmful to oneself or others.

Tension increases before the individual commits the act and derives excitement or gratification when the act is committed. The release of tension is perceived as pleasurable, but remorse and regret usually follow the act. The disruptive behavior disorders, which include oppositional defiant disorder and conduct disorder, are a group of conditions marked by significant problems of conduct. See [Chapter 37](#).

Intermittent Explosive Disorder

Episodes of aggressiveness that result in assault or destruction of property characterize people with **intermittent explosive disorder**. The severity of aggressiveness is out of proportion to the provocation. The episodes can have serious psychosocial consequences, including job loss, interpersonal relationship problems, school expulsion, divorce, automobile accidents, or jail. This diagnosis is given only after all other disorders with aggressive components (e.g., delirium, dementia, head injury, BPD, ASPD, substance use) have been excluded. Little is known about this disorder, but it is a more common condition than previously thought.

Aggression is a destructive behavior that imposes a considerable burden on individuals and society. In clinical settings, recurrent problematic aggression is identified as IED. Intermittent explosive disorder is associated with significantly more aggression than are BPD or ASPD alone (Fanning et al., 2019).

The prevalence of IED in the United States is about 2.7%. The onset is most common in childhood or adolescence and rarely begins for the first time after the age 40 years. The mean age at onset is 14 years. It is more prevalent in individuals with a high school education or less (APA, 2013). The anger experience and expression of anger contribute to suicidality (McCloskey & Ammerman, 2018).

The treatment of this disorder is multifaceted. Psychopharmacologic agents are sometimes used as an adjunct to psychotherapeutic, behavioral, and social interventions. Serotonergic antidepressants and gamma-aminobutyric acid-ergic mood stabilizers have been used. Anxiolytics are used to treat obsessive patients who experience tension states and explosive outbursts. Medication alone is insufficient, and anger management should be included in the treatment plan.

Kleptomania

In **kleptomania**, individuals cannot resist the urge to steal, so they independently steal items that they could easily afford. These items are not particularly useful or wanted. The underlying issue is the act of stealing. The term *kleptomania* was first used in 1838 to describe the behavior of several kings who stole worthless objects (Aboujaoude & Koran, 2010). These individuals experience an increase in tension and then pleasure and relief at the time of the theft. Kleptomania occurs in about 4% to 22% of individuals arrested for shoplifting. Its prevalence in the general population, however, is very rare, at approximately 0.3% to 0.6%. Kleptomania or compulsive stealing remains poorly understood with limited data regarding its underlying pathophysiology and appropriate treatment choices. Severity of kleptomania behaviors is associated with having more frequent urges to steal, feeling excited by stealing, having a current eating disorder, and having a current diagnosis of OCD. Furthermore, worse symptom severity was associated with a shorter transition time (between first stealing and developing kleptomania), as well as with more chance of stealing from relatives and seeking treatment at some point. The association of worse kleptomania severity with stealing-related reward and disorder of compulsivity (OCD, anorexia nervosa) may provide clues for appropriate targets for cognitive behavioral therapy or pharmacotherapy (Grant & Chamberlin, 2018).

Females outnumber males at a ratio of 3:1 (APA, 2013). Because it is considered a “secret” disorder, little is known about it, but it is believed to last

for years despite numerous convictions for shoplifting. It appears that kleptomania often has its onset during adolescence (Grant & Kim, 2005).

Some shoplifting appears to be related to anxiety and stress in that it serves to relieve symptoms. In a few instances, brain damage has been associated with kleptomania (Blum et al., 2018). Depression is the most common symptom identified in a compulsive shoplifter.

Kleptomania is difficult to detect and treat and means of treatment are little known. It appears that behavior therapy is frequently used. Medication that helps relieve the depression has been successful in some cases. Despite being described in the medical literature for nearly two hundred years, kleptomania still remains poorly understood with limited data regarding its underlying pathophysiology, and appropriate treatment choices.

Medications capable of dampening urges (such as naltrexone and others) may be worth exploring in clinical trials. Medication that helps relieve depression has been successful in some cases. Naltrexone is also promising in the treatment of kleptomania. More investigation is needed (Chamberlain & Grant, 2019).

Pyromania

Irresistible impulses to start fires characterize pyromania, repeated fire setting with tension or arousal before setting fires; fascination or attraction to the fires; and gratification when setting, witnessing, or participating in the aftermath of fire. These individuals often are regular “fire watchers” or even firefighters. They are not motivated by aggression, anger, suicidal ideation, or political ideology. Little is known about this disorder because only a small number of deliberate fire starters are apprehended, and of those individuals, only a few undergo a psychiatric evaluation. The prevalence of fire setting in the general population is about 1%, but most fire setting is not done by people with pyromania, which occurs infrequently, mostly in men. However, those with a history of fire setting are most likely male, young, and never married and are more likely to have other psychiatric issues such as ASPD, substance use, and impulsivity (Tanner et al., 2016). Prevalence rates are lower among African Americans and Hispanics (Vaughn et al., 2010).

Early research demonstrated low serotonin and norepinephrine levels associated with arson. Little is known about treatment, and as with the other impulse-control disorders, no approach is uniformly effective. Historically, fire starters generally possess poor interpersonal skills, exhibit low self-esteem,

battle depression, and have difficulty managing anger. Education, parenting training, behavior contracting with token reinforcement, problem-solving skills training, and relaxation exercises may all be used in the management of the patient's responses (Tanner et al., 2016).

Continuum of Care for Disruptive, Impulse-Control Disorders

Impulse-control disorders require long-term treatment, usually in an outpatient setting. Group therapy is often a facet of treatment because patients can talk in a community where people share common experiences. Hospitalization is rare except when patients have comorbid psychiatric or medical disorders.

SUMMARY OF KEY POINTS

- A personality is a complex pattern of characteristics, largely outside of the person's awareness, that comprise the individual's distinctive pattern of perceiving, feeling, thinking, coping, and behaving.
- A personality disorder is an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment.
- For many patients with personality disorders, maintaining a therapeutic nurse–patient relationship can be one of the most helpful interventions. Through this therapeutic relationship, the patient experiences a model of healthy interaction, establishing trust, consistency, caring, boundaries, and limitations that help to

build the patient's self-esteem and respect for self and others. In some personality disorders, nurses will find it more difficult to engage the patient in a true therapeutic relationship because of the patient's avoidance of interpersonal and emotional attachment (i.e., ASPD or paranoid personality disorder).

- Patients with personality disorders are rarely treated in an inpatient facility except during periods of destructive behavior or self-injury. Treatment is delivered in the community and over time. Continuity of care is important in helping the individual change lifelong personality patterns.
- People with BPD have difficulties regulating emotion and have extreme fears of abandonment, leading to dysfunctional relationships; they often engage in self-injury.
- Medications, including mood stabilizers, antidepressants, and antipsychotics, are useful in regulating the symptoms. They should, however, only be taken for target symptoms for a short time because patients may already be taking other medications, particularly for a comorbid disorder.
- During hospitalizations, keeping the patients safe by preventing self-harm is priority. Open communication and use of DBT techniques are important interventions.
- Recovery-oriented approaches are grounded in cognitive behavioral therapy. The interdisciplinary treatment or recovery team needs to maintain open communication to work effectively with a person with BPD.
- ASPD, often synonymous with psychopathy, includes people who

have no regard for and refuse to conform to social rules.

- The primary characteristic of disruptive, impulse-control disorders is impulsivity, which leads to inappropriate social behaviors that are considered harmful to oneself or others and that give the patient excitement or gratification at the time the act is committed.

CRITICAL THINKING CHALLENGES

1. Define the concepts *personality* and *personality disorder*. When does a normal personality become a personality disorder?
2. Karen, a 36-year-old woman receiving inpatient care, was admitted for depression; she also has a diagnosis of BPD. After a telephone argument with her husband, she approaches the nurse's station with her wrist dripping with blood from cutting. What nursing approach best fits this behavior? What interventions should the nurse use with the patient after the self-injury is treated?
3. A 22-year-old man with BPD is being discharged from the mental health unit after a severe suicide attempt. As his primary psychiatric nurse, you have been able to establish a therapeutic relationship with him but are now terminating the relationship. He asks you to meet with him "for just a few sessions" after his discharge because his therapist will be on vacation. What are the issues underlying this request? What should you do? Explain and justify.
4. Compare the biologic theory with the psychoanalytic and Linehan's biosocial theory. What are the primary differences between these theories?
5. Compare the characteristics, epidemiology, and etiologic theories of antisocial and BPDs.
6. Discuss the differences between histrionic and OCPD.

7. Compare and contrast ASPD with narcissistic personality trait.
8. Define and summarize personality disorders. Compare the following among the Cluster A, B, and C disorders:
 - a. Defining characteristics
 - b. Epidemiology
 - c. Biologic, psychological, and social theories
 - d. Key nursing assessment data
 - e. Priority of care and outcomes
 - f. Specific issues related to a therapeutic relationship
 - g. Interventions
9. Define and summarize the impulse-control disorders. Compare the following among kleptomania, pyromania, and conduct disorders:
 - a. Defining characteristics
 - b. Epidemiology
 - c. Biologic, psychological, and social theories
 - d. Key nursing assessment data
 - e. Nursing priorities and outcomes
 - f. Interventions

Movie Viewing Guides

Fatal Attraction: (1987) This award-winning film portrays the relationship between a married attorney, Dan Gallagher (played by Michael Douglas), and Alex Forest, a single woman (played by Glenn Close). Their one-night affair turns into a nightmare for the attorney and his family as Alex becomes increasingly possessive and aggressive, demonstrating behaviors characteristic of borderline personality disorder, including anger, impulsivity, emotional lability, fear of rejection and abandonment, vacillation between adoration and disgust, and self-mutilation.

Viewing Points: Identify the behaviors of Alex that are characteristics of borderline personality disorder. Identify the feelings that are generated by the

movie. With which characters do you identify? For which characters do you feel sympathy? If Alex had lived and been admitted to your hospital, what would be your first priority?

Grey Gardens: (1975) This documentary by Albert and David Maysles is the unbelievable true story of Mrs. Edith Bouvier Beale and her daughter Edie, who are the aunt and first cousin of Jacqueline Kennedy Onassis. The film depicts mother and daughter, known as “Big Edie” and “Little Edie,” who have descended into a strange life of dependence and eccentricity.

Living in a world of their own in a decaying 28-room East Hampton mansion, their living conditions—infested by fleas, inhabited by numerous cats and raccoons, deprived of running water, and filled with garbage—give viewers a glimpse into schizotypal personality disorder.

Viewing Points: Identify the behaviors of Big Edie and Little Edie that are characteristic of schizotypal personality disorder. Do “Big Edie” and “Little Edie” exhibit a folie à deux (a shared psychotic disorder)? Why or why not?

Addiction and Substance Use-Related Disorders

Nursing Care of Persons with Alcohol and Drug Use Disorders

Susan Dawson and Patricia E. Freed

KEYCONCEPTS

- addiction
- denial
- motivation

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of addiction in substance-related disorders.
2. Differentiate alcohol effects, overdose and alcohol withdrawal syndrome.
3. Identify prolonged use effects of alcohol, marijuana, stimulants, tobacco, hallucinogens, opioids, and inhalants.
4. Identify medications used to prevent alcohol use relapse.
5. Differentiate the medications used to treat opioid overdose and opioid maintenance treatment.
6. Identify the similarities between a substance-related and non-substance-

related disorder.

7. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with a substance-related disorder.
8. Differentiate motivational interviewing, harm reduction, and peer support self-help groups.
9. Apply a person-centered, recovery-oriented nursing process for persons with a substance-related disorder.

KEY TERMS

- Alcohol withdrawal syndrome
- Alcoholics Anonymous
- Brief interventions
- Codependence
- Confabulation
- Confrontation
- Craving
- Delirium tremens
- Denial
- Detoxification
- Gambling disorder
- Hallucinogen
- Harm reduction
- Inhalants
- Intoxication
- Korsakoff amnestic syndrome
- Methadone maintenance
- Motivation
- Motivational interviewing
- Opioids
- Recovery
- Relapse
- Substance-induced disorder
- Substance use disorder

- Sudden sniffing death
 - Tolerance
 - Wernicke–Korsakoff syndrome
 - Wernicke encephalopathy
 - Withdrawal
-

Case Study

Gladys, a 68-year-old widow, lives by herself in a comfortable apartment. She spends her days with friends and visiting her grandchildren. At night, she frequently has an alcoholic drink to relax her and help her sleep. She denies that she has a drinking problem.

INTRODUCTION

The human use and abuse of alcohol and other drugs has been around since the beginning of history; so too have the subsequent social and emotional problems that accompany substance use. This chapter reviews the concept of addiction, types of substance use, biologic and psychological effects, current theories of substance-related disorders, and interventions. Gambling disorder is a non–substance-related disorder that is also discussed in this chapter. Gambling behaviors and their consequences have similar characteristics to the behaviors associated with substance disorders. The nurse’s role in helping persons with these disorders recover is discussed. Professional issues related to chemical dependency within the nursing profession are also examined.

SUBSTANCE USE AND ABUSE OVERVIEW

Alcohol, tobacco, marijuana, and illegal prescription drug use has reached epidemic proportions in the United States, with the incidence rising in younger age groups, particularly among adolescents and young adults. One of the goals

of *Healthy People 2020* is “to reduce substance abuse to protect the health, safety, and quality of life for all, especially children” (U.S. Department of Health and Human Services, 2020). A major challenge facing our country is the opioid epidemic. The overriding concern about using mind-altering substances is that these substances compromise health, and the continued use will lead to addiction.

KEYCONCEPT **Addiction** is a condition of continued use of substances (or reward-seeking behaviors) despite adverse consequences.

Many mind-altering substances are physiologically addicting and easily can lead to severe health and legal problems. Use by ingestion, smoking, sniffing, or injection of some mind-altering substances such as alcohol, pain medication, tobacco, or caffeine is legal for adults. State laws on marijuana use are changing rapidly as more states legalize and decriminalize use for medicinal and/or recreational purposes. Other substances such as cocaine and heroin are illegal in the United States. Abuse occurs when a person uses alcohol or drugs for the purpose of intoxication or, in the case of prescription drugs, for purposes other than their intended use. Substance-related disorders involve substances that are commonly abused.

Physiologic dependence can develop with many different types of medications such as beta-blockers, antidepressants, opioids, antianxiety agents, and others. As long as medications are used for their intended purposes and under the supervision of qualified health care providers, physiologic dependence is an expectation of treatment. That is, dependence can be a normal response to some medications (American Psychiatric Association [APA], 2013).

Diagnostic Criteria

Substance-related disorders are categorized into two categories: substance use disorders and substance-induced disorders. Substance-induced disorders occur when medications used for other health problems or medical/mental health disorders cause intoxication, withdrawal, or other health-related problems. A substance use disorder occurs when an individual continues using substances despite cognitive, behavioral, and physiologic symptoms. The *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* identifies 10 diagnostic

categories of substances including alcohol, caffeine, cannabis (marijuana), hallucinogens, inhalants, opioids, sedative–hypnotics, stimulants, tobacco, and others (APA, 2013). Gambling disorder is included within the substance use disorder category because gambling behaviors can activate the brain’s reward system similar to the substance use disorders.

A substance use disorder occurs when there is an underlying change in brain circuitry that may persist after detoxification, the process of safely and effectively withdrawing a person from an addictive substance, usually under medical supervision. These brain changes lead to pathologic behaviors that occur with repeated relapses and intense drug cravings when exposed to drug-related cues (e.g., a party, emotional experiences) (APA, 2013).

BOX 1.1

Medical Complications of Alcohol Abuse

- **Cardiovascular system:** Cardiomyopathy, congestive heart failure, hypertension
- **Respiratory system:** Increased rate of pneumonia and other respiratory infections
- **Hematologic system:** Anemias, leukemia, hematomas
- **Nervous system:** Withdrawal symptoms, irritability, depression, anxiety disorders, sleep disorders, phobias, paranoid feelings, diminished brain size and functioning, organic brain disorders, blackouts, cerebellar degeneration, neuropathies, palsies, gait disturbances, visual problems
- **Digestive system and nutritional deficiencies:** Liver diseases (fatty liver, alcoholic hepatitis, cirrhosis), pancreatitis, ulcers, other inflammations of the GI tract, ulcers and GI bleeds, esophageal varices, cancers of the upper GI tract, pellagra, alcohol-amnestic disorder, dermatitis, stomatitis, cheilosis, scurvy
- **Endocrine and metabolic systems:** Increased incidence of diabetes mellitus, hyperlipidemia, hyperuricemia, and gout
- **Immune system:** Impaired immune functioning, higher incidence of infectious diseases, including tuberculosis and other bacterial infections
- **Integumentary system:** Skin lesions, increased incidence of infection, burns, and other traumatic injury

- **Musculoskeletal system:** Increased incidence of traumatic injury, myopathy
- **Genitourinary system:** Hypogonadism, increased secondary female sexual characteristics in men (hypoandrogenization and hyperestrogenization), erectile dysfunction in men, electrolyte imbalances due to excess urinary secretion of potassium and magnesium

Epidemiology

Age of Onset

In the United States, alcohol is the most abused substance, followed by marijuana. Alcohol use is at historically low levels for adolescents. In 2019, 7.9% of 8th graders, 18.4% of 10th graders, and 29.3% of 12th graders reported getting drunk in the previous month. In 2018, less than 14% of high school seniors reported binge drinking—a drop of a more than one third since the late 1990s—but illicit drug use continues to be a concern. In 2019, 1.3% of 8th graders, 4.8% of 10th graders, and 6.4% of 12th graders used marijuana daily (NIDA, 2019e). Marijuana use reflects a change in attitude and perception that marijuana is a safe drug, especially in light of recent legalization of marijuana in some states (National Institute of Drug Abuse [NIDA], 2019f).

The nonmedical use of prescription and over-the-counter (OTC) medicines continues to represent a significant part of adolescent drug use, but prescription opioids have significantly decreased over the last 5 years. Fewer teens smoke cigarettes daily (1.8% of middle school students and 2.4% high school students). Vaping, on the other hand, has increased, with 35.7% of middle schoolers and 30.95 of high schoolers reporting monthly use (NIDA, 2018f). Thousands of people with serious lung illness and dozens of deaths have been associated with vaping, and a thickening agent, vitamin E acetate, is a prime chemical of concern (NIDA, 2019i).

Diversity and Disparity

Epidemiologic data show that in the United States, sex/race/ethnic groups differ in drug preferences, use, accessibility, and risk (Substance Abuse and Mental Health Services Administration [SAMSHA], 2018a). Such identified differences should be used to direct the service needs for the population. For instance, youth identifying as sexual minorities were found to have higher substance use, experienced more violence victimization, and were at a higher risk for suicide than other teens (Johns et al., 2018). These teens need more access to crisis services, anti-bullying approaches, and more screening for suicide prevention. Furthermore, racial/ethnic minorities are disproportionately incarcerated for drug crimes and placed in facilities that have insufficient substance abuse treatment and follow-up (Sanmartin et al., 2020). Identifying differences and disparities among the diverse US population is essential to the design of programs, services, and policies that can effectively address specific population needs.

Comorbidity

Many people who abuse substances have other mental disorders. Some disorders are in part a byproduct of long-term substance use; others predispose the individual to alcohol or drug abuse. Whatever the reason, nurses should be aware that patients who abuse substances often have psychotic, anxiety, mood, or personality disorders (SAMHSA, 2018). More than 67,300 Americans died from drug-involved overdose in 2018, including illicit drugs and prescription opioids (Fig. 31.1).

FIGURE 31.1 National drug overdose deaths number among all ages, by gender, 1999–2018. Overdose death rates. National Institute on Drug Abuse. <https://www.drugabuse.gov/related-topics/trends-statistics/overdose-death-rates>

Consider Gladys

She is also depressed and spends many days in bed. During the last few months, her alcohol consumption has increased significantly.

Individuals who abuse substances are at high risk for death from drug overdoses and are at increased risk for death from other causes, including homicide, suicide, accidents, and opportunistic infections (such as human immunodeficiency virus [HIV]) secondary to drug injection. Earlier studies have documented the connection between alcohol abuse and increased risk for diabetes mellitus (DM), gastrointestinal (GI) problems, hypertension, liver disease, and stroke (Winhusen et al., 2019).

Etiology

Substance abuse encompasses the body, the mind, and society's influences. Human and animal studies confirm a genetic predisposition for drinking and drug-abusing behaviors and self-administering mind-altering drugs. As yet, no precise genetic marker has been established, though clusters of genes are being identified that may play a role in addictions (NIDA, 2019b). Temperament, stress, self-concept, age, motivation for change, social consequences for problematic behaviors, parental and family relationships, and peer pressure all contribute to expression of substance abuse—a chronic and progressive disorder.

Family Responses to Substance Use and Abuse

Abuse of substances by one or more members has devastating effects on families, their functioning, and the community. Fetal alcohol syndrome (FAS) results from drinking alcohol during pregnancy and is one of the leading causes of irreversible mental retardation. Addictions lead to loss of jobs and family relationships due to behaviors such as lying, stealing, and putting the addiction before the well-being of one's self and family. Use of illegal substances can lead to arrest and prison and heated disputes over child custody.

Many families try to help their family member learn to abstain or reduce the use of substances. Support groups provide education and help in understanding the addiction. Conversely, some persons who recover from substance abuse find that they must distance themselves from families that are actively using and abusing alcohol and drugs. Poor family relationships and dysfunction are important predictors of addictions to all psychoactive substances.

Treatment and Recovery

The goal for persons abusing substances is to recover from the abuse. Recovery involves a partnership between health care providers and the individual and family. For many individuals, a period of intense treatment is necessary to safely manage the physical and psychological withdrawal symptoms that occur when a substance is no longer used. Specific withdrawal symptoms depend on the addictive substance and are explained in the following sections as the substances are discussed. The withdrawal process usually involves detoxification. After a person has safely withdrawn from the substance of abuse, the real work toward recovery can begin. A primary concern is relapse, the recurrence of alcohol- or drug-dependent behavior in an individual who has previously achieved and maintained abstinence for a significant time beyond the period of detoxification. Relapse is an expected part of the chronic disease of addiction, and the cycle of use-detoxification-sobriety and relapse will likely continue for years.

TYPES OF SUBSTANCES AND RELATED DISORDERS

Alcohol

Alcohol (or ethanol) found in various proportions in liquor, wine, and beer relaxes inhibitions and heightens emotions. Mood swings can range from bouts of gaiety to angry outbursts, aggression, and assaultive behavior. Cognitive impairments can vary from reduced concentration or attention span to impaired judgment and memory. Alcohol ultimately produces a sedative effect by depressing the central nervous system (CNS). Depending on the amount of alcohol ingested, the effects can range from feelings of mild sedation and relaxation to confusion and serious impairment of motor functions and speech to severe intoxication that can result in coma, respiratory failure, and death.

[Table 31.1](#) provides a summary of the effects of abused substances.

TABLE 31.1 SUMMARY OF EFFECTS OF ABUSED SUBSTANCES, OVERDOSE, WITHDRAWAL SYNDROMES, AND

PROLONGED USE

Substance	Route	Effects (E) and Overdose (O)	Withdrawal Syndrome	Prolonged Use
Alcohol	PO	E: Sedation, decreased inhibitions, relaxation, decreased coordination, slurred speech, nausea O: Respiratory depression, cardiac arrest	Tremors; seizures, elevated temperature, pulse, and blood pressure; delirium tremens	Affects all systems of the body. Can lead to other dependencies, and malnutrition
Stimulants (e.g., amphetamines, cocaine)	PO, IV, inhalation, smoking	E: Euphoria, initial CNS stimulation and then depression, wakefulness, decreased appetite, insomnia, paranoia, aggressiveness, dilated pupils, tremors O: Cardiac arrhythmias or arrest, increased or lowered blood pressure, respiratory depression, chest pain, vomiting, seizures, psychosis, confusion, seizures, dyskinesias, dystonias, coma	Depression: psychomotor retardation at first and then agitation; fatigue and then insomnia; severe dysphoria and anxiety; cravings, vivid, unpleasant dreams; increased appetite. Amphetamine withdrawal is not as pronounced as cocaine withdrawal.	Often alternates with use of depressants. Weight loss and resulting malnutrition and increased susceptibility to infectious diseases. May produce schizophrenia-like syndrome with paranoid ideation, thought disturbance, hallucinations, and stereotyped movements. Deviated nasal septum, irreversible nasal damage
Cannabis (marijuana, hashish, THC)	Smoking, Ingesting, Skin patches	E: Euphoria or dysphoria, relaxation and drowsiness, heightened perception of color and sound, poor physical coordination, spatial perception and time distortion, unusual body sensations (e.g., weightlessness, tingling), dry mouth, dysarthria, and cravings for particular foods O: Increased heart rate, reddened eyes, dysphoria, lability, disorientation		Can decrease motivation and cause cognitive deficits (e.g., inability to concentrate, impaired memory). Lung damage, may precipitate psychosis
Hallucinogens (LSD, MDMA)	PO	E: Euphoria or dysphoria, altered body image, distorted or sharpened visual and auditory perceptions, depersonalization, bizarre behavior, confusion,	"Flashbacks" or Hallucinogenic Persisting perception disorder (HPPD) may occur after termination of use.	

		<p>incoordination, impaired judgment and memory, signs of sympathetic and parasympathetic stimulation, palpitations (blurred vision, dilated pupils, sweating)</p> <p>O: Paranoia, ideas of reference, fear of losing one's mind, depersonalization, derealization, illusions, hallucinations, synesthesia, self-destructive or aggressive behaviors, tremors</p>		
PCP	PO, inhalation, smoking	<p>E: Feeling superhuman, decreased awareness of and detachment from the environment, stimulation of the respiratory and cardiovascular systems, ataxia, dysarthria, decreased pain perception</p> <p>O: Hallucinations, paranoia, psychosis, aggression, adrenergic crisis (cardiac failure, cerebrovascular accident, malignant hyperthermia, status epilepticus, severe muscle contractions)</p>		<p>"Flashbacks," HPPD, organic brain syndromes with recurrent psychotic behavior, which can last up to 6 months after not using the drug, numerous psychiatric hospitalizations and police arrests</p>
Opioids (heroin, codeine)	PO, injection, smoking	<p>E: Euphoria, sedation, reduced libido, memory and concentration difficulties, analgesia, constipation, constricted pupils</p> <p>O: Respiratory depression, stupor, coma</p>	<p>Abdominal cramps, rhinorrhea, watery eyes, dilated pupils, yawning, "goose flesh," diaphoresis, nausea, diarrhea, anorexia, insomnia, fever</p>	<p>Can lead to criminal behavior to get money for drugs, risk for infection related to needle use (e.g., HIV, endocarditis, hepatitis, abscesses)</p>
Sedatives, hypnotics, anxiolytics	PO, injection	<p>E: Euphoria, sedation, reduced libido, emotional lability, impaired judgment</p> <p>O: Respiratory depression, cardiac arrest</p>	<p>Anxiety rebound and agitation, hypertension, tachycardia, sweating, hyperpyrexia, sensory excitement, motor excitation, insomnia, possible tonic-clonic convulsions, nightmares, delirium,</p>	<p>Often alternated with stimulants, use with alcohol enhances chance of overdose, risk for infection related to needle use</p>

			depersonalization, hallucinations	
Inhalants (e.g., glue, lighter fluid), gasoline, screen-cleaners, hair spray (other aerosol sprays)	Inhalation	E: Euphoria, giddiness, excitement O: CNS depression: ataxia, nystagmus, dysarthria, coma, and convulsions	Similar to findings with alcohol but milder, with anxiety, tremors, hallucinations, and sleep disturbance as the primary symptoms	Long-term use can lead to hepatic and renal failure, blood dyscrasias, damage to the lungs; CNS damage (e.g., OBS, peripheral neuropathies, cerebral and optic atrophy, parkinsonism)
Nicotine	Smoking	E: Stimulation, enhanced performance and alertness, and appetite suppression O: Anxiety	Mood changes (e.g., craving, anxiety) and physiologic changes (e.g., poor concentration, sleep disturbances, headaches, gastric distress, and increased appetite)	Increased chance for cardiac disease and lung disease (COPD, Cancer)
Caffeine	PO	E: Stimulation, increased mental acuity, inexhaustibility O: Restlessness, nervousness, excitement, insomnia, flushing, diuresis, gastrointestinal distress, muscle twitching, rambling flow of thought and speech, tachycardia or cardiac arrhythmia, agitation	Headache, drowsiness, fatigue, craving, impaired psychomotor performance, difficulty concentrating, yawning, nausea	Physical consequences are under investigation, may have risks and benefits

CNS, central nervous system; CVA, cerebrovascular accident; HIV, human immunodeficiency virus; HPPD, hallucinogen persisting perceptual disorder; LSD, d-lysergic acid diethylamide; MDMA, 3,4-methylenedioxymethamphetamine; OBS, organic brain syndrome; PO, oral; PCP, phencyclidine; THC, D-9-tetrahydrocannabinol.

All patients should be screened not only for alcohol use disorders but also for drinking patterns or behaviors that may place them at increased risk for experiencing adverse health effects or alcoholism. A frequently used screening tool is the CAGE Questionnaire. This tool consists of four self-report responses to questions about respondents' beliefs of cutting down on their drinking, their experience of others criticizing their drinking, the presence of guilt about drinking, and early morning drinking (Ewing, 1984). People who abuse alcohol exhibit various patterns of use. Some engage in heavy drinking on a regular or daily basis, others may abstain from drinking during the week and engage in

heavy drinking on the weekends, and still others experience longer periods of sobriety interspersed with bouts of binge drinking (several days of intoxication). Another early detection screening tool commonly used is The Alcohol Use Disorders Identification Test (AUDIT), a 10-item tool developed by the World Health Organization, which has been validated for use across genders and racial groups and is approved for adolescents aged 14 to 18 (Society for Adolescent Health and Medicine [SAHM], 2011).

The level of CNS impairment while under the influence of alcohol depends on how much has been consumed in a given period of time and how rapidly the body metabolizes it. Intoxication is determined by the level of alcohol in the blood, called blood alcohol level (BAL). The body can metabolize 1 oz of liquor, a 5-oz glass of wine, or a 12-oz can of beer per hour without intoxication. [Table 31.2](#) lists behavioral responses at various BALs.

TABLE 31.2 BLOOD ALCOHOL LEVELS (BAL) AND BEHAVIOR

Number of Drinks	BAL (mg%)	Behavior
1–2	0.05	Impaired judgment, giddiness, mood changes
5–6	0.10	Difficulty driving and coordinating movements
10–12	0.20	Motor functions severely impaired, resulting in ataxia; emotional lability
15–20	0.30	Stupor, disorientation, and confusion
20–24	0.40	Coma
25	0.50	Respiratory failure, death

Current blood and breath alcohol concentrations (BAC) in all 50 states is .08—Concentrations at or over .08 are considered legally impaired for operating machinery or driving any type of vehicle. Some states are considering lowering the BAC to .05.

Effects of Long-Term Use

People who use alcohol regularly usually develop alcohol tolerance, the ability to ingest an increasing amount of alcohol before they experience a “high” or a “buzz” and show cognitive and motor effects. The locus coeruleus, which normally inhibits the action of ethanol, is believed to be instrumental in the development of alcohol tolerance. Even though these individuals do not appear

intoxicated, their BALs reflect the increased amount of alcohol, which affects their bodies, as described in [Table 31.1](#). Excessive or long-term abuse of alcohol can adversely affect all body systems; the effects can be serious and permanent. [Box 31.1](#) lists the major physical complications of alcohol abuse for the major organ systems.

Alcohol Withdrawal and Detoxification

Withdrawal from alcohol presents many physiologic and psychological challenges. Because of physiologic addiction, abrupt cessation of alcohol ingestion can cause mild-to-severe physical withdrawal symptoms, depending on the length and amount of alcohol use. Alcohol withdrawal syndrome is characterized by an increased heart rate and blood pressure, diaphoresis, mild anxiety, restlessness, and hand tremors. The most severe symptoms are delirium tremens (autonomic hyperarousal, disorientation, hallucinations), grand mal (tonic-clonic) seizures, and even status epilepticus (continuous seizures, lasting more than 30 minutes). These symptoms can be life threatening ([Table 31.3](#)). In patients with alcoholism and in chronic drinkers, the alcohol withdrawal syndrome usually begins within 12 hours after abrupt discontinuation or attempt to decrease consumption. If seizures occur, they usually do so within the first 48 hours of withdrawal.

Alcohol withdrawal can be accomplished safely without a person experiencing serious physical consequences. **Detoxification** is period of time where the patient is observed, usually in a hospital setting, and given medications to avoid withdrawal symptoms. Uncomplicated alcohol withdrawal is usually completed within 48 to 96 hours. Assessing for vital sign changes, nausea, vomiting, tremors, perspiration, agitation, headache, and change in mental status are important nursing interventions. The Clinical Institute Withdrawal Assessment for Alcohol Scale (CIWA-Ar) is frequently used for assessment ([Box 31.2](#)). Close monitoring continues until there is no indication of withdrawal symptoms.

TABLE 31.3 ALCOHOL WITHDRAWAL SYNDROME

	Stage II: Moderate	Stage III: Severe
Stage I: Mild		

Vital signs	Heart rate elevated, temperature elevated, normal or slightly elevated systolic blood pressure	Heart rate, 100–120 bpm; elevated systolic blood pressure and temperature	Heart rate, 120–140 bpm; elevated systolic and diastolic blood pressures; elevated temperature
Diaphoresis	Slight	Usually obvious	Marked
Central nervous system	Oriented; no confusion; no hallucinations Mild anxiety and restlessness Restless sleep Hand tremors; “shakes”; no convulsions	Intermittent confusion; transient visual and auditory hallucinations and illusions (mostly at night) Painful anxiety and motor restlessness Insomnia and nightmares Visible tremulousness, rare convulsions	Marked disorientation, confusion, disturbing visual and auditory hallucinations, misidentification of objects, delusions related to the hallucinations, delirium tremens, disturbances in consciousness Agitation, extreme restlessness, and panic states Unable to sleep Gross uncontrollable tremors, convulsions common
Gastrointestinal system	Impaired appetite, nausea	Anorexia, nausea and vomiting	Rejecting all fluid and food

Box 31.2

Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

Patient: _____ **Date:** _____ **Time:** _____ (24-h clock, midnight = 00:00)

Pulse or heart rate, taken for 1 min: _____ **Blood pressure:** _____

NAUSEA AND VOMITING – Ask, “Do you feel sick to your stomach? Have you vomited?”
Observation.
0 no nausea and no vomiting
1 mild nausea with no vomiting
2
3

TACTILE DISTURBANCES – Ask, “Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?” Observation.
0 none
1 very mild itching, pins and needles, burning or numbness
2 mild itching, pins and needles, burning or numbness
3 moderate itching, pins and needles, burning or numbness
4 moderately severe hallucinations

4 intermittent nausea
with dry heaves
5
6
7 constant nausea,
frequent dry heaves
and vomiting

5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

TREMOR – Arms
extended and fingers
spread apart.
Observation.
0 no tremor
1 not visible but can be
felt fingertip to
fingertip
2
3
4 moderate, with
patient's arms
extended
5
6
7 severe, even with
arms not extended

AUDITORY DISTURBANCES – Ask, “Are you
more aware of sounds around you? Are they harsh?
Do they frighten you? Are you hearing anything that
is disturbing to you? Are you hearing things you
know are not there?” Observation.
0 not present
1 very mild harshness or ability to frighten
2 mild harshness or ability to frighten
3 moderate harshness or ability to frighten
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

**PAROXYSMAL
SWEATS** –
Observation.
0 no sweat visible
1 barely perceptible
sweating, palms moist
2
3
4 beads of sweat
obvious on forehead
5
6
7 drenching sweats

VISUAL DISTURBANCES – Ask, “Does the light
appear to be too bright? Is its color different? Does it
hurt your eyes? Are you seeing anything that is
disturbing to you? Are you seeing things you know
are not there?” Observation.
0 not present
1 very mild sensitivity
2 mild sensitivity
3 moderate sensitivity
4 moderately severe hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

ANXIETY – Ask,
“Do you feel
nervous?”

Observation.

0 no anxiety, at ease

1 mild anxious

2

3

4 moderately anxious,
or guarded, so anxiety
is inferred

5

6

7 equivalent to acute
panic states as seen in
severe delirium or
acute schizophrenic
reactions

HEADACHE, FULLNESS IN HEAD – Ask,
“Does your head feel different? Does it feel like
there is a band around your head?” Do not rate for
dizziness or lightheadedness. Otherwise, rate
severity.

0 not present

1 very mild

2 mild

3 moderate

4 moderately severe\

5 severe

6 very severe

7 extremely severe

AGITATION –
Observation.

0 normal activity

1 somewhat more than
normal activity

2

3

4 moderately fidgety
and restless

5

6

7 paces back and forth
during most of the
interview, or
constantly thrashes
about

**ORIENTATION AND CLOUDING OF
SENSORIUM** – Ask, “What day is this? Where are
you? Who am I?”

0 oriented and can do serial additions

1 cannot do serial additions or is uncertain about
date

2 disoriented for date by no more than 2 calendar
days

3 disoriented for date by more than 2 calendar days

4 disoriented for place/or person

Total **CIWA-Ar** Score _____

Rater’s Initials _____

Maximum Possible Score 67

The CIWA-Ar is not copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal.

Sullivan, J. T., Sykora, K., Schneiderman, J., Naranjo, C. A., & Sellers, E. M. (1989). Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (**CIWA-Ar**). *British Journal of Addiction*, 84, 1353–1357.

Several medications are used to prevent physiologic complications and provide a gradual withdrawal from alcohol. Antianxiety and sedating drugs, such as benzodiazepines, are titrated downwardly over several days as a substitution for alcohol. Chlordiazepoxide (Librium) and diazepam have longer half-lives and smoother tapers. Lorazepam (Ativan) is better for older adults and people with liver impairment. Antidepressants are usually initiated to treat mood states, and sleep medication is used to promote a regular sleep pattern. Anticonvulsive and antipsychotic medications are also used if needed.

Alcohol withdrawal symptoms can occur in any patient who abuses alcohol and is forced to stop drinking because of an admission to a hospital or any alcohol-free environment. Patients who abuse alcohol for long periods of time are at high risk for alcohol withdrawal syndrome. Observing for signs of seizure activity is a priority nursing intervention.

Remember Gladys?

Gladys abruptly stopped her alcohol intake when she was admitted to the hospital for depression and suicidal thoughts. She did not tell her primary care provider that her intake of alcohol was significant. She began to go through withdrawal.

Alcohol-Induced Amnestic Disorders

Although certain alcohol-related cognitive impairments are reversible with abstinence, long-term alcohol abuse can cause specific neurologic complications that lead to organic brain disorders, known as alcohol-induced amnestic disorders. Alcohol is directly toxic to the brain, causing atrophy of the frontal cortex and eventually chronic brain syndrome. Patients with alcohol-induced amnestic disorders usually have a history of many years of heavy alcohol use and are generally older than 40 years. Poor dietary intake leads to deficiencies or insufficiencies in folic acid and thiamine (and other B vitamins), which are particularly important to numerous aspects of brain functioning (Lewis, 2020).

Wernicke encephalopathy, a degenerative brain disorder caused by thiamine deficiency, is characterized by vision impairment, ataxia, hypotension, confusion, and coma. Korsakoff amnestic syndrome, associated with alcoholism, involves the heart and the vascular and nervous systems, but the primary problem is acquiring new information and retrieving memories. Symptoms include amnesia, confabulation (i.e., telling a plausible but imagined scenario to compensate for memory loss), attention deficit, disorientation, and vision impairment. Although Wernicke encephalopathy and Korsakoff amnestic syndrome can appear as two different disorders, they are generally considered to be different stages of the same disorder called Wernicke–Korsakoff syndrome, with Wernicke encephalopathy representing the acute phase and Korsakoff amnestic syndrome the chronic phase. Early symptoms can be reversed, but without long-term treatment, the prognosis is poor (Yoon et al., 2019).

Prevention of Relapse

Relapse prevention is important in the recovery of people with substance-related disorders, and alcohol addiction is no exception. Psychosocial interventions such

as self-help groups, psychoeducation, and cognitive behavioral therapy (CBT) are designed specifically for those with alcohol addictions. These interventions are discussed later in this chapter.

Other medications are used for those who are recovering. Disulfiram (Antabuse) is neither a treatment nor a cure for alcoholism, but it can be used to help deter some individuals from drinking while using other treatment modalities to teach new coping skills to alter abuse behaviors. Disulfiram plus even small amounts of alcohol produces episodes of severe nausea and vomiting. These unpleasant reactions are expected to deter drinking. Severe reactions may also occur, and these include respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death. Those taking this drug must be informed about consuming unexpected sources of alcohol (wine and malt vinegar, baked goods, nonalcoholic beer, and others) and that alcohol can be absorbed transdermally through the use of aftershaves, or lotions that contain alcohol. Informed consent is required to initiate disulfiram therapy, and there is some conjecture that disulfiram's effectiveness for alcohol aversion is attributable to the patient's awareness of having consumed it (Stokes & Abdijadid, 2020).

Acamprosate calcium is a delayed-release tablet that decreases alcohol intake and reduces the risk of returning to drink alcohol in the person who is alcohol-dependent. It is indicated for the maintenance of abstinence from alcohol in patients who are alcohol-dependent. Acamprosate is effective only if the individual is abstinent from alcohol prior to its initiation (2015). The maintenance dose (333 to 666 mg orally) must be taken with meals three times daily, which can discourage compliance with treatment.

Naltrexone was originally used as a treatment for heroin abuse, but it is now approved for the treatment of alcohol dependence (see [Box 31.3](#)). Naltrexone is formulated in a once-daily pill and a monthly injection (Vivitrol). Naltrexone does not treat withdrawal symptoms; its effects are due to blocking the mu receptors (opioid) in the brain. It has no abuse potential and does not result in the development of physical dependence. Reports from successfully treated patients suggest three kinds of effects: (1) it can reduce craving (the urge or desire to drink or use drugs despite negative consequences), (2) it can help maintain abstinence, and (3) it can interfere with the tendency to want to drink more if a recovering patient slips and has a drink. Naltrexone may be particularly useful in patients who continue to drink heavily. Some controversy still remains

about the effectiveness of these harm-reduction medications in promoting abstinence or reducing alcohol consumption. Patients have been known to stop using naltrexone if they plan to drink alcohol and restart it later, leaving them open to relapsing. More research considering other harm-reduction outcomes (reduced mortality, reduced incidence of adverse events) and studies that are better controlled to avoid attrition and selection bias are needed (Farhadian et al., 2020).

Naltrexone can also be administered via an intramuscular injection (Vivitrol), which must be given after opioid detoxification and may cause injection site reactions, including intense hip pain, induration, swelling, bruising, and severe reactions such as open wounds or sterile abscesses. Patients must have adequate gluteal muscle mass to support 4cc injection, and nurses must carefully monitor and rotate injection sites. Adverse reactions and pain at the injection site can contribute to nonadherence with therapy.

Box 31.3

Drug Profile: Naltrexone (Relistor)

DRUG CLASS: Narcotic antagonist

RECEPTOR AFFINITY: Binds to opioid receptors in the CNS and competitively inhibits the action of opioid drugs, including those with mixed narcotic agonist–antagonist properties

INDICATIONS: Adjunctive treatment of alcohol or narcotic dependence as part of a comprehensive treatment program

DOSAGE AND ADMINISTRATION: Available in 50-mg tablets

Adults: For alcoholism: 50 mg/day PO; for narcotic dependence: initial dose of 25 mg PO; if no signs or symptoms seen, complete dose with 25 mg. Usual maintenance dose is 50 mg/day PO.

Injectable intramuscular dose 380 mg/month, rotate and inspect gluteal sites of injection.

Children: Safety has not been established for use in children younger than 18 yrs.

HALF-LIFE (PEAK EFFECT): 3.9–12.9 h (60 min)

SELECTED SIDE EFFECTS: Difficulty sleeping, anxiety, nervousness, headache, low energy, abdominal pain or cramps, nausea, vomiting, delayed ejaculations, decreased potency, rash, chills, increased thirst, joint and muscle pain

WARNINGS: Contraindicated in pregnancy and patients allergic to narcotic antagonists. Use cautiously in narcotic addiction because the drug may produce withdrawal symptoms. Do not administer unless patient has been opioid free for 7–10 days; verify with a negative urine screen. Also, use cautiously in patients with acute hepatitis, liver failure, depression, or suicidal tendencies and in those who are breastfeeding. Must make certain patient is opioid free before administering naltrexone. Always give naloxone challenge test before using, except in patients showing clinical signs of opioid withdrawal.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Understand that this drug will help facilitate abstinence from alcohol and block the effects of narcotics.
- Wear a medical identification tag to alert emergency personnel that you are taking this drug.
- Avoid use of heroin or other opioid drugs; small doses may have no effect, but large doses can cause death, serious injury, or coma.
- Report any signs and symptoms of adverse effects.
- Notify other health care providers that you are taking this drug.
- Keep appointments for follow-up blood tests and treatment program.
- CNS, central nervous system; PO, oral.

Promotion of Health: Adequate Nutrition and Supplemental Vitamins

Multivitamins and adequate nutrition are essential for patients who are withdrawing from alcohol. Because malnutrition is common, other vitamin replacement may be necessary for certain individuals. Thiamine (vitamin B₁) is initiated during detoxification, given to decrease ataxia and other symptoms of deficiency. It is usually given orally, 100 mg three to four times daily, but can be given intramuscularly or by intravenous infusion with glucose. Folic acid deficiency is corrected with administration of 1.0 mg orally four times daily. Magnesium deficiency is also found in those with long-term alcohol dependence. Magnesium sulfate, which enhances the body's response to thiamine and reduces seizures, is given prophylactically for patients with histories of withdrawal seizures. The usual dose is 1.0 g intramuscularly, four times daily for 2 days.

Stimulants

Cocaine

Cocaine (also known as coke, snow, nose candy, flake, blow, big c, lady, white, or snowbirds) is made from the leaves of the *Erythroxylon coca* plant, turned into a coca paste that is refined into cocaine hydrochloride, a crystalline form (thus the white powder appearance), which is commonly inhaled or “snorted” in the nose, injected intravenously (with water), or smoked. The smokable form of

cocaine, often called *free-base cocaine*, can be made by mixing crystalline cocaine with ether or sodium hydroxide. Crack cocaine, often simply called “crack,” is a form of free-base cocaine produced by mixing the crystal with water and baking soda or sodium bicarbonate and boiling it until a rock precipitant remains. The hardened crystal is then broken into pieces (“cracked”) and smoked in cigarettes or water pipes. This extremely potent form produces a rapid high with intense euphoria and a dramatic crash. It is extremely addictive because of the intense and rapid onset of euphoric effects, which leave users craving for more.

After cocaine is inhaled or injected, the user experiences a sudden burst of mental alertness and energy (“cocaine rush”) and feelings of self-confidence, being in control, and sociability, which last 10 to 20 minutes. Enhanced sexual experiences and drive can get many started on regular use. This high is followed by an intense let-down effect (“cocaine crash”), in which the person feels irritable, depressed, tired, and craves more of the drug. Users experience a serious psychological addiction and pattern of abuse. Although cocaine users typically report that the drug enhances their feelings of well-being and reduces anxiety, cocaine is also known to bring on panic attacks in some individuals and may also contribute to sexual assault, as the user may not realize how rough they are being. This behavior can also contribute to sexually transmitted infections as condoms break, membranes tear, and blood or body fluids are exchanged. Long-term cocaine use leads to increased anxiety. Increased use of cocaine is associated with stress and drug craving (NIDA, 2018a), and toxic, potentially catastrophic cardiovascular problems, which may become chronic even in those whose exposure to cocaine is limited to occasional, recreational use.

Biologic Responses to Cocaine

Cocaine is absorbed rapidly through the blood–brain barrier and is also readily absorbed through skin and mucous membranes. Rapid intoxication occurs when cocaine is injected intravenously or inhaled. Cocaine increases dopaminergic and serotonergic activity by attaching to transport proteins and, in turn, by blocking neurotransmitter reuptake. Increased dopamine causes euphoria and psychotic symptoms. Cocaine increases norepinephrine levels in the blood, causing tachycardia, hypertension, dilated pupils, and rising body temperatures. Serotonin excess contributes to sleep disturbances and anorexia. With prolonged cocaine use, these neurotransmitters are eventually depleted.

Cocaine Intoxication

Intoxication causes CNS stimulation, the length of which depends on the dosage and route of administration. With steadily increasing doses, restlessness proceeds to tremors and agitation followed by convulsions and CNS depression. In lethal overdose, death generally results from respiratory failure. Toxic psychosis is also possible; it may be accompanied by physical signs of CNS stimulation (e.g., tachycardia, hypertension, cardiac arrhythmias, sweating, hyperpyrexia, convulsions).

Cocaine and alcohol taken together could cause a potentially dangerous reaction. Taken in combination, the two drugs are converted by the body to cocaethylene, which has a longer duration of action in the brain and is more toxic than either drug individually. Notably, this mixture of cocaine and alcohol is a common two-drug combination that frequently results in drug-related death (Singh, 2019).

Cocaine Withdrawal

Severe anxiety, along with restlessness and agitation, is among the major symptoms of cocaine withdrawal. Users quickly seek more cocaine or other drugs, such as alcohol, marijuana, or sleeping pills, to rid themselves of the terrible effects of crashing. Withdrawal causes intense depression, craving (i.e., a strong desire to use cocaine despite negative consequences), and drug-seeking behavior that may last for weeks. Individuals who discontinue cocaine use often relapse.

Long-term cocaine use depletes norepinephrine, resulting in a “crash” when use of the drug is discontinued that causes the user to sleep 12 to 18 hours. On awakening, withdrawal symptoms may occur, characterized by sleep disturbances with rebound rapid eye movement (REM) sleep, anergia (i.e., lack of energy), decreased libido, depression with possible suicidality, anhedonia, poor concentration, and cocaine craving. Treating individuals with cocaine addiction is complex because it involves assessing the psychobiologic, social, and pharmacologic aspects of abuse.

NCLEXNOTE In cocaine withdrawal, patients are excessively sleepy because of norepinephrine depletion. Recovery is difficult because of the intense cravings. Nursing interventions should focus on helping patients solve

problems related to managing these cravings.

Amphetamines

Amphetamines, known on the street as speed, uppers, ups, black beauties, pep pills, or copilots, were first synthesized for medical use in the 1880s. Amphetamines (Biphetamine, Delcobese, dextroamphetamine) and other stimulants, such as phenmetrazine and methylphenidate (Ritalin, Focalin), act on the CNS and peripheral nervous system. They are used to treat ADHD (Attention Deficit Hyperactivity Disorder) in adults and children, narcolepsy, depression, and obesity (on a short-term basis). Some people abuse these drugs to achieve the effects of alertness, increased concentration, a sense of increased energy, euphoria, and appetite suppression. Amphetamines are indirect catecholamine agonists and cause the release of newly synthesized norepinephrine. Similar to cocaine, they block the reuptake of norepinephrine and dopamine, but they do not affect the serotonergic system as strongly. They also affect the peripheral nervous system and are powerful sympathomimetics, stimulating both α - and β -receptors. This stimulation results in tachycardia, arrhythmias, increased systolic and diastolic blood pressures, and peripheral hyperthermia. The effects of amphetamine use, and the clinical course of an overdose, are similar to those of cocaine.

Methamphetamine

Methamphetamine, also known as meth, speed, ice, chalk, crank, fire, glass, and crystal, is an illegal potent CNS stimulant that releases excess dopamine responsible for the drug's toxic effects, including damage to nerve terminals. Highly addictive, it comes in many forms and can be smoked, snorted, orally ingested, or injected. A brief, intense sensation, or rush, is reported by those who smoke or inject methamphetamine. Oral ingestion or snorting produces a long-lasting high instead of a rush, which can continue for as long as half a day. This illegal substance is cheap, easy to make, and has devastating consequences.

High doses can elevate body temperature and stimulate seizures. Methamphetamine has a longer duration of action than cocaine and leads to

prolonged stimulant effects. Long-term effects include dependence and addiction psychosis (e.g., paranoia, hallucinations), mood disturbances, violent behavior, repetitive motor activity, stroke, contracting HIV and hepatitis, intense itching leading to skin sores from scratching, weight loss, and extensive tooth decay (Fig. 31.2) (NIDA, 2019g).

FIGURE 31.2 Severe tooth decay caused by abuse of methamphetamine.

Methamphetamine is often used in a “binge and crash” pattern. Tolerance occurs within minutes, and the pleasurable effect disappears even before the drug concentration in the blood falls significantly. After being assessed, referral of the patient to a drug treatment program is necessary. Long-term meth use can cause cardiac arrhythmias, similar to cocaine use. Babies born to meth-addicted mothers are highly irritable and frequently present with learning or other developmental delays. Parents addicted to methamphetamine often cannot meet

parenting responsibilities even after abstaining. They often need continuing support to achieve the parenting role, including interdisciplinary support from child welfare and addiction treatment services (Dyba et al., 2019).

MDMA and Other “Club Drugs”

The drug 3,4-methylenedioxymethamphetamine (MDMA), also known as Ecstasy or Molly, is known as a “club drug” because it is used by teens and young adults as part of the nightclub, bar, and rave scenes. MDMA, chemically similar to both stimulants and hallucinogens, causes activity of dopamine, norepinephrine, and serotonin to increase. It produces feelings of increased energy, pleasure, emotional warmth, and distorted sensory and time perception. MDMA can cause hallucinations, confusion, depression, paranoia, sleep problems, drug craving, severe anxiety, nausea, muscle cramping, involuntary teeth clenching, blurred vision, chills, and sweating. In higher doses, MDMA can sharply increase body temperature (i.e., malignant hyperthermia), leading to muscle breakdown, kidney and cardiovascular failure, and death. MDMA effects last about 3 to 6 hours (NIDA, 2018b).

Other drugs abused, such as Rohypnol gamma-hydroxybutyrate (GHB) and ketamine, which are predominantly CNS depressants, are also considered to be “club drugs.” Often colorless, tasteless, and odorless, the drugs can be ingested unknowingly. Known also as “date rape” drugs when mixed with alcohol, they can be incapacitating, causing a euphoric, sedative like effect and producing an “anterograde amnesia,” which means that individuals may not remember events they experience while under the influence of these drugs. Ketamine is associated with an increased heart rate and blood pressure, impaired motor function, memory loss, numbness, and vomiting. At high doses, delirium, depression, respiratory depression, and cardiac arrest can occur (NIDA, 2019a). Ketamine is used as an anesthetic in veterinary practice and is now an accepted treatment for depression related to chronic pain (Humo et al., 2020).

Nicotine

Nicotine, the addictive chemical mainly responsible for the high prevalence of

tobacco use, is the primary reason tobacco is named a public health menace. Smoking is more prevalent among people with alcoholism, polysubstance users, and persons with mental disorders than among the general population. Smoking is two to three times more prevalent in persons with mental illnesses than the general population and is two to six times higher among those with schizophrenia, bipolar disorder, post-traumatic stress disorder (PTSD), and alcohol/illicit drug use disorders (Smith et al., 2020).

Biologic Response to Nicotine

Nicotine stimulates the central, peripheral, and autonomic nervous systems, causing increased alertness, concentration, attention, and appetite suppression. Readily absorbed, it is carried in the bloodstream to the liver, where it is partially metabolized. It is also metabolized by the kidneys and excreted in urine (NIDA, 2020a).

Nicotine acts as an agonist of the nicotinic cholinergic receptor sites and stimulates autonomic ganglia in both the parasympathetic and sympathetic nervous systems, resulting in increased release of norepinephrine or acetylcholine. The release of epinephrine by nicotine from the adrenal medulla increases fatty acids, glycerol, and lactate levels in the blood, thereby increasing the risk for atherosclerosis and cardiac muscle pathology.

Other medical complications of nicotine use are numerous. Smoking cigarettes and cigars causes respiratory problems, lung cancer, emphysema, heart problems, and peripheral vascular disease. In fact, smoking is the largest preventable cause of premature death and disability. Cigarette smoking kills at least 480,000 people in the United States each year and makes countless others ill. The use of smokeless tobacco is also associated with serious health problems (NIDA, 2018c).

Repeated use of nicotine produces both tolerance and addiction. Recent research has shown that nicotine addiction is extremely powerful and is at least as strong as addictions to other drugs; most of those who quit relapse within 1 year (NIDA, 2020a).

Nicotine Withdrawal and Smoking Cessation

Nicotine withdrawal is marked by mood changes (e.g., craving, anxiety, irritability, depression) and physiologic changes (difficulty in concentrating,

sleep disturbances, headaches, gastric distress, increased appetite). Nicotine replacements, such as nicotine transdermal patches, nicotine gum, nasal spray, and inhalers, have been used successfully to assist in withdrawal by reducing the craving for tobacco. Patches are rotated on skin sites and help maintain a steady blood level of nicotine. They are used daily, with the decrease in strength of nicotine occurring during a period of 6 to 12 weeks.

Successful smoking cessation usually requires more than one type of intervention, including social support and education. However, studies do show that even giving a brief instruction to patients about quitting smoking can be effective. Medications are often used as a smoking cessation strategy. The antidepressant bupropion is marketed as Zyban to help people quit smoking. Another medication, varenicline tartrate (Chantix), reduces the craving and rewarding effects of nicotine by preventing nicotine from accessing one of the acetylcholine receptor sites involved with nicotine dependence, but it can cause depression and related psychiatric symptoms in some people. This side effect may limit its usefulness for some people with psychiatric disorders (Singh & Saadabadi, 2020).

Auricular therapy, or ear acupuncture, is being studied as a potential adjunctive treatment for nicotine addiction. Acupuncture is based on the principles of an ancient Chinese system of medicine with a goal of returning the body to a harmonic balanced state. Through stimulating acupoints on the ear, endogenous endorphin levels and regulation of the sympathetic nervous system changes the taste for tobacco, suppressing nicotine addiction, decreasing nicotine withdrawal symptoms, reducing the desire to smoke, and promoting cessation for a short period of time. Emerging research into this therapy shows positive effects (Vieira et al., 2018).

Electronic cigarettes (e-cigarettes) were introduced as smoking cessation aids. They are smokeless, battery-operated devices designed to deliver nicotine with flavorings or other chemicals to the lungs without burning tobacco to do so. They resemble regular tobacco cigarettes, cigars, or pipes. More than 250 e-cigarette brands are on the market. E-cigarettes are designed to simulate the act of tobacco smoking without the toxic chemicals produced by burning tobacco leaves. Their safety and effectiveness in smoking cessation are being studied because e-cigarettes deliver highly addictive nicotine into the lungs, and the vapor of some of them contains known carcinogens and toxic chemicals. Additionally, adolescents are increasingly using e-cigarettes believing they are safe, but they may instead serve as a gateway to try other tobacco products. On

May 5, 2016, the Food and Drug Administration (FDA) announced that nationwide tobacco regulations now extend to all tobacco products including e-cigarettes and their liquid solutions, cigars, hookah tobacco, and pipe tobacco (NIDA, 2016).

Caffeine

Caffeine is a stimulant found in many drinks (coffee, tea, cocoa, soft drinks), chocolate, and OTC medications, including analgesics, stimulants, appetite suppressants, and cold relief preparations. Metabolism of caffeine is very complicated, involving more than 25 metabolites, and varies among different populations. Recently, high-energy drinks, consisting of alcohol and caffeine, are being marketed to reduce the impairment caused by ingestion of alcohol. The reality is that these energy drinks give a false sense of physical and mental competence and decrease the awareness of impairment. Deaths have been associated with these drinks though causation is difficult to prove (Higgins, 2018)

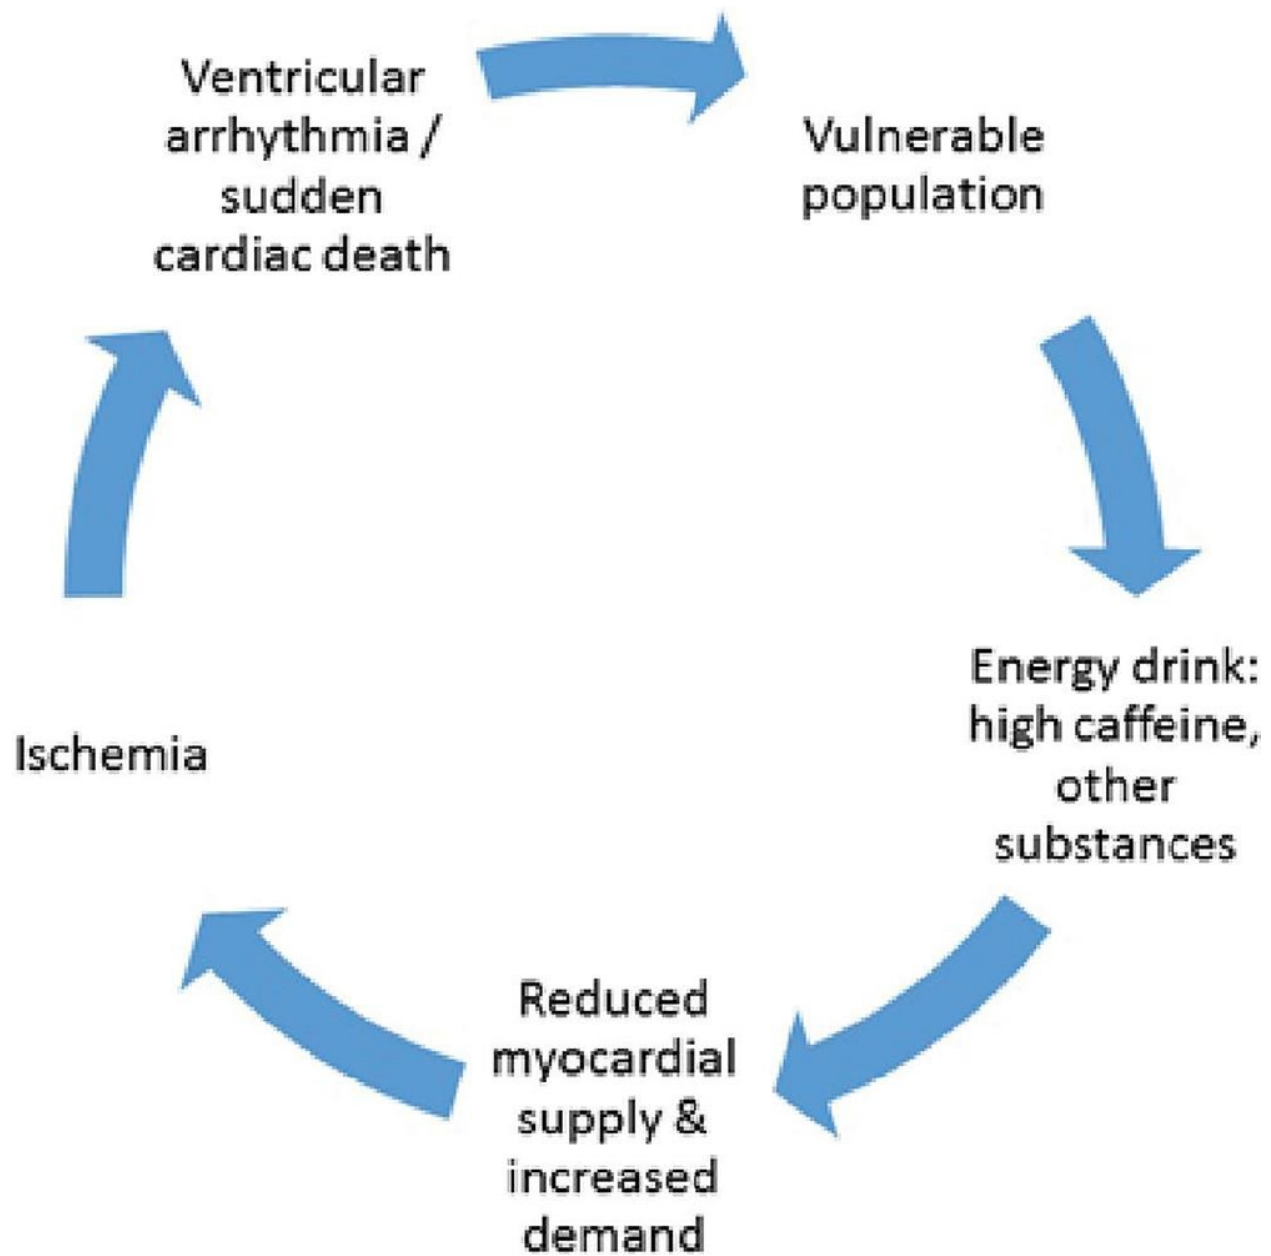

FIGURE 31.3 Possible mechanisms of sudden cardiac death associated with energy drink consumption. <https://www.acc.org/latest-in-cardiology/articles/2018/02/28/10/46/stimulant-containing-energy-drinks>

A suggested relationship between energy drinks and death can be seen in Figure 31.3.

Symptoms of caffeine intoxication can include the following: scattered thoughts, excessive talking, inability to focus on anything, irritability, elevated blood pressure, increased heart rate, nausea, anxiety, heart palpitations

(arrhythmias), insomnia, sweating, dizziness, vomiting, cardiac arrest. These may also appear in persons with no tolerance or high caffeine sensitivity (Caffeineinformer, 2020).

Caffeine withdrawal syndrome involves headache, drowsiness, and fatigue, sometimes with impaired psychomotor performance; difficulty concentrating; craving; and psychophysiologic complaints, such as yawning or nausea. Patients with caffeine dependence can be supported in their efforts at withdrawal by learning about the caffeine content of beverages and medication, using decaffeinated beverages, and managing individual withdrawal symptoms.

Cannabis

Marijuana is the common name for the plant *Cannabis sativa*, also known as hemp and many other names. Two main cannabinoids from the marijuana plant are well known: cannabidiol (CBD) and D-9-tetrahydrocannabinol (THC). Hashish, a resin found in flowers of the mature *C. sativa* plant, is its strongest form, containing 10% to 30% THC. Although there are other active ingredients in marijuana, THC gets the most attention because of its psychoactive properties.

Marijuana is fat soluble and is absorbed rapidly after being smoked or taken orally. After ingestion, THC binds with an opioid receptor in the brain—the μ -receptor. This action engages endogenous brain opioid receptors, which are associated with enhanced dopamine activity because THC blocks dopamine reuptake. THC can be stored for weeks in fat tissue and in the brain and is released extremely slowly. Long-term use leads to the accumulation of cannabinoids in the body, primarily the frontal cortex, the limbic areas, and the brain's auditory and visual perception centers. In other areas of the brain, it exerts cardiovascular effects, results in ataxia, and causes increased psychotropic effects. Marijuana use impairs the ability to form memories, recall events, and shift attention from one thing to another. It disrupts coordination of movement, balance, and reaction time. Contrary to popular belief, marijuana is addictive, is an irritant to the lungs, and can produce the same respiratory problems experienced by tobacco users (i.e., daily cough, phlegm). People who smoke marijuana miss work more often than those who do not smoke it, but it is not yet known whether marijuana smoke contributes to the risk of lung cancer (NIDA, 2019g).

Marijuana is usually smoked and causes relaxation, euphoria, at times

dyscoria (i.e., abnormal pupillary reaction or shape), spatial misperception, time distortion, and food cravings. It also causes relaxation and drowsiness, unlike other hallucinogens, and is often associated with decreased motivation after long-term use. Effects begin immediately after the drug enters the brain and last from 1 to 3 hours.

The FDA has approved drugs containing marijuana, such as dronabinol (Marinol) and nabilone (Cesamet), which contain THC and are used to treat nausea caused by chemotherapy. The known safety issues related to marijuana include impairment of short-term memory, altered judgment and decision-making, anxiety, and paranoia or psychosis, especially in high doses (NIDA, 2019g). Marijuana is legal as a recreational drug in some states in the United States.

“Spice” and “K2” are terms used for synthetic cannabinoid compounds found in various herbal mixtures that produce an experience similar to that of marijuana. Spice mixtures of this type are illegal to sell in the United States because of their addictive properties. The effects of synthetic cannabinoids can be unpredictable and severe or even life threatening. Some of these compounds bind more strongly to the same receptors as THC and could produce a more powerful and unpredictable effect. Spice products are popular among young people and are second only to marijuana among illegal drugs, used mostly by high school seniors. Emergency departments are seeing an alarming increase in adolescents being treated for severe adverse events related to synthetic cannabinoid use. Fatalities can occur, and there is no antidote available (NIDA, 2018e, 2018i).

Hallucinogens and Dissociative Drugs

The term *hallucinogen* refers to drugs that produce euphoria or dysphoria, altered body image, distorted or sharpened visual and auditory perception, confusion, lack of coordination, and impaired judgment and memory. Hallucinogens cause hallucinations and profound distortions in a person’s perceptions of reality. These drugs can be made from plant sources and mushrooms or are man made. They are categorized as hallucinogens and dissociative drugs. When under the influence of either type of drug, people report rapid, intense emotional swings and seeing images, hearing sounds, and feeling sensations that seem real but are not. Severe reactions may cause

paranoia, fear of losing one's mind, depersonalization, illusions, delusions, and hallucinations. Hallucinogens typically affect the autonomic and regulatory nervous systems first, increasing heart rate and body temperature, and slightly elevating blood pressure. The individual may experience a dry mouth, dizziness, and subjective feelings of being hot or cold. Gradually, these physiologic changes fade, but then perceptual distortions and hallucinations may become prominent. Intense mood and sexual behavior changes may occur; the user may feel unusually close to others or distant and isolated. Classic hallucinogens include LSD (d-lysergic acid diethylamide), psilocybin (4-phosphoryloxy-*N*, *N*-dimethyltryptamine), Peyote (Mescaline), DMT (dimethyltryptamine), and Ayahuasca (an ethnogenic brew, often used for spiritual ceremonies). Dissociative drugs include PCP (phencyclidine), DXM (dextromethorphan), *Salvia divinorum*, and ketamine (see later). DXM is a cough suppressant and expectorant ingredient in some OTC cold and cough medicines and is commonly abused by adolescents and young adults (NIDA, 2017).

The true content of hallucinogenic drugs purchased on the street is always in doubt; they are often misidentified or adulterated with other drugs. There are more than 100 different hallucinogens with substantially different molecular structures (NIDA, 2019c).

Patients in acute states of intoxication or in dissociated states may become combative. During the acute state, the primary intervention goals are to reduce stimuli, maintain a safe environment for the patient and others, manage behavior, and observe the patient carefully for medical and psychiatric complications. Instructions to the patient should be clear, short, and simple, and delivered in a firm but nonthreatening tone.

Prescription and Over-the-Counter Drugs

The overall opioid prescribing rate in the United States has been declining since 2012, after peaking and leveling off in 2010–2012, but the amount of opioids prescribed per person is still around three times higher than it was in 1999 (NIDA, 2020b). The United States is still in the midst of an epidemic of prescription opioid overdose deaths. In 2017, an average of 41 persons died each day from an overdose. The highest overdose death rates were in West Virginia, Delaware, Maryland, Pennsylvania, and Ohio (NIDA, 2020). Abuse of prescription and OTC drugs occurs when one of the following criteria is met:

- Taking a medication that has been prescribed for someone else
- Taking a drug in higher quantity or in another manner than prescribed
- Taking a drug for another purpose than prescribed (NIDA, 2018d)

The opioids (e.g., oxycodone, hydrocodone, morphine, fentanyl, codeine) prescribed for pain are some of the more commonly abused prescription medications. The most commonly abused CNS depressants are the benzodiazepines [diazepam, alprazolam, clonazepam, lorazepam]), which are prescribed for anxiety and sleep. The *DSM-5* diagnosis *Sedative, hypnotic, or anxiolytic use disorder* would be given when these drugs are abused. Amphetamines (Adderall, Dexedrine) and methylphenidate (Concerta, Ritalin) are stimulants prescribed for ADHD that are also frequently abused or diverted for illicit purposes. Nurses are well positioned to address the significant public health problem of opioid (and other drug) diversion, through patient education and medication monitoring. Often, patients combine these drugs with alcohol, which is extremely dangerous and can put patients at risk for overdose, causing coma or death.

OTC cough medicine containing DXM can produce the same effects as those of ketamine or PCP, such as impaired motor function, numbness, nausea or vomiting, and increased heart rate and blood pressure. In some cases, severe respiratory depression and hypoxia have occurred (NIDA, 2017).

Opioids and Morphine Derivatives

The term **opioid** refers to any substance that binds to an opioid receptor in the brain to produce an agonist action. Derived from poppies, opioids are powerful drugs that have been used for centuries to relieve pain. They include opium, heroin, fentanyl, morphine, and codeine. Even centuries after their discovery, opioids are still the most effective pain relievers. They also cause CNS depression, sleep, or stupor. Although heroin has no medicinal use, other opioids, such as morphine and codeine, are used to treat pain related to illnesses (e.g., cancer) and during medical and dental procedures. When used as directed by a clinician, opioids are safe and generally do not produce addiction. However, opioids also possess very strong reinforcing properties and can quickly trigger addiction when used improperly.

Two important effects produced by opioids are pleasure (or reward) and pain

relief. The brain itself also produces substances known as endorphins that activate the opioid receptors. Opioids cause tolerance and physical dependence that appear to be specific for each receptor subtype. Tolerance develops, particularly to the analgesic, respiratory depression, and sedative actions of opioids. Often, a 100% increase in dose is used to achieve the same physical effects when tolerance exists. Physical dependence can develop rapidly. When the use of the drug is discontinued, after a period of continuous use, a rebound hyperexcitability withdrawal syndrome usually occurs. [Table 31.4](#) describes the onset, duration, and symptoms of mild, moderate, and severe withdrawal symptoms.

Heroin is an illegal, highly addictive drug that is mostly abused and the most rapidly acting of the opioids. Typically sold as a white or brownish powder or as the black sticky substance known as “black tar heroin” on the streets, it is frequently “cut” with other substances, such as sugar, starch, powdered milk, quinine, and strychnine, or other poisons. It can be sniffed, snorted, and smoked but is most frequently injected, which poses risks for transmission of HIV devices and other diseases resulting from the sharing of needles or other injection equipment.

Naturally occurring neurotransmitters normally bind to the μ -opioid receptors, which are involved in pain, hormonal release, and feelings of well-being. When heroin enters the brain, it is converted to morphine and immediately binds to the μ -opioid receptors, stimulating the release of dopamine, which causes an intense pleasurable rush. Usually, the individual also experiences a warm flushing of the skin, dry mouth, and a heavy feeling in the limbs. Side effects include nausea, vomiting, and severe itching. Following these initial side effects, drowsiness, clouded mental function, slowing of the heart rate, and extreme slowing of breathing can occur (NIDA, 2019d).

One of the most detrimental long-term side effects of heroin is addiction itself, which causes neurochemical and molecular changes and profoundly alters brain structure and composition. Enlarged ventricular spaces and loss of frontal volume are reported. Heroin also produces profound degrees of tolerance and physical dependence, which are powerful motivating factors for compulsive use and abuse. After becoming addicted, heroin users gradually spend more and more time and energy obtaining and using the drug until these activities become their primary purpose in life (NIDA, 2019c). Recently, there has been a sharp increase in opioid deaths, attributed to illegally produced fentanyl. While the prescription rates have remained relatively stable, there have been unprecedented

increases in the global supply, processing, and distribution of fentanyl by criminal elements beginning in 2013. An urgent, collaborative public health and law enforcement response is recommended by the Centers for Disease Control and Prevention (CDC, 2020). See [Figure 31.4](#).

Opioid Intoxication or Overdose

Emergency treatment of individuals with opioid intoxication is initiated with an assessment of CNS functioning, specifically arousal and respiratory functioning. Naloxone, an opioid antagonist, is given as a rescue drug when extreme drowsiness, slowed breathing, or loss of consciousness occurs. It reverses respiratory depression, sedation, and hypotension caused by the opioid agent. Administration of naloxone is life-saving. Naloxone is administered intravenously, intramuscularly, or intranasally. When administered intravenously, the pharmacologic effect is generally apparent within 2 minutes. When administered through other routes, the effect is more prolonged. Naloxone is active for 30 to 81 minutes. Depending upon the strength of the opiate, a second dose is often needed when reversing the overdose.

TABLE 31.4 SEVERITY OF OPIOID WITHDRAWAL SYNDROME

Initial Onset and Duration	Mild Withdrawal	Moderate Withdrawal	Severe Withdrawal
Onset: 8–12 h after last use of short-acting opioids. 1–3 days after the last use for longer acting opioids, such as methadone	Physical: yawning, rhinorrhea, perspiration, restlessness, lacrimation, sleep disturbance	Physical: dilated pupils, bone and muscle aches, sensation of “goose flesh,” hot and cold flashes	Nausea; vomiting; stomach cramps; diarrhea; weight loss; insomnia; twitching of muscles and kicking movements of legs; increased blood pressure, pulse, and respirations
Duration: Severe symptoms peak between 48 and 72 h. Symptoms abate in 7–10 days for short-acting opioids. Methadone withdrawal symptoms can last several weeks	Emotional: increased craving, anxiety, dysphoria	Emotional: irritability, increased anxiety, and craving	Emotional: depression, increased anxiety, dysphoria, subjective sense of feeling “wretched”

FIGURE 31.4 Fentanyl. <https://www.cdc.gov/drugoverdose/data/fentanyl.html>

Initial Opioid Detoxification

Ideally, opioid detoxification is achieved by gradually reducing an opioid dose over several days or weeks. Many treatment programs include administering low doses of a substitute drug, such as buprenorphine, or methadone, which can help satisfy the drug craving without providing the same subjective high. If opioids are abruptly withdrawn (“cold turkey”) from someone who is physically dependent on them, severe physical symptoms occur, including body aches, diarrhea, tachycardia, fever, runny nose, sneezing, sweating, yawning, nausea or vomiting, nervousness, restlessness or irritability, shivering or trembling, abdominal cramps, weakness, elevated blood pressure, and severe distress.

Maintenance Treatment

Methadone maintenance is the treatment of people with opioid addiction with a daily stabilized dose of methadone. Methadone is used because of its long half-life of 15 to 30 hours. It is a potent opioid and is physiologically addicting, but it satisfies the opioid craving without producing the subjective high of heroin (Box 31.4).

Detoxification is accomplished by setting the beginning methadone dose and then slowly reducing it during the next 21 days. Treatment programs determine the dose of methadone that will block subjective feelings of craving and will not cause somnolence or intoxication in patients. The initial dose of methadone is determined by the severity of withdrawal symptoms and is usually 20 to 30 mg orally. If symptoms persist after 1 to 2 hours, the dosage can be raised. Dosage should then be re-evaluated daily during the first few days of treatment. Initial doses exceeding 40 mg can cause severe discomfort as the detoxification proceeds.

Patients receive this dose daily in conjunction with regular drug abuse counseling focused on the elimination of illicit drug use; lifestyle changes, such as finding friends who do not use drugs or achieving stability in one's living situation; strengthening social supports; and structuring time into pursuits that do not involve drug use. After illicit drug use ceases for a period of time, major lifestyle changes have been made, and social supports are in place, patients may gradually detoxify from methadone with continuing support through community support groups, such as Narcotics Anonymous.

The length of methadone treatment varies for each patient. The protocol for starting detoxification from methadone varies widely, depending on the patient's commitment to abstinence, lifestyle changes that have occurred, and strong peer group support, all of which are needed to sustain the patient during methadone detoxification when increased cravings often occur. Methadone treatment combined with behavioral therapy and counseling has been used effectively and safely to treat opioid addiction for more than 40 years. Combined with behavioral therapy and counseling, methadone enables patients to stop using heroin.

Drug Profile: Methadone (Dolophine)

DRUG CLASS: Narcotic agonist, analgesic

RECEPTOR AFFINITY: Binds to opioid receptors in the CNS to produce analgesia, euphoria, sedation; the receptors mediating the effects of endogenous opioids, which are thought to be enkephalins or endorphins

INDICATIONS: Detoxification and temporary maintenance treatment of narcotic addiction; relief of severe pain

DOSAGE AND ADMINISTRATION: Available in 5-, 10-, and 40-mg tablets; oral concentrate

Adults: Detoxification: Initially 15–30 mg. Increase dosage to suppress withdrawal signs. 40 mg/day in single or divided dose is usually an adequate stabilizing dose; continue stabilizing dose for 2–3 days; then gradually decrease dosage. Usual maintenance dose is 20–120 mg/day in single dosing.

Half-Life (Peak Effect):

PO 90–120 min

IM 1–2 h

SC 1–2 h

SAFE HANDLING: Store in a safe, locked place, use a calibrated measuring device, supervised compliance may continue for at least 6 months or longer. Dispense in a child-resistant container if home consumption is planned.

SELECTED SIDE EFFECTS: Light-headedness, dizziness, sedation, nausea, vomiting, facial flushing, peripheral circulatory collapse, arrhythmia, palpitations, urethral spasm, urinary retention, respiratory depression, circulatory depression, respiratory arrest, shock, cardiac arrest

WARNINGS: Never administer in the presence of hypersensitivity to narcotics, diarrhea caused by poisoning (before toxins are eliminated), bronchial asthma, or chronic obstructive pulmonary disease. Use caution in the presence of acute abdominal conditions and cardiovascular disease. Increased effect and toxicity of methadone are observed if taken concurrently with cimetidine and/or ranitidine. Methadone hydrochloride tablets are for PO administration only and *must not* be used for injection. It is recommended that methadone hydrochloride tablets, if dispensed, be packaged in child-resistant containers and kept out of the reach of children to prevent accidental injection.

SPECIFIC PATIENT AND FAMILY EDUCATION: AVOID USE OF ALCOHOL IN ANY FORM.

- Take drug exactly as prescribed.
- Take the drug with food while lying quietly; this should minimize nausea.
- Eat small, frequent meals to treat nausea and loss of appetite.
- If experiencing dizziness and drowsiness, avoid driving a car or performing other tasks that require alertness.
- Administer mild laxative for constipation.
- Report severe nausea, vomiting, constipation, shortness of breath, or difficulty breathing. Methadone products, when used for treatment of narcotic addiction, shall be dispensed only by approved hospital and community pharmacies and maintenance programs approved by the FDA and designated state authority.
- CNS, central nervous system; COPD, chronic obstructive pulmonary disease; IM, intramuscular;

Naltrexone, similar to naloxone, has been used successfully to treat opioid addiction. It binds to opioid receptors in the CNS and competitively inhibits the action of opioid drugs, including those with mixed narcotic agonist–antagonist properties, thereby blocking the intoxicating effects. It differs from naloxone in that naltrexone is longer acting and is formulated as a 50 mg tablet given once daily. Naltrexone is not used as a rescue drug for respiratory depression associated with an opioid overdose. However, if an opioid-addicted individual takes naltrexone before they are fully detoxified from opioids, withdrawal symptoms may appear (see [Table 31.4](#)).

Buprenorphine is a long-acting partial agonist that acts on the same receptors as heroin and morphine, relieving drug cravings without producing the same intense “high” or dangerous side effects. At low doses, buprenorphine produces sufficient agonist effect to enable opioid-addicted individuals to discontinue the misuse of opioids without experiencing withdrawal symptoms. Buprenorphine carries a lower risk of abuse, addiction, and side effects, compared with full opioid agonists. Buprenorphine is highly bound to plasma proteins and metabolized by the liver. The half-life of buprenorphine is 24 to 60 hours. Buprenorphine has poor oral bioavailability and moderate sublingual bioavailability. Formulations for opioid addiction treatment are given as sublingual tablets, skin patches, or buccal films. Patients need careful instructions on handling and applying the films to achieve the correct dosage of medication. Buprenorphine and naloxone are combined into one formulation with a brand name of *Bunavail*, *Suboxone*, or *Zubsolv*, and are indicated for the maintenance treatment of opioid addiction. The medication is administered sublingually as a single dose, which may be repeated up to three times per day. The purpose of adding naloxone to buprenorphine is to protect the patient from an overdose in case the patient has been misusing opiates. Otherwise, naloxone has no beneficial purpose, due to the very low dose within this medication.

Subutex, a buprenorphine-only preparation, is safe in pregnant women and provides consistent support. Fetal exposure to buprenorphine in utero is associated with significantly shorter hospital stays, shorter length of neonatal abstinence syndrome (NAS), and decreased duration and frequency of pharmacotherapy for NAS (Bivin et al., 2019). There is no need to decrease dosage as delivery nears because there is no evidence of buprenorphine having differential neurodevelopmental outcomes among infants with NAS (Watchman

et al., 2018) (see [Box 31.5](#)).

Inhalants

Inhalants are organic solvents, also known as *volatile substances* that are CNS depressants. When inhaled, they cause euphoria, sedation, emotional lability, and impaired judgment. Intoxication can result in respiratory depression, stupor, and coma. Inhalants are typically abused by young children, with adolescents using less than younger children. Different inhalants tend to be used by various age groups. New users (ages 12 to 15) are more likely to abuse glue, shoe polish, hair spray, spray paints, gasoline, and lighter fluids. The 16- to 17-year-olds most commonly abuse nitrous oxide or “whippets” and adults a class of nitrites such as amyl nitrites or “poppers.” Addiction is rare, but inhalants can be intermediate between legal and illegal drugs, and their use can be fatal (NIDA, 2018g).

Most inhalants are common household or industrial products that give off mind-altering chemical fumes when sniffed. They include the following:

- **Volatile Solvents:** Liquids that vaporize at room temperature, such as paint thinners or removers, degreasers, dry-cleaning fluids, gasoline, and lighter fluid. Office supply solvents include correction fluids, felt-tip marker fluid, electronic contact cleaners, and glue.
- **Aerosols:** Sprays that contain propellant and solvents, such as spray paint, hair spray, fabric protector spray, aerosol computer cleaning products, vegetable oil spray, analgesics, asthma sprays, deodorants, and air fresheners.
- **Gases:** Household or commercial products, such as butane lighters and propane tanks, whipped cream aerosols or dispensers, and refrigerant gases, and medical anesthetics such as ether, chloroform, halothane, and nitrous oxide (“laughing gas”).
- **Nitrites:** Organic nitrites include cyclohexyl, butyl, and amyl nitrites. When marketed for illicit uses, organic nitrates are sold in small brown bottles labeled “video head cleaner,” “room odorizer,” “leather cleaner,” or “room deodorizer” (NIDA, 2012).

Box 31.5

Drug Profile: Buprenorphine (Suboxone, Bunavail, Zubsolv)

DRUG CLASS: Partial opioid agonist/antagonist

RECEPTOR AFFINITY: Partial agonist at the μ -opioid receptor and an antagonist at the kappa receptor. Will displace morphine, methadone, and other opioid full agonists from the receptor

INDICATIONS For pain management and during detoxification and opioid addiction, and long-term maintenance treatment of opioid addiction. May be initiated while the person is actively withdrawing from opioids.

DOSAGE AND ADMINISTRATION: Adults 4 mg to 36 mg/day in divided doses. Dosage level is related to the amount of narcotic and length of time patient has used opioids. The label indicates the dosage of buprenorphine and naloxone (4 mg/1 mg; 8 mg/2 mg, or 12 mg/3 m.

Available as a sublingual film or sublingual tablet.

HALF-LIFE (PEAK EFFECT): Buprenorphine can take up to 37 (two days to excrete 50% of the dose) naloxone has a shorter elimination half-life, 2–12 hours,

WARNING: Pregnant women should receive the buprenorphine-only sublingual tablet (Subutex).

SAFE HANDLING: Pill counts may be useful to encourage treatment adherence. Because the injectable is a narcotic, arrangements should be made to have the injection delivered by the pharmacy to the office where it will be administered. Prescribing qualifications are required. Keep out of the reach of children. Store in a closed container at room temperature, away from heat, moisture, and direct light; keep from freezing. Dispose medications in Drug Enforcement Administration (DEA) approved locations.

SELECTED SIDE EFFECTS: Lightheadedness, dizziness or fainting with position changes, cough, feeling of warmth or heat, flushing, headache, painful or difficult urination, slower back or side pain.

DRUG INTERACTIONS:

Multiple drug interactions including antianxiety, antidepressant or antipsychotic medications, and many others. can also cause serious allergic reactions and life-threatening anaphylaxis requiring immediate attention.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Stopping this medication may cause withdrawal symptoms.
- Do not take other medications without first checking with your doctor.
- Tell your provider/dentist that you are using this medicine prior to any procedure
- Notify your physician if you experience darkening or yellowing of the skin, diarrhea, tenderness in the upper stomach, pale stools, loss of appetite, nausea, or vomiting.
- Notify your physician should a rash, hives, hoarseness, trouble breathing or swallowing, swelling of hands, face, or mouth occur while you are using this medication.

Most inhalants other than nitrites depress the CNS in a manner similar to alcohol

(e.g., slurred speech, lack of coordination, euphoria, dizziness). They may cause light-headedness, hallucinations, and delusions. The nitrites enhance sexual pleasure by dilating and relaxing blood vessels. They are thought to be antagonistic at the NMDA receptor and may cause neuronal damage in the mesolimbic system (Cruz et al., 2019).

Inhalant Intoxication

Inhalants are easily absorbed through the lungs and are widely distributed in the body, reaching the highest concentrations in fat tissue and the nervous system, where the most profound effects are exhibited. Mild intoxication occurs within minutes and can last as long as 30 minutes. Often, the drugs are inhaled repeatedly to maintain an intoxicated state for hours. Initially, the person experiences a sense of euphoria, but as the dose increases, confusion, perceptual distortions, and severe CNS depression occur. Inhalant users are also at risk for sudden sniffing death, which can occur when the inhaled fumes replace oxygen in the lungs and CNS, causing the user to suffocate. Inhalants can also cause death by disrupting the normal heart rhythm, which can lead to cardiac arrest (NIDA, 2018h).

Long-Term Complications

Chronic neurologic syndromes can result from long-term use, which is linked to widespread brain damage and cognitive abnormalities that can range from mild impairment to severe dementia. In recent studies, considerably more inhalant users than cocaine users had brain abnormalities, and their damage was more extensive. Inhalant users also performed significantly worse on tests of working memory with diminished ability to focus attention, plan, and solve problems. However, inhalants can change brain chemistry and may permanently damage the brain and CNS. Magnetic resonance imaging scans of users demonstrate severe changes in cerebral white matter (NIDA, 2018h).

Steroids

Anabolic steroid is the name for synthetic substances related to the male sex hormones (androgens). Developed in the late 1930s to treat hypogonadism, they are also used to treat delayed puberty, some types of impotence, and wasting of the body caused by HIV infection or other diseases. They promote growth of skeletal muscle and the development of male sexual characteristics. More than 100 different types exist; to be used legally, all require a prescription. Some dietary supplements, such as dehydroepiandrosterone (DHEA) and androstenedione (Andro), can be purchased in commercial health stores. They are often used in the belief that large doses can convert into testosterone or a similar compound in the body that promotes muscle growth. They can be taken orally or intramuscularly. Some are applied to the skin as a cream or gel. When abused, these preparations are taken at 10 to 100 times higher doses than are used for medical disorders. Although use among men is higher than among women, use among women is growing (NIDA, 2018g).

Case reports and small studies indicate that in high doses, anabolic steroids increase irritability and aggression, “roid rage.” Some steroid users report that they have committed aggressive acts, such as physical fighting, armed robbery, using force to obtain something, committing property damage, domestic violence, stealing from stores, or breaking into a house or building. Users engage in these behaviors more often when they take steroids than when they are drug free. Other behavioral effects include euphoria, increased energy, sexual arousal, mood swings, distractibility, forgetfulness, and confusion (Ganson & Cadet, 2018.)

Anabolic steroids do not trigger a rapid increase in dopamine or cause the “high” associated with other drugs of abuse. However, long-term use can affect neurotransmitter pathways that regulate mood and behavior. With time, anabolic steroid use is associated with an increased risk for heart attacks and strokes, blood clotting, cholesterol changes, hypertension, depressed mood, fatigue, restlessness, loss of appetite, insomnia, reduced libido, muscle and joint pain, and severe liver problems (including hepatic cancer). Males can have reduced sperm production, shrinking of the testes, and difficulty or pain in urinating. Other undesirable body changes include breast enlargement in men and masculinization of women’s bodies. Both sexes may experience hair loss and acne. Intravenous or intramuscular use of the drug and needle sharing put users at risk for HIV, hepatitis B and C, and infective endocarditis, as well as bacterial infections at injection sites (NIDA, 2018g).

EMERGING DRUGS AND TRENDS

New drugs and drug-use trends rapidly enter our communities. The NIDA continuously reports on these drugs. Some of the newer drugs include synthetic cathinones (bath salts, Flakka), Krokodil (toxic homemade opioid), and synthetic hallucinogens (N-bomb).

Bath salts contain cathinone, an amphetamine like stimulant naturally found in the Khat plant (*Catha edulis*). Severe intoxication and dangerous health effects are associated with these drugs. These drugs, which are chemically similar to methamphetamines and MDMA, produce euphoria, increased sociability, and increased sex drive, as well as paranoia, agitation, and hallucinatory delirium. Indication is that they are strongly linked to abuse (NIDA, 2018j).

Synthetic hallucinogens (e.g., the N-bomb) are being sold as substitutes for LSD or mescaline. These chemicals, considered more powerful than LSD, act on serotonin receptors and can cause seizures, heart attack, or respiratory arrest and death (NIDA, 2018j).

NON-SUBSTANCE-RELATED ADDICTIVE DISORDERS

The *DSM-5* reflects developing understandings that certain compulsive behaviors characterized by risky use, urges, cravings, and “highs” make them similar to substance intoxication and dependence. Behavioral addictions may have similar neurocircuitry involved in reward, motivation as substance use disorders. Gambling disorder was included in the *DSM-5* and studies on other addictive behaviors (such as internet addiction, sex addiction, and food addiction) are accumulating (Petry et al., 2018). Gambling addiction is characterized by compulsive and problematic gambling behavior that leads to significant impairments in functioning or distress (APA, 2013). Some evidence shows that changes in the serotonin system are associated with addiction behavior, similar to results reported for nicotine and alcohol dependence (van Timmeren et al., 2018). Individuals with gambling problems are more likely to commit suicide than those who do not have a gambling problem and are less likely to seek mental health treatment (Karlsson & Håkansson, 2018)([Table](#)

31.5).

Compulsive gamblers feel omnipotent in their ability to win back what was lost. This omnipotence serves as self-deception that leads to denial. Care of these patients involves confronting such omnipotent beliefs. These individuals quickly irritate staff with their self-assurance and overbearing attitude. Staff education about the disorder is important. Family involvement is also crucial. Families often have been dealing with the patient in a dysfunctional manner. Relapse prevention involves learning about specific cues that trigger the gambling behavior.

TABLE 31.5 GAMBLING DISORDER CHARACTERISTICS AND CRITERIA

The individual with problematic and compulsive gambling leading to significant impairment in functioning or distress exhibits four (4) or more of the following over a 12-month course.

Need to use increasing amounts of money in order to achieve desired level of excitement.

Is restless or excessively irritable when attempting to control or abstain from gambling.

Repeated unsuccessful attempts made to control, reduce, or abstain from gambling.

Regularly preoccupied with gambling.

Seeks out gambling in order to cope with feelings of distress.

Regularly attempts to 'get even' by returning to gamble after losing large quantities of money.

Exhibits erratic behavior, such as lying in order to minimize or conceal gambling involvement.

Impairments noted in terms of interpersonal relationships, functioning at work, or performance in school.

Is reliant on others financially as the result of gambling.

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH SUBSTANCE-RELATED DISORDERS

The assessment process is, in part, a treatment intervention. Patients are often in denial about the severity of the problem and about its emotional, social, legal, vocational, or other consequences.

Mental Health Nursing Assessment

Assessment is crucial to understanding level of use, abuse, or dependence and to determining the patient's denial or acceptance of treatment. Assessment is often detailed and may involve family members and other loved ones. Along with the psychiatric nursing interview (see [Chapter 11](#)), specific areas should be assessed. [Box 31.6](#) gives examples of typical behaviors exhibited by individuals that are associated with each level of use, abuse, and addiction. The nurse can use the Substance Abuse Assessment as a guide in eliciting a substance use history in the assessment process ([Box 31.7](#)).

Usually, nurses encounter individuals during crisis when they are seeking professional help. These situations offer an opportunity to explore the denial that keeps their addiction thriving. The nurse's approach should be caring, matter-of-fact, gentle, and direct. Approaches that are punitive or attempt to elicit feelings of guilt or shame are destructive to the therapeutic relationship. Nursing Care Plan 31.1, which sets forth a plan of care for Gladys.

Box 31.6

Behaviors in Substance Use, Abuse, and Addiction

SUBSTANCE USE

- Does not have possible danger or potential legal problems
- Engages in use to enhance social situations and interaction
- Is not intended to result in intoxication
- Has control of the amount and frequency of use
- Exhibits socially acceptable behavior while using

PRESCRIPTION MEDICATION USE

- Use is for the dose, frequency, and indication prescribed.
- Use is for the particular episode of the condition for which it was prescribed.
- Use is coordinated among prescribing physicians.

SUBSTANCE ABUSE

- Use for intoxication or feeling of being “high”
- Use that interferes with normal life functions (e.g., producing sleep when inappropriate, excitability,

or irritability interfering with social interaction)

- Potential harm to self or others (e.g., driving while intoxicated, use of injection drug equipment)
- Use that has legal consequences (e.g., all uses of illicit drugs)
- Use resulting in socially unacceptable behavior (e.g., public drunkenness, verbal or physical abuse)
- Use to alter normal feeling states such as sadness or anxiety

PRESCRIPTION MEDICATION ABUSE

- Use is at a higher dose and greater frequency than prescribed
- Use is for indications other than prescribed or for self-diagnosed condition
- Use results in feeling tired, having a clouded mental state, or feeling “hyperactive” or nervous
- Supplementing medication with alcohol or drugs
- Soliciting more than one physician for the same medication
- Inability to control the amount and frequency of use
- Tolerance to larger amounts of the substance
- Withdrawal symptoms when stopping use
- Severe consequences from alcohol or drug use

SUBSTANCE ADDICTION

- Drug craving
- Compulsive use
- Presence of aberrant drug-related behaviors
- Repeated relapse into drug use after withdrawal

ABUSE INDICATORS

1. Tolerance (increasing use of drug or alcohol with the same level of intoxication): _____
2. Withdrawal symptoms: a. Shakes? _____ b. Tremors? _____ c. Cramps, diarrhea, or rapid pulse? _____ d. Feeling paranoid, fearful? _____ e. Difficulty sleeping? _____
3. Consequences of use (e.g., presenting problems, persistent or recurrent emotional, social, legal, or other problems): _____
4. Loss of control of amount, frequency, or duration of use: _____
5. Desire or efforts to decrease use or control use: _____
6. Preoccupation (increasing focus or time spent on use and obtaining substances): _____
7. Social, vocational, recreational activities affected by use: _____
8. Previous alcohol or drug abuse treatment: _____

NURSING CARE PLAN 31.1

The Patient with Alcoholism

Gladys is a 68-year-old widow admitted for depression and thoughts of committing suicide by carbon monoxide poisoning. On admission, she denied abuse of alcohol or other substances. She is placed on suicide precautions.

Gladys denies that she currently has suicidal ideation and admits that she was angry with her son, who would not let her see her grandchildren. She reports that she just wanted to go to sleep and not wake up. According to her son, he was concerned about the safety of his children when his mother was intoxicated. He found several wine and liquor bottles in her apartment.

Setting: Inpatient Detoxification Unit, Veterans Administration Medical Center

Baseline Assessment: First admission, last drink 7 PM. Admission vital signs: T 99.2°F, HR 98, R 20, BP 140/88 on admission to the ED. BAL of 0.07 mg%, becoming increasingly anxious and restless. Her CIWA-Ar was 16. She was given chlordiazepoxide 50 mg PO.

Four hours after admission, vital signs were T 99.8°F, HR 110, R 22, BP 152/100. Her CIWA-Ar was 13. She continued to be anxious and was tremulous, diaphoretic, and nauseous. According to CIWA-Ar protocol she was given chlordiazepoxide 25 mg. PO.

Associated Psychiatric Diagnosis

Alcohol withdrawal

Medications

Thiamine

Folic acid

Multivitamins

Chlordiazepoxide according to CIWA-Ar protocol

Priority of Care: Complications of Alcohol Withdrawal

Important Characteristics Associated Considerations

BAL

Abrupt cessation of alcohol intake

hyperactivity

History of heavy drinking

Outcomes

Initial

1. Minimize alcohol withdrawal symptoms.

Discharge

2. Relate an intent to practice selected prevention measures such as maintaining sobriety, removing loose throw rugs, using adequate lighting.

Interventions

Interventions

Rationale

Ongoing Assessment

Implement CIWA-Ar to identify stage of alcohol withdrawal and severity of symptoms. Monitor gait and motor coordination, presence of tremors, mental status, electrolyte balance, and seizure activity. The more severe the reactions, the more likely that disorientation, confusion, and restlessness increase. As the patient move from stage I to III, he become at higher risk for a fall or injury.

Determine whether Gladys is becoming more disoriented, increasing his risk for injury.

Institute seizure precautions (bed in low position, padded side rails). Withdrawal seizures usually occur within 48 hours after last drink.

Monitor for seizure activity.

Orient the patient to her surroundings and location of call light; maintain a

Disorientation often occurs as BAL drops. These symptoms can last several

Determine Gladys's level of orientation

consistent environment.	physical days.	to surroundings. Determine whether she can use a call light.
Avoid sudden moves, loud noises, discussion of patient with colleagues at bedside, and lighting that casts shadows downward.	Decreased stimulation helps calm the patient, which, in turn, promotes optimal CNS responses.	Observe reactions to loud noises and monitor room environment.

Evaluation

Outcomes (at 3 Days)	Revised Outcomes	Interventions
Gait steady; hydrated. No activity. Gladys is oriented, no increase in CIWA-Ar score.	Maintain current level of orientation.	Continue to monitor for any signs of disorientation.
BAL, blood alcohol level; BP, blood pressure; CNS, central nervous system; GAF, Global Assessment of Functioning; HR, heart rate; IM, intramuscular; PO, oral; PRN, as needed; R, respirations; T, temperature.		

Denial of a Problem

Denial can be expressed in diverse behaviors and attitudes and may not be

expressed as an overt denial of the problem. For example, patients may admit to a problem and even thank the nurse for helping them to realize they have a problem but insist they can overcome the problem on their own and do not need outside help.

KEYCONCEPT Denial is the patient's inability to accept their loss of control over substance use or the severity of the consequences associated with the substance abuse or addiction. Remember that denial may appear as confusion, distorted comparisons with other's drinking, difficulty reconciling past positive alcohol experiences with current problems, misunderstanding about the diagnosis of substance use, misguided beliefs that one can overcome an addiction by sheer will power, and refusal to believe that alcohol has had an effect on one's thoughts, feeling, behaviors, or relationships with others.

This quandary about the nature of the problem has often been met with confrontation by nurses and other professionals in the past. But argumentation, presenting evidence of addiction, and lecturing often fail to elicit admission of a problem or induce behavior change.

Gladys and Denial

Gladys continues to deny that she has a drinking problem. She is angry with her son for suggesting that she has a problem and refuses to sign a release of information for him.

Motivation for Change

Motivation is a key predictor of whether individuals will change their substance use behavior, but addiction is a chronic, relapsing biological condition. Motivation alone may be insufficient without additional support and treatment. People can only become addicted to substances that have receptors in the brain, which can be hi-jacked by the substance. This means that in the absence of the substance, the user does not experience pleasure and nothing besides the substance can take its place (not food, sex, or family). Urges to use can be so powerful that they overcome the best of motivations, even the desire to regain custody of one's children or to avoid going to jail. Over time, addiction dominates every aspect of the individual's life. While nurses can capitalize on the individual's motivation to change, they can't really be helpful unless they understand that recovery is a life-long process, requiring dramatic changes at the individual and family level, which must indeed be dealt with, "one day at a time."

KEYCONCEPT Motivation is a goal-oriented attitude that propels action for change and can help sustain the development of new activities and behaviors when additional support and treatment are available

Motivational interviewing is a method of therapeutic intervention that seeks to elicit self-motivational statements from patients, which creates a disconnect between the patient's goals and their continued alcohol and substance use disorder. The acronym FRAMES (which is short form for feedback, responsibility, advice, menu of strategies, empathy, and self-efficacy) summarizes elements of brief interventions with patients using motivational interviewing ([Box 31.8](#)).

Box 31.7

FRAMES—Effective Elements of Brief Intervention

FEEDBACK

Provide patients with personal feedback regarding their individual status, such as personal alcohol and other drug consumption relative to norms, information about elevated liver enzyme values, and other factors.

RESPONSIBILITY

Emphasize the individual's freedom of choice and personal responsibility for

change. General themes are as follows:

1. It's up to you; you're free to decide to change or not.
2. No one else can decide for you or force you to change.
3. You're the one who has to do it if it's going to happen.

ADVICE

Include a clear recommendation or advice on the need for change, typically in a supportive and concerned, rather than in a judgmental, manner.

MENU

Provide a menu of treatment options from which patients may pick those that seem more suitable or appealing.

EMPATHIC COUNSELING

Show warmth, support, respect, and understanding in communication with patients.

SELF-EFFICACY

Reinforce self-efficacy or an optimistic feeling that they can change.

NCLEXNOTE Motivational approaches are priority interventions for patients with substance-related disorders. They help patients recognize a problem and begin to develop change strategies for continuing recovery and relapse prevention.

Countertransference

Countertransference is the total emotional reaction of the treatment provider to the patient (see [Chapter 10](#)). Patients with substance-related disorders can generate strong feelings and reactions in nurses and other health care providers. These feelings can be generated by overtly unpleasant behaviors of the substance-dependent persons, such as lying, deceit, manipulation, or hostility, or these feelings may be more subconscious and stem from past experiences with people with alcoholism or addicts or even from dealing with situations in the health care provider's own family. To be able to overcome countertransference feelings, nurses must recognize that the patient's behaviors are a part of the disease process involved in addiction. This also requires that nurse reflect on how their own behaviors toward patients with addictions can contribute or

detract from the care they wish to provide.

Codependence

The concept of codependence emerged out of studies of women's relationships with husbands who abused alcohol. Today, the scope of codependency includes both men and women who grew up in any type of dysfunctional family system in which substance abuse may or may not have been a problem. Codependence has also been described as "enabling," in which an individual in a relationship with a person who abuses alcohol inadvertently reinforces the drinking behavior of the other person. The codependency label remains controversial and is viewed by some as an oversimplification of complex emotions and behaviors of family members. Mental health professionals should be careful not to use it as a catch-all diagnosis and to take special care to assess and plan interventions that address each person's particular situation, problems, and needs (Mental Health America, 2021).

CLINICAL JUDGMENT

For a hospitalized patient, the first priority is to determine whether the person will be withdrawing. After the person is no longer in danger of withdrawal symptoms, the nurse can discuss the use of substance and encourage the individual to seek help for the addiction. A patient's denial of a problem with substances is common and often a priority.

THERAPEUTIC RELATIONSHIP

It is critical that the nurse establish a therapeutic relationship with patients and families (Box 31.8). Several general guidelines are available for establishing therapeutic interactions with patients in substance abuse treatment programs:

- Encourage honest expression of feelings.
- Listen to what the individual is really saying.

- Express caring for the individual.
- Hold the individual responsible for their behavior.
- Provide fair and consistent consequences for negative behavior.
- Talk about specific objectionable actions.
- Do not compromise your own values or nursing practice.
- Communicate the treatment plan to the patient and to others on the treatment team.
- Monitor your own reactions to the patient.

Confrontation, or pointing out the inconsistencies in thoughts, feelings, and actions, can promote the person's experience of the natural consequences of one's behavior. Learning from previous behavior and its consequences is how change occurs. Confrontation can be very threatening to patients and should only occur within the context of a trusting relationship.

BOX 31.9 • THERAPEUTIC DIALOGUE: THE PATIENT WITH ALCOHOLISM

INEFFECTIVE APPROACH

Nurse: I would like to talk with you about your problem with alcoholism.

Gladys: Alcoholism! It's not that bad. Everyone has a few drinks now then!

Nurse: You tell me why you were drinking. Your wife left you. You drink a quart of vodka a day. Your BAL was 0.15% when you were admitted.

Gladys: So, what! I do have some problems, or I wouldn't be here. But, I'm not an alcoholic. (Denial)

Nurse: Do you know what an alcoholic is?

Gladys: Sure, I do. My father was one. He was a useless bum. I'm not anything like him.

Nurse: It sounds like you are a lot like him.

Gladys: I think I need to rest now. My back is killing me (avoidance).

EFFECTIVE APPROACH

Nurse: I would like to talk with you about what happens when you drink.

Gladys: It's not that bad. Everyone has a few drinks now and then!

Nurse: What concerns do you have about your drinking?

Gladys: I'm not really concerned. My son is. He thinks I drink too much.

Nurse: What does he tell you about that?

Gladys: Well, complains about it, but I just have a glass of wine at night.

Nurse: It sounds as if he is concerned about this, but you have your doubts about how serious it is. Your son is invited to our family education group, so he can learn about alcohol abuse.

Gladys: I have a lot of problems besides alcohol. I never use drugs. I only drink because it relaxes me and makes it easier to deal with stress.

Nurse: Many people drink to help them cope with stress. Sometimes the drinking itself can cause stress. While you are here,

do you think it would be useful to look at the stress in your life and how it relates to your drinking?

Gladys: Yes. But I only drink when things get too out of hand. My health is pretty good.

Nurse: We can provide information about your health and alcohol use. To evaluate what information may be helpful, I would like to get a little more information about your drinking.

CRITICAL THINKING CHALLENGE

- What effect did the nurse have on the patient in using the word **alcoholism** in the first interaction?
- Discuss what communication approaches the nurse used in the second scenario to engage the patient in disclosing problems with alcohol and her relationship with her son. How does this nurse's approach vary from the one in the first interaction?

MENTAL HEALTH NURSING INTERVENTIONS

Several treatment modalities are used in most addiction treatment (pharmacologic modalities were discussed earlier in this chapter), including 12-step program-focused, cognitive or psychoeducation, behavioral, group psychotherapy, and individual and family therapy. Discharge planning and relapse prevention are also essential components of successful treatment and so are incorporated into most programs. See [Table 31.6](#) for an overview of the different treatment approaches used in drug and alcohol addiction. Principles of effective treatment for addictions can be seen in [Box 31.10](#).

Because patients with substance-related disorders differ greatly, no single type of treatment program will work for every individual. Often, several approaches can work together, but others may be inappropriate. Treatment programs usually combine many different interventions to provide a comprehensive approach based on the individual's needs. Nursing interventions vary depending on the nature of the current problems and their severity. For a patient who is being

detoxified, physical interventions (e.g., monitoring vital signs and neurologic functioning) are necessary. When the substance use disorder is secondary to other physical or psychiatric problems, education of patient and family may be a priority.

Assessment and interventions should include culturally relevant data, such as unique physiologic responses to substances, behavioral responses to dependence, and social expectations and sanctions. Staff who are knowledgeable about cultural differences and issues are integral to successful treatment.

TABLE 31.6 CHEMICAL DEPENDENCE TREATMENT APPROACHES: PAST AND PRESENT

Approach	Conception of Etiology	Conception of Patient	Conception of Treatment Outcome	Conception of Treatment Process	Advantages of Approach	Disadvantages of Approach
Psychiatric	Symptom underlying emotional problem	of Emotionally disturbed	Emotional conflicts are resolved; emotional health improves	Psychotherapy, Not medication to treat cause of substance abuse	Not punitive, treats comorbidity	Focus is on mental health
Social	Society and environment cause dependence	and Victim circumstance	of Improved social functioning or improved environment	Removal of environmental influences and increasing coping responses to it	Stresses social supports and coping skills	Blames person and society” person responsible having addiction
Moral	Person morally —can’t “no”	is weak morally say deficient Addict	Moral recovery, increased willpower, self-control, and responsible behavior	“Street addict” behavior and manipulation confronted	Holds person responsible for actions and making amends	Punitive and low failure. an medical
Learning	Abuse is learned, reinforced behavior	a Has distorted thinking, poor coping skills	Patient learns new ways of thinking and coping skills	Cognitive therapy and techniques and coping skills taught	Not punitive; teaches new coping skills	Places emphasis on control
Disease	Probably caused by genetic	Has chronically or progressive	a Abstinence, arresting disease	Is treated as a primary disease,	Not punitive, stresses support	Minimizes health and discount

	biologic factors	disease	progression, and beginning of recovery process	reinforces patient is an addict and is sick	education	social u
12-Step	Combination of disease concept and “spiritual bankruptcy”	Has addiction and is powerless over substances	Abstinence, ongoing spiritual recovery	Use 12 steps, seeking spiritual support, making amends, serving others in need	Widespread success, emphasis is on quality of life and spiritual growth	Self-help not a program
Dual diagnosis	Both a primary substance dependency and a mental health disorder	Has both mental and substance abuse disorder	Improvement in both mental and substance abuse disorders	Concurrent treatment of both disorders	Treats both mental health disorder and dependency, minimizing relapse potential	Not enough; include other issues
Biopsychosocial	Biologic basis, with social and psychological influences	Has deficiencies in all three interacting areas	Improvement in mental and physical health, utilization of social supports	Concurrent treatment of all issues	Uses different modalities; more inclusive	Does not address patient's needs
Multivariant	Many different causes; may be different for each individual	Has multiple issues to be assessed and addressed	Particular issues for individual addressed, so improvement occurs	Treatment strategies are matched with individual patient needs	Treatment matched to individual's needs	Logistic problem to occur implementation
Neurobiological Medication-Assisted Treatment (MAT)	Primarily addiction is a brain-based disorder, involving the neurocircuitry in the brain associated with memory, reward and motivation and hijacking of mu receptors in the brain	Modification of behaviors related to alcohol or substance use and addictive behaviors	Use of medications to re-establish brain functions and support person through detoxification and recovery to prevent relapse using	Medication-assisted treatment improves quality of life, allows person to resume functioning and goal-oriented behavior unrelated to drug-seeking.	Controversial Access issues for many; Cost	

Box 31.10

Principles of Effective Treatment for Addiction

1. Addiction is a complex but treatable disease that affects brain function and behavior.
2. No single treatment is appropriate for everyone.
3. Treatment needs to be readily available.
4. Effective treatment attends to multiple needs of the individual, not just their drug use.
5. Remaining in treatment for an adequate period of time is critical.
6. Behavioral therapies—including individual, family, or group counseling—are the most commonly used forms of drug abuse treatment.
7. Medications are an important element of treatment for many patients, especially when combined with counseling and other behavioral therapies.
8. An individual's treatment and service plan must be assessed continually and modified as necessary to ensure that it meets their changing needs.
9. Many drug-addicted individuals also have concurrent mental disorders.
10. Medically assisted detoxification is only the first stage of addiction treatment and by itself does little to change long-term drug abuse.
11. Treatment does not need to be voluntary to be effective.
12. Drug use during treatment must be monitored continuously because lapses during treatment do occur.
13. Treatment programs should provide assessment for HIV/AIDS, hepatitis B and C, tuberculosis, and other infectious diseases, as well as provide targeted risk-reduction counseling, linking patients to treatment as necessary.

National Institute on Drug Abuse. (2018). *Principles of drug addiction treatment: A research-based guide* (3rd ed., pp. 3–4). Bethesda, MD <https://www.drugabuse.gov/publications/principles-drug-addiction-treatment-research-based-guide-third-edition/principles-effective-treatment>.

Brief Intervention

A growing body of evidence indicates that brief interventions are more effective than no treatment, and indications suggest that they are as effective as more intensive interventions. Screening, brief intervention, and referral to treatment (SBIRT) have been shown to be effective in helping individuals with high-risk alcohol use to seek help (Biroscak et al., 2019). Within the alcohol and other drugs field, brief intervention is a highly developed, researched, and widely accepted approach.

Screening and brief intervention are two separate skills that can be used together to reduce risky substance use. Screening involves asking questions

about alcohol or drug use. A **brief intervention** is a negotiated conversation between the professional and patient designed to reduce or eliminate alcohol and drug use.

Not everyone who is screened will need a brief intervention, and not everyone who needs a brief intervention will require treatment. In fact, the goals of screening and brief intervention are to reduce risky substance use before people become dependent or addicted.

Brief intervention is effective for several reasons. Research indicates that brief interventions are an appropriate response to patients presenting in a general health or community setting and who are unlikely to need, seek, or attend specialist treatment. Brief intervention—to be given clear concise information by a professional—may be all the patients may want. It is also an important part of the overall approach to harm reduction (discussed later in this chapter).

Brief intervention is most successful when working with people who

- Are experiencing few problems with their drug use
- Have low levels of dependence
- Have a short history of drug use
- Have stable backgrounds
- Are unsure or ambivalent about changing or ending their drug use

It is recommended that brief intervention at a minimum include

- Advising how to reduce patient's drug use
- Providing harm reduction information or self-help manuals relevant to the patient
- Giving the patient relevant information about the following:
 - The consequences of a drug conviction in terms of international travel and employment
 - Consequences of further or heavier drug charges

Discussing harm reduction strategies, especially those relating to the following:

- Overdose
- Violence
- Driving under the influence

- Safe practices (e.g., safe injecting, safe sex)
- Offering and arranging a follow-up visit

Cognitive and Cognitive Behavioral Interventions and Psychoeducation

Cognitive approaches to addiction hypothesize that if a patient can change the way they think about a situation, both the emotional reaction to it and the behavioral response will change. Psychoeducational materials, groups, and one-on-one interactions with nurses also impart information to reduce knowledge deficits related to alcohol and drug dependence (Box 31.11). CBT is a brief structured treatment that focuses on immediate problems. It enables patients to examine the thinking process that leads to decisions to use substances, analyze distortions in thinking, and develop rational responses to these distortions.

Enhancing Coping Skills

Improving coping skills is thought to be one component of preventing relapse into alcohol and drug use. Coping skills include the ability to use thought, emotion, and action effectively to solve interpersonal and intrapersonal problems and to achieve personal goals. Groups in addiction treatment programs that also have a relapse prevention component look at coping. The skills listed in Box 31.12 are often taught as coping strategies for dealing with alcohol and drug cravings. Patients role-play new behaviors and learn from the feedback they receive from other group members. They also increase their sense of competency to use these skills in real-life situations.

Group Interventions and Early Recovery

Isolation and alienation from friends and family are common themes in patients with substance-related disorders. In addition, thinking that has become distorted is left unchallenged without contact with others; thus, change is difficult. When a

patient enters a group that is working with the goals of continuing recovery, numerous healing advantages can occur.

Groups in treatment settings focus on immediate goals of maintaining sobriety and not on childhood issues. The emphasis is on using problem solving and other skills to deal with stressful events that threaten abstinence. This type of support group is also extremely effective in outpatient treatment settings. After a period of successful abstinence, group therapy can focus more on traditional psychotherapy work.

Box 31.11

Substance Abuse

When caring for the patient and family with substance abuse, be sure to include the following topic areas in the family's teaching plan:

- Psychopharmacologic agents, if used, including drug action, dosage, frequency, and possible side effects
- Manifestations of intoxication, overdose, and withdrawal
- Emergency medical system activation
- Nutrition
- Coping strategies
- Structured planning
- Safety measures
- Available treatment programs
- Family therapy referral
- Self-help groups and other community resources
- Follow-up laboratory testing, if indicated

Box 31.12

Skills Training Group Topics

INTERPERSONAL

Starting conversations

Giving and receiving compliments

Nonverbal communication

Receiving criticism

- Receiving criticism about drinking
- Drink and drug refusal skills
- Refusing requests
- Close and intimate relationships
- Enhancing social support networks
- Recognizing and Expressing Emotions

INTRAPERSONAL

- Managing thoughts about alcohol
- Problem solving
- Increasing pleasant activities
- Relaxation training
- Awareness and management of anger
- Awareness and management of negative thinking
- Planning for emergencies
- Coping with persistent problems

Individual Therapy

Often, individual therapy is helpful, particularly in conjunction with group therapy or family therapy. In addiction treatment settings, counselors meet with individuals to maintain focus on the goals and objectives of their treatment, to review the fears and anxieties that often arise in early recovery, and to devise new and healthy responses and solutions to stressful and difficult situations. Therapy shouldn't be considered as one size fits all. For instance, anxiety disorders are common comorbidities in substance abuse, but individuals with social anxiety whose anxiety becomes alarmingly high when they are asked to speak in public shouldn't be expected to participate in groups. Forcing their group participation would be counterproductive not only to the individual but also for others in the group.

Family Interventions

Family therapy, a vital part of addiction treatment, can be used in several beneficial ways to initiate change and help the family when the substance-abusing person is unwilling to seek treatment. Behavioral couples therapy for people with alcoholism can improve family functioning, reduce stressors, smooth marital adjustment, and lessen domestic violence and verbal conflict.

When the substance-abusing person seeks help, family therapy can help stabilize abstinence and relationships. Often, inpatient substance abuse treatment programs have family education and group therapy components that help meet these goals. Family therapy can also help to maintain long-term recovery and prevent relapse. Goals of family therapy should be realistic and obtainable. Action plans must be specific and organized into manageable increments. Target dates should be realistic, so pressure is minimal, yet there is motivation to act in a timely manner. Planning for the future is very difficult as long as alcohol or drug abuse continues.

Harm-Reduction Strategies

Harm reduction, a community health intervention designed to reduce the harm of substance use to the individual, the family, and society, has replaced a moral or criminal approach to drug use and addiction. It recognizes that the ideal is abstinence but works with the individual regardless of their commitment to reduce use. The goal is to reduce the potential harm of the associated behavior. Harm reduction initiatives range from widely accepted designated driver campaigns to controversial initiatives, such as provision of condoms in schools, safe injection rooms, needle exchange programs, and heroin maintenance programs.

Peer Support Self-Help Group

Alcoholics Anonymous (AA) was the first 12-step, self-help program (see [Box 31.13](#) for a list of these steps). AA is a worldwide fellowship of people with alcoholism who provide support, individually and at meetings, to others who seek help. The program steps include spiritual, cognitive, and behavioral components. Many treatment programs discuss concepts from AA, hold meetings at the treatment facilities, and encourage patients to attend community meetings when appropriate. They also encourage continuing use of AA and other self-help groups as part of an ongoing plan for continued abstinence. Twelve-step programs do not solicit members; engage in political or religious activities; make medical or psychiatric diagnoses; engage in education about addiction to

the general population; or provide mental health, vocational, or legal counseling (Alcoholics Anonymous, 2020). Using peer support and support groups is an accepted approach with many beneficial outcomes for participants, since nurses are often responsible for the selection and training of individuals who will serve as peer support specialists (PSS). Much can be learned from studies that reveal member's ideas about what works best, and who they can best work with (see Research Update [Box 31.14](#)).

Box 31.13

The 12 Steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God *as we understood Him*.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and, when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God, as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as a result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs.

The Twelve Steps are reprinted with permission of Alcoholics Anonymous World Services, Inc. (“A.A.W.S.”). Permission to reprint the Twelve Steps does not mean that A.A.W.S. has reviewed or approved the contents of this publication, or that A.A. necessarily agrees with the views expressed herein. A.A. is a program of recovery from alcoholism only - use of the Twelve Steps in connection with programs and activities which are patterned after A.A., but which address other problems, or in any other non-A.A. context, does not imply otherwise.

Alternative peer support groups differ from these programs in their approach. Four such groups in the United States are Women for Sobriety, Moderation Management, Men for Sobriety, and Self-Management and Recovery Training (SMART) Recovery. These groups are based on harm reduction philosophies and missions. Other harm reduction strategies for prevention of alcohol abuse can be seen in [Box 31.15](#).

Evaluation and Treatment Outcomes

Recovery from alcoholism is a journey, often lasting a lifetime. Recovery involves a change in lifestyle and, often, new relationships. Short-term outcomes can be evaluated within the treatment setting. Long-term outcomes are established and evaluated by the patient who often continues to use professional and nonprofessional support as needed.

Box 31.14

Research for Best Practices: Peer Support Services for Perinatal Opioid Users

Fallin Bennett, A., Elswick, A., & Ashfrord, K. (2020). Peer support specialists and perinatal opioid use disorder: Someone that's been there, lived it, seen it. Addictive Behaviors, 102(3), 106–204. doi:10.1016/j.addbeh

QUESTION: How do perinatal women who receive peer support services (PSS) during treatment for their substance use disorders describe the experience, and how can these services be improved?

METHODS: Focus groups were conducted in a clinic that serves postpartum women with perinatal opioid use disorder (OUD) who were parenting a child under the age of 5. From recorded interviews, content themes were analyzed in MAXQDA (software used for analysis of data in qualitative and mixed

FINDINGS: Four themes, 1. Feeling supported by peer support specialists, 2. Qualities of an 'ideal' peer support specialist, 3. Strategies to improve communication interactions with PSS, and 4. The importance of communication across the perinatal period was identified. Participants reported that PSS had a strong positive influence on their recovery and

offered strategies for others to further improve interactions with peer supports.

IMPLICATIONS FOR NURSING: As resources are strained and more women are diagnosed with perinatal opioid use disorder (OUD), nurses must be involved in searching for innovative, cost-effective ways to provide services. Nurses can be involved in selecting and training those who can best offer peer support. This study identified quality improvement ideas directly from service users, highlighting nurse's commitment to patient-centered care, while alerting nurse researchers to design studies that can determine the long-term contributions of peer

Expectancy Challenge Interventions Expectancy challenge interventions do not focus on abstinence or scare tactics but on an individual's perceptions of alcohol's effects and providing accurate information.

Negative expectancies are associated with reducing alcohol consumption and other negative consequences of use. This intervention has been delivered in different ways, including experiential learning, informational campaigns, and peer-support sessions.

Resisting Negative Peer Pressure Strategies to resist peer-pressure for drinking are taught and practiced. Strategies include what to say to peers, and what to do under continued pressure. Situations are rehearsed in anticipation of pressure, until the teen feels confident and comfortable using them.

CHEMICAL DEPENDENCY AND PROFESSIONAL NURSES

Although accurate epidemiologic data specific to nursing are scarce, evidence suggests that the prevalence of substance use disorders among nurses is similar to that of the general public (Kunyk, 2015). A nurse is just as susceptible to addiction as any other individual, but additional risk factors exist, such as access and availability of drugs, training in the administration and injection of drugs, and a familiarity with and a frequency of administering drugs. Working conditions may be difficult and involve staffing shortages, acutely ill patients, inadequate patient-to-nurse ratios, shift rotation, shifts lasting longer than 8 hours, and increased overtime all add additional stress to the nurse, which increases the risk of substance abuse. Because of the risk of losing a license to practice, nurses are very reluctant to seek help. To protect patients' safety and maintain the standards of the profession, many states have mandatory reporting laws. According to the nurse practice acts, any nurse who knows of any health care provider's incompetent, unethical, or illegal practice must report that information through proper channels.

In 1982, the American Nurses Association House of Delegates adopted a national resolution to provide assistance to impaired nurses. The peer assistance programs strive to intervene early, reduce hazards to patients, and increase prospects for the nurse's recovery. The program offers consultation, referral, and monitoring for nurses whose practice is impaired, or potentially impaired, because of the use of illicit drugs or alcohol or a psychological or physiologic condition.

A referral can be made confidentially by the employer, Employee Assistance Program, coworker, family member, friend, or the nurse herself or himself. If the nurse is willing to undergo a thorough evaluation to determine the extent of the problem and any treatment needed, all information is kept confidential from the Board of Nursing, so that the nurse does not face disciplinary action against their nursing license.

Some signs of substance abuse in nurses include mood swings, inappropriate behavior at work, frequent days off for implausible reasons, noncompliance with acceptable policies and procedures, deteriorating appearance, deteriorating job performance, sloppy illegible charting, errors in charting, alcohol on the breath,

forgetfulness, poor judgment and concentration, lying, and volunteering to act as the medications nurse.

Other characteristics of nurses with substance abuse include high achievement, both as a student and a nurse; volunteering for overtime and extra duties; no drug use unless prescribed after surgery or for a chronic illness; and family history of alcoholism or addiction.

SUMMARY OF KEY POINTS

- Substance use disorders are categorized according to the following substances: alcohol, caffeine, cannabis (marijuana), hallucinogens, inhalants, opioids, sedative-hypnotics, stimulants, tobacco, and others.
- Addiction is a condition of continued use of substances despite adverse consequences. Abuse occurs when a person uses alcohol or drugs for the purpose of intoxication or, in the case of prescription drugs, for purposes beyond their use.
- Accurate and comprehensive assessment is crucial in planning addiction treatment interventions. This assessment should consider all substances for pattern of use, including factors of tolerance; withdrawal symptoms; consequences of use; loss of control over amount, frequency, or duration of use; desire or efforts to cease or control use; and social, vocational, and recreational activities affected by use, history of previous addiction treatment, and family and social support systems.
- Denial of a substance use disorder is the individual's attempt to avoid accepting the diagnosis; it can be manifest in attempts to rationalize the substance use, minimize the harmful results, deflect attention from one's own problem to society's or someone else's, or blame childhood trauma.
- Nurses should use a nonconfrontational approach when dealing with patients in denial of their problems. Motivational interviewing approaches are most effective, using empathy and a nonjudgmental approach, to help the patient to realize the discrepancy between life goals and engaging in substance use, thus, motivating patients to change their self-destructive behaviors and make personal choices regarding treatment goals.
- Several effective modalities are used in addiction treatment, and many programs combine them, which may include 12-step programs, social skills groups, psychoeducational groups, group therapy, and individual and family therapies. No one best treatment method exists for all people.
- Substance use disorders have many social and political ramifications. No health profession is immune to having members who suffer with substance use disorders.

Unfolding Patient Stories: Andrew Davis

Part 1

Andrew Davis is 56 years old and voluntarily admitted himself to an alcohol rehabilitation facility after his wife asked him to move out of their home. Of his three children, only his son will speak to him. He refuses to attend group therapy and an Alcoholics Anonymous (AA) meeting. How can the nurse establish a therapeutic relationship during the treatment stage of withdrawal and throughout recovery? Why is it important to cultivate trust between the nurse, Andrew, and his family? How can the nurse encourage him to attend group therapy and the AA meeting?

CRITICAL THINKING CHALLENGES

1. Jeff H, a 35-year-old patient who abuses cocaine, has entered a rehabilitation program. What goals do you believe would be realistic to achieve by the end of his projected 30-day inpatient stay?
2. You are working in an orthopedic unit, and Mary L has been admitted for treatment for a fractured femur. She has been drinking recently and has a BAL of 0.08%. What further information in the following areas would you need to plan her care?
 - a. Medical
 - b. Alcohol and drug use related
 - c. Other psychosocial issues
3. Normal adolescent behavior is often similar to that associated with substance abuse. How would you differentiate this normal behavior from possible

substance abuse or addiction?

- i. John M has sought treatment for depression and job stress. He came to your psychiatric assessment unit smelling of alcohol. He believes that he does not have a drinking problem but a job problem. What interventions would you use for possible alcohol abuse or addiction?
- j. Sylvia G has been abusing heroin intravenously heavily for 2 years. She has come into the hospital with an abscess on her leg. What symptoms would you expect to observe as she experiences withdrawal? What medications would likely be used to ease these symptoms?
- j. After Sylvia G is free from withdrawal symptoms, she expresses interest in obtaining drug treatment. What are her options? How would you describe them to her?

Raymond L has been treated for hypertension at your clinic. You notice that he complains of peripheral neuropathy and has an unsteady gait. What other medical signs would corroborate alcoholism? What experiences have you had with addictions? What was your response? How do you think those experiences will affect you as you build your practice to help others with addictions and substance misuse?

Movie Viewing Guides

2019: *Uncut Gems* “Everything I do is not going right,” sobs Howard.

This film depicts the experience of a charismatic jeweler named Howard Ratner, who is involved in high-stakes betting scheme that could lead to a lifetime windfall or to the loss of everything he owns, including his family and even his life. The jeweler is entrenched in the fantasy world of gambling addiction, needing high and higher stakes to sustain the pleasure, and ultimately rocketing out of control. Winning or losing doesn’t really matter, so long as Howard gets an opportunity to make another bet and get on the roller coaster again. The film unfolds over a couple of days, but tension escalates at a rapid, high-adrenalin pace, that the viewer, for the space of this movie (only 135 minutes), is transported into the world of pathological gambling. When the movie ends, there is an audible sigh of relief on the part of the audience.

VIEWING POINTS: Identify the *DSM-5* criteria associated with behavioral use

disorder depicted and alluded to in the film. Notice how the addiction to gambling takes over Howard's life and the costs he is willing to pay in order to experience the high of gaming. Notice his alertness and arousal as he is preoccupied with the bet and notice too, how short the pleasure lasts, before Howard must once again engage in another high-stakes game. Look for Howard's lies, the level of his activity, the extent of measures he takes to hide his addiction. See if you recognize other comorbidities in Howard's behavior. Were you concerned about his safety? What was Howard's level of self-deception and how did he maintain it? Could you identify the phases of gambling addiction: winning, losing, desperation, and hopelessness? How did you feel as you witness Howard self-destruct? What would it be like to have Howard in treatment?

Eating Disorders

Nursing Care of Persons with Eating and Weight-Related Disorders

Mary Ann Boyd

KEYCONCEPTS

- body dissatisfaction
- body image distortion
- dietary restraint
- drive for thinness
- emotional dysregulation
- perfectionism

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of body image, body dissatisfaction, and gender identity in eating disorders.
2. Delineate the clinical symptoms of anorexia nervosa (AN) from those of bulimia nervosa (BN).
3. Analyze the primary theories explaining anorexia nervosa and bulimia

nervosa.

1. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with anorexia nervosa.
2. Apply a person-centered, recovery-oriented nursing process for persons with anorexia nervosa.
3. Identify medications used to treat people with anorexia nervosa.
4. Develop wellness strategies for persons with anorexia nervosa.
5. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
6. Discuss the importance of integrated health care for persons with anorexia nervosa.
7. Describe other eating and weight-related disorders.

KEY TERMS

- Anorexia nervosa (AN)
- Binge eating
- Binge eating disorder (BED)
- Bulimia nervosa (BN)
- Enmeshment
- Night eating syndrome
- Purging disorder
- Refeeding
- Refeeding syndrome
- Self-monitoring

Case Study

Ellen is a 20-year-old college sophomore admitted to an inpatient mental health unit after treatment in a medical unit, where she was

admitted for dehydration and electrolyte imbalance. Ellen has been bingeing and purging while in school to maintain a normal body weight.

INTRODUCTION

Since the 1970s, eating disorders have received national attention, primarily because several high-profile personalities and athletes with these disorders have received front-page news coverage. Since the 1960s, the increased incidence of anorexia nervosa and bulimia nervosa has prompted mental health professionals to address their causes and devise effective treatments.

Wellness depends on good nutritional status and healthy eating. Frequently, nurses will recommend reduction or increase of body to maintain physical health and well-being. In some people, eating and body weight determine their behavior, self-esteem, and self-concept. They strive to reach an unrealistic and unhealthy body weight leading to the development of an eating disorder. Even though eating disorders are defined as mental disorders, the consequences of their disordered eating lead to serious impairment of physical health and sometimes death. All nurses should be able to recognize the symptoms of an eating disorder.

EATING DISORDERS OVERVIEW

Eating disorders are characterized by disturbed eating and eating-related behaviors. The *DSM-5* classification of eating disorders includes pica (eating nonnutritive, nonfood substances), rumination disorder (repeated regurgitation of food), avoidant/restrictive food intake disorder (avoiding food, lack of interest in food), anorexia nervosa, bulimia nervosa, binge eating disorder (BED), and other disorders (APA, 2013). Disordered eating behaviors are often classified as subclinical or subthreshold cases of true eating disorders, such as anorexia nervosa and bulimia nervosa, which are psychiatric diagnoses. These individuals still need treatment despite not meeting the diagnostic criteria.

Even though eating disorders differ in definition, clinical course, etiologies,

and interventions, symptoms of these disorders, such as dieting, binge eating, and preoccupation with weight and shape, overlap significantly. Viewing the symptoms along a continuum from less to more severe eating behaviors helps with this conceptualization, as shown in [Figure 32.1](#). There are also common psychological characteristics of people with eating disorders ([Box 32.1](#)). This chapter highlights anorexia nervosa (AN), emphasizes bulimia nervosa (BN), and briefly discusses BED.

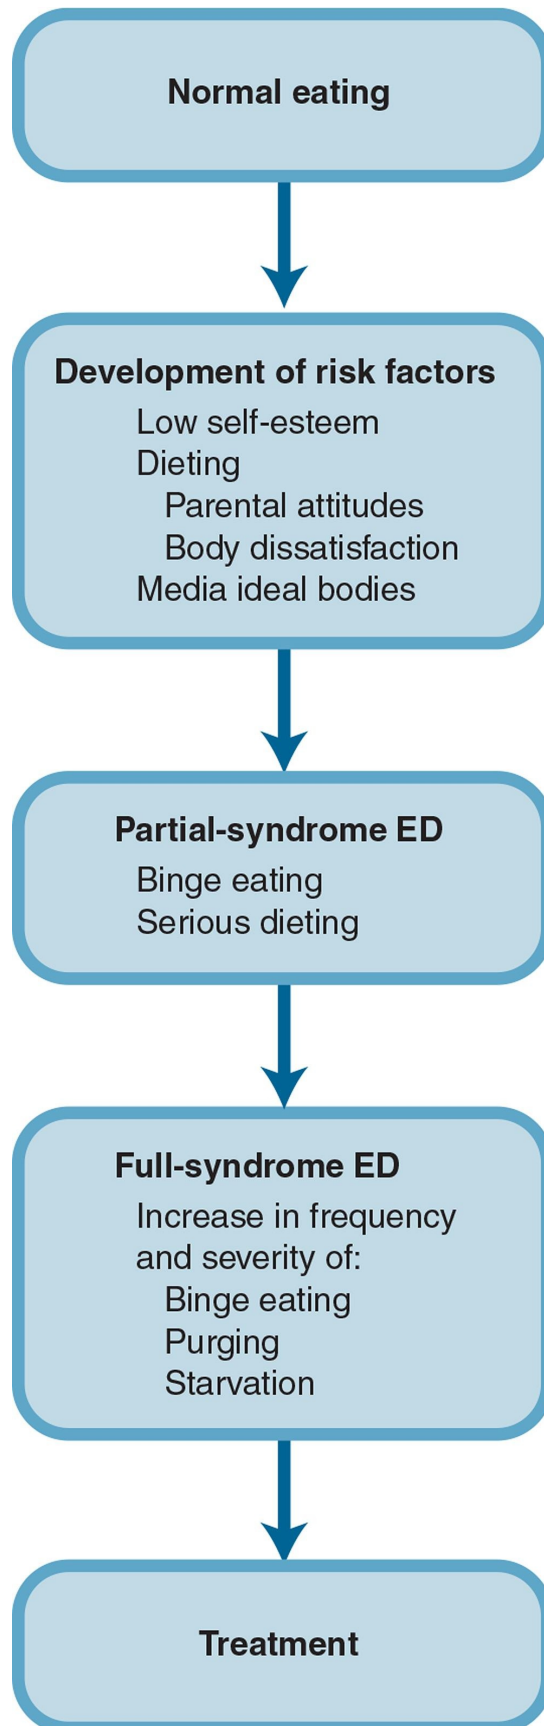

FIGURE 32.1 Progression of symptoms leading to an eating disorder.

ANOREXIA NERVOSA

Anorexia Nervosa is a mixture of symptoms that include significantly low body weight, intense fear of gaining weight or becoming fat, and a disturbance in experiencing body weight or shape (undue influence or distorted self-evaluation of body weight or shape or lack of recognition of the seriousness of low body weight).

Anorexia nervosa is further categorized into two major types: *restricting* (dieting and exercising with no binge eating or misuse of laxatives, diuretics, or enemas) and *binge eating and purging* (binge eating and misuse of laxatives, diuretics, or enemas). Malnutrition and semistarvation result in a preoccupation with food, binge eating, depression, obsession, and apathy, as well as compromising several body systems, leading to medical complications and, in some instances, death (APA, 2013).

Clinical Course

The onset of AN usually occurs in early adolescence. The onset can be slow, with serious dieting occurring before an emaciated body—the result of starvation—is noticed. This discovery often prompts diagnosis. Because the incidence of subclinical or partial-syndrome cases, in which the symptoms are not severe enough to use an anorexia nervosa diagnosis, is higher than that of anorexia nervosa, many young women may not receive early treatment for their symptoms, or in some cases, they receive no treatment. The individual's refusal to maintain a normal weight because of a distorted body image and an intense fear of becoming fat make individuals with this disorder difficult to identify and treat.

Box 32.1

Psychological Characteristics Related to Eating Disorders

ANOREXIA NERVOSA

- Sexuality conflict or fears
- Maturity fears
- Ritualistic behaviors
- Perfectionism
- Emotional Dysregulation

BULIMIA NERVOSA

- Impulsivity
- Boundary problems
- Limit-setting difficulties

ANOREXIA NERVOSA AND BULIMIA NERVOSA

- Difficulty expressing anger
- Low self-esteem
- Body dissatisfaction
- Powerlessness
- Ineffectiveness
- Perfectionism
- Dietary restraint
- Obsessiveness
- Compulsiveness
- Nonassertiveness
- Cognitive distortions

It can be a chronic condition with relapses characterized by significant weight loss. Reporting conclusive outcomes for anorexia nervosa is difficult because of the variety of definitions used to determine recovery. Although patients considered to have recovered have restored normal weight, menses, and eating behaviors, some continue to have distorted body images and be preoccupied with weight and food; many develop bulimia nervosa, and many continue to have symptoms of other psychiatric illnesses, especially of the anxiety disorders.

Body Distortion

For most individuals, body image (a mental picture of one's own body) is consistent with how others view them. However, individuals with anorexia nervosa have a body image that is severely distorted from reality. Because of this distortion, they see themselves as obese and undesirable even when they are emaciated. They are unable to accept objective reality and the perceptions of the outside world.

KEYCONCEPT **Body image distortion** occurs when the individual perceives their body disparately

from how the world or society views it.

Concept Mastery Alert

People with anorexia nervosa have a distorted image of the appearance of their bodies. They can be very thin and still perceive that they are heavy and need to lose weight.

Drive for Thinness

Because of body distortion, individuals with anorexia nervosa have an intense drive for thinness. They see themselves as fat, fear becoming fatter, and are “driven” to work toward “undoing” this fear.

KEYCONCEPT Drive for thinness is an intense physical and emotional process that overrides all physiologic body cues.

The individual with anorexia nervosa ignores body cues, such as hunger and weakness, and concentrates all efforts on controlling food intake. The entire mental focus of the young patient with anorexia nervosa narrows to only one goal: weight loss. Typical thought patterns are as follows: “If I gain a pound, I’ll keep gaining.” This all-or-nothing thinking keeps these patients on rigid regimens for weight loss.

The behavior of patients with anorexia nervosa becomes organized around food-related activities, such as preparing food, counting calories, and reading cookbooks. Much behavior concerning what, when, and how they eat is ritualistic. Food combinations and the order in which foods may be eaten, and under which circumstances, can seem bizarre. One patient, for example, would eat only cantaloupe, carrying it with her to all meals outside of her home and consuming it only if it were cut in smaller than bite-sized pieces and only if she could use chopsticks, which she also carried with her.

KEYCONCEPT Emotional dysregulation is a difficulty regulating expression of feelings. Emotional dysregulation and increased sensory sensitivity are linked to anorexia nervosa. Emotion dysregulation comprises one’s inability to accept one’s emotional responses, to accomplish goals in the midst of distress, and to be aware of and acknowledge the significance of developing and implementing coping strategies to influence and manage emotions effectively (Rotella et al., 2018).

NCLEXNOTE The emotional dysregulation model links deficits in emotional regulation with anorexia nervosa, that is, those with anorexia nervosa have deficits in the ability to understand and modulate emotions, which results in experiencing emotions as overwhelming and unmanageable. Consequently, those with anorexia nervosa use disordered eating to regulate their affective state by either reducing negative affect or increasing positive affect, and thus disordered eating, through reinforcement, is maintained (Rotella et al., 2018). Treatment programs that address emotional regulation and focus on teaching skills to regulate emotions may therefore be effective, especially with anorexia nervosa patients.

Guilt and Anger

Patients with anorexia nervosa tend to avoid conflict and have difficulty expressing negative emotions, especially anger (Duarte et al., 2016). They have an overwhelming sense of guilt and anger, which leads to conflict avoidance, which is common in families of those with anorexia nervosa. Because of the ritualistic behaviors, an all-encompassing focus on food and weight, and feelings of inadequacy, social contacts are gradually reduced, and the patient becomes isolated. More severe weight loss is associated with other symptoms, such as apathy, depression, and even mistrust of others.

Perfectionism

Emotional dysregulation is hypothesized to relate to perfectionism. Perfectionistic behavior, such as making sure that everything is symmetrical or that objects are placed at the same distance from each other, or in performance-based tasks, is a typical significant symptom of anorexia nervosa and bulimia nervosa and is hypothesized to develop long before eating symptoms occur. Findings from research demonstrate that perfectionism is a significant personality symptom risk factor in eating disorders (Wagner & Vitousek, 2019).

KEYCONCEPT Perfectionism consists of personal standards (the extent to which the individual sets and tries to achieve high standards for oneself) and concern over mistakes and their consequences for their self-worth and others' opinions.

-

It is now accepted that perfectionism precedes the development of weight and shape concerns. The more severe the disorder, the more perfectionistic. As symptoms are resolved, perfectionism may decrease (Larsson et al., 2018).

Guilt and Anger

Patients with anorexia nervosa tend to avoid conflict and have difficulty expressing negative emotions, especially anger (Duarte et al., 2016; Monell et al., 2018). They have an overwhelming sense of guilt and anger, which leads to conflict avoidance, common in these families. Because of the ritualistic behaviors, an all-encompassing focus on food and weight, and feelings of inadequacy, social contacts are gradually reduced, and the patient becomes isolated. More severe weight loss is associated with other symptoms, such as apathy, depression, and even mistrust of others.

Diagnostic Criteria

The diagnosis of anorexia is made when there is a restriction of intake, leading to significantly low body weight. The BMI is used as a measure of severity. Other criteria include an intense fear of gaining weight or becoming fat, and body image issues including an undue influence of body weight on self-concept and lack of recognition of seriousness of low body weight (APA, 2013). See Key Diagnostic Characteristics 32.1 for an overview of diagnostic criteria and associated findings.

Anorexia Nervosa Across the Life Span

Anorexia nervosa is primarily diagnosed in adolescence, with 90% of the cases in women (Andrade et al., 2017). There are reports of AN being diagnosed as young as 8 years old (Kwok et al., 2020). Anorexia nervosa is also the most common eating disorder diagnosed in individuals over 50 years of age. Late-onset AN is mostly diagnosed in women. AN in older adults is associated with significant psychiatric comorbidities and overall morbidity (Zayed & Garry,

2017).

Epidemiology

The 12-month prevalence of anorexia nervosa among young females is approximately 0.4%, but many researchers believe this figure does not reflect the true prevalence of this serious disorder (APA, 2013). Adjusted approximations estimate that eating disorders affect over 13% of adolescents and adult women, and 1% to 2% of men. The age of onset is typically between 14 and 16 years but can occur much earlier. Adolescents are vulnerable because of stressors associated with their development, especially concerns about body image, autonomy, and peer pressure, and their susceptibility to such influences as the media, which extols an ideal body type (Cheng et al., 2019; Mangweth-Matzek & Hoek, 2017).

Gender

Females are 10 times more likely than males to develop anorexia nervosa. This disparity has been attributed to society's influence on females to internalize a thin body as ideal highlights some of the findings about eating disorders in males. See [Box 32.2](#).

Key Diagnostics Characteristics: Anorexia Nervosa

- A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.
- B. Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
- C. Disturbance in the way in which one's body weight or shape is

experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

- **Restricting type:** During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.
- **Binge-eating/purging type:** During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Specify if:

- **In partial remission:** After full criteria for anorexia nervosa were previously met, Criterion A (low body weight) has not been met for a sustained period, but either Criterion B (intense fear of gaining weight or becoming fat or behavior that interferes with weight gain) or Criterion C (disturbances in self-perception of weight and shape) is still met.
- **In full remission:** After full criteria for anorexia nervosa were previously met, none of the criteria have been met for a sustained period of time.

Specify current severity:

The minimum level of severity is based, for adults, on current body mass index (BMI) (see later) or, for children and adolescents, on BMI percentile. The ranges given next are derived from World Health Organization categories for thinness in adults; for children and adolescents, corresponding BMI percentiles should be used. The level of severity may be increased to reflect clinical symptoms, the degree of functional disability, and the need for supervision.

- **Mild:** BMI ≥ 17 kg/m²

- **Moderate:** BMI 16 to 16.99 kg/m²
- **Severe:** BMI 15 to 15.99 kg/m²
- **Extreme:** BMI <15 kg/m²

Box 32.2

Adolescent Boys and Young Men with Eating Disorders

Eating disorders in boys and men are becoming more prevalent. Males present with eating disorders between the ages of 16 and 24 with different concerns than females with other specified eating disorders, night eating syndrome, and bulimia nervosa as the most prevalent disorders. Adolescent males are more likely to try to gain weight or bulk up and engage in muscle-enhancing behaviors, such as eating more or differently, using supplements, and taking androgenic-anabolic steroids. Overweight and obesity in males may be associated with disordered eating behaviors, including fasting, skipping meals, vomiting, laxatives, diuretics, or binge-eating. The stigma that eating disorders are a women's disease or the paucity of research related to eating disorders in males may inhibit identification in primary care. Because many of the assessment instruments and treatment protocols are geared toward females, males suffer from a lack of early identification of their disorders and early as well as successful treatment.

Nagata, J. M., Ganson, K. T., & Murray, S. B. (2020). Eating disorders in adolescent boys and young men: an update. *Current Opinion in Pediatrics*, 32(4), 476–481. <https://doi.org/10.1097/MOP.0000000000000911>

Ethnicity and Culture

In the United States, eating disorders occur in all ethnic and racial groups, and recent studies show there are very few differences in prevalence among European Americans, Latinex Americans, Asian Americans, and African Americans (Cheng et al., 2019). However, research findings demonstrate that Asian Americans have a higher level of belief that the ideal body is thinner than do other groups (Cheng et al., 2019). In Asian countries, eating disorders have risen over the last 10 years, attributed to not only the influence of Western countries' media but also to economic development itself (Pike & Dunne, 2015).

Risk Factors

Research demonstrates that genetic risks play an important role in the development of eating disorders in both men and women. Eating disorders are highly inheritable. Puberty is a risk period for the development of anorexia nervosa. Girls often begin to diet at an early age because of body dissatisfaction, and the need for control of prepubertal weight increases. Restricting food can lead to starvation, binge eating, and purging. Males are more likely to engage in physical activity than dieting. Females demonstrate a drive for thinness; males have increased concern with muscularity and shape (Timko et al., 2019).

Psychiatric disorders increase the risks of eating disorders. Low self-esteem, body dissatisfaction, and feelings of ineffectiveness also put individuals at risk. Bullying and weight teasing are other risk factors for the development of an eating disorder (Lie et al., 2019).

Elite athletes participating in lean sports, such as running and gymnastics, and nonelite athletes taking part in nonlean sports, such as soccer, experience a triad of symptoms (disordered eating, menstrual dysfunction, and osteoporosis). See [Box 32.3](#). Athletes involved in lean sports are at higher risk of developing an eating disorder.

Comorbidity

Depression is common in individuals with anorexia nervosa, and these individuals are at risk for suicide attempts (Sagiv & Gvion, 2020). Anxiety disorders such as obsessive-compulsive disorder (OCD), phobias, and panic disorder are strongly associated with anorexia nervosa. In many individuals with

anorexia nervosa, OCD symptoms predate the anorexia nervosa diagnosis by about 5 years, leading many researchers to consider OCD a causative or risk factor for anorexia nervosa (Udo & Gilo, 2019). In fact, perfectionism is an aspect of both OCD and anorexia nervosa and is considered a risk factor for anorexia nervosa (Wagner & Vitousek, 2019). These comorbid conditions may often resolve when anorexia nervosa has been treated successfully. However, in many cases, an anxiety disorder may continue even following successful treatment of anorexia nervosa.

Etiology

The etiology of anorexia nervosa is multidimensional. Some of the risk factors (discussed later) and the etiologic factors overlap. For example, dieting is a risk factor for the development of anorexia nervosa, but it is also an etiologic factor, and in its most serious form—starving—it is also a symptom.

Biologic Theories

There is evidence that the volume of gray and white matter in the brains of persons with anorexia nervosa is reduced but is normalized during weight restoration. These deficits may reflect malnourishment. Other studies suggest that there may structural alterations even after long-term recovery (Curzio et al., 2020). Research is ongoing.

Box 32.3

Eating Disorders and NCAA Collegiate Athletes

McDonald, A. H., Pritchard, M., & McGuire, M. K. (2020). Self-reported eating disorder risk in lean and non-lean NCAA Collegiate Athletes. *Eating and Weight Disorders: EWD*, 25(3), 745–750. <https://doi.org/10.1007/s40519-019-00681-0>

THE QUESTION: Are there gender differences in the overall scores of the Eating Attitudes Test (EAT-26) in National Collegiate Athletic Association

(NCAA) college athletes in “lean” sports versus “nonlean” sports.

(Lean sports defined as those for which there is a presumed competitive advantage with a thin shape, lean body, and/or low weight such as aesthetic (i.e., gymnastics, diving, etc.), endurance (i.e., running, cycling, etc.), and weight-class (i.e., wrestling, martial arts, etc.) sports. Nonlean includes all other sports.)

METHODS: Using a self-report survey design, this study examined eating disorder risk in 121 NCAA college athletes, using the EAT-26. A high score (over 20) indicates further investigation is needed.

FINDINGS: Those in lean sport reported higher scores on behavior, whereas those in nonlean sports scored high in attitude. Looking at gender, females scored high on both attitudinal and behavioral sections. Males in lean sports report higher scores than males in nonlean sports.

IMPLICATIONS FOR NURSING: Nurses should be aware that both male and female athletes have higher rates of disordered eating and should be assessed for eating disorders. Nurses can teach parents and adolescents about the value of healthy athletic competition and the need to maintain healthy eating habits. Coaches as well as parents should be involved in educational programs, highlighting the risk factors for eating disorders and symptom identification. An accurate assessment of each young athlete, male or female, is important.

Genetic Theories

First-degree relatives of people with anorexia nervosa have higher rates of this disorder. Rates of partial-syndrome or subthreshold cases among female family members of individuals with anorexia nervosa are even higher (Bulik et al., 2019). Female relatives also have high rates of depression, leading researchers to hypothesize that a shared genetic factor may influence development of both disorders.

Genetic research shows that a genetic vulnerability to anorexia nervosa exists, especially in females. Genetic heritability accounts for an estimated 50% to 80% of the risk of developing an eating disorder. Separating genetic influences from

environmental influences is difficult when twins share a similar family environment (Bulik et al., 2019).

Neuroendocrine and Neurotransmitter Changes

Several neurobiologic changes occur in an eating disorder. The most common findings are increased activation of the amygdala and changes in the activation of the cingulate cortex. An increase in endogenous opioids (through exercise) contributes to denial of hunger. Malnutrition leads to a decrease in thyroid function. Serotonergic functioning is also blunted in low-weight patients (Foldi et al., 2020; Scharner & Stengel, 2019; Smith et al., 2020).

Psychological Theories

Historically, the most widely accepted explanation of anorexia nervosa was the psychoanalytic paradigm that focused on conflicts of separation–individuation and autonomy. Usually diagnosed between 14 and 18 years of age, anorexia nervosa was thought to occur as a result of a developmental arrest of normal adolescent struggles around identity and role, body image formation, and sexuality (Bruch, 1973). Dieting and weight control were viewed as a means to defend against these feelings of inadequacy and growing into adulthood.

The psychoanalytic paradigm explained the disparity in the prevalence of eating disorders between boys and girls as being related to the development of self-esteem in adolescent girls. It was believed that the normal adolescent increase in self-doubt was linked to naturally occurring pubertal weight gain, which in turn resulted in confusion about one's identity. Unfortunately, this psychoanalytic perspective tended to blame parents, especially mothers, for the development of their child's illness. Today, the psychoanalytic theory is used in some psychotherapies, but it is no longer a competing theory of causation.

Internalization of Peer Pressure

Some adolescents have reported that dieting, binge eating, and purging initially began as a result of peer pressure and a need to conform. Subsequently, many factors then converge that influence the initial behaviors to develop into a full

syndrome eating disorder. Peers and friends, as well as peers in the larger school system, influence unhealthy weight-control behaviors among preadolescent and adolescent girls (Smink et al., 2018).

Body Dissatisfaction

Once the body is considered all important, the individual begins to compare their body with others, such as those of celebrities. Images from television and fashion magazines are particularly powerful for young girls and adolescents struggling with the tasks of identity and body image formation. Body dissatisfaction resulting from this comparison, in which one's own body is perceived to fall short of an ideal, may be dissatisfaction about one's weight, shape, size, or even a certain body part. Even in the absence of overweight, most adolescents surveyed in numerous studies were dissatisfied with their bodies (Waszczuk et al., 2019). Because this factor is so prevalent in women and especially adolescents in this country, body dissatisfaction is considered less predictive for a diagnosis of anorexia nervosa (APA, 2013). Yet it remains an important factor that follows the internalizing of an idea body weight.

KEYCONCEPT **Body dissatisfaction** occurs when the body is viewed negatively and becomes overvalued as a way of determining one's worth.

Many adolescents attempt to overcome this dissatisfaction through dieting and overexercising.

Social Theories

More than with any other psychiatric condition, society plays a significant role in the development of eating disorders with conflicting messages that young women receive from society about their roles in life. Young girls may interpret expectations about how they should look, what roles they should perform, and what they should achieve in society. Exposure to social media sites idealizing excessively thin bodies and glorifying extreme caloric restriction is associated with disordered eating behaviors (Griffiths et al., 2018).

The media, the fashion industry, and peer pressure are significant social influences. Magazines, television, videos, and the Internet depict young girls and

adolescents, with thin and often emaciated bodies, as glamorous, successful, popular, and powerful. Girls diet because they want to be similar to these models both in character and appearance.

Preoccupation with body image and weight is also influenced by the obesity epidemic. A study on body dissatisfaction demonstrated that high BMIs and body dissatisfaction were more likely to occur in adolescents who later developed eating disorder symptoms (Goldstein & Gvion, 2019).

Preadolescent children are extremely susceptible to the message to reduce intake and increase exercise as a way to lose weight and maintain health. Coupled with Internet videos that sanction self-starvation, emerging adolescents are already dissatisfied with their bodies and have the tools to lose weight through dieting and exercise.

Feminists have focused on the role of this pressure regarding the female body as one part of an explanation for the significant increase in eating disorders and for the greater prevalence in females. [Box 32.4](#) outlines some feminist assumptions regarding role, feminism, and the development of eating disorders.

Box 32.4

Feminist Ideology and Eating Disorders

Since the 1970s, proponents of the feminist cultural model of eating disorders have advanced a position to explain the higher prevalence of these disorders in women. Feminists believe there is a struggle women have today similar to ones they believe women have had in history. They believe that during the Victorian era, “hysteria,” a well-known emotional illness, developed as a result of oppression when women were not allowed to express their feelings and opinions and were “silenced” by a male-dominated society. Feminist scholars today have advanced the feminist relational model to understand the development of eating disorders. They view a major issue in development that causes conflict for young girls as the need to be connected versus society’s view of the importance of separation. This confusion can be a stress that may be converted into disordered eating. Often at the base of symptoms such as severe food restriction is the gaining of power, lost possibly because of this confusion in one’s development (Holmes, Drake, Odgers, Wilson, 2017).

Family Response to Disorder

Historically, the family of the patient with anorexia was labeled as overprotective, enmeshed, being unable to resolve conflicts, and being rigid regarding boundaries. Although an uninformed family can delay and complicate treatment, there is no evidence that family interactions are the cause of eating disorders but can contribute to its development (Kluck et al., 2017). Some family interactions can be problematic for the adolescent with an eating disorder. For example, when conflict erupts between two family members and direct communication is blocked, interaction patterns are changed that may result in a dysfunction relay of messages through other family members.

Enmeshment refers to an extreme form of intensity in family interactions and represents low individual autonomy in a family. In an enmeshed family, the individual gets lost in the family system. The boundaries that define individual autonomy are weak. This excessive togetherness intrudes on privacy (Minuchin et al., 1978).

Overprotectiveness is defined as a high degree of concern for one another and can be detrimental to children at high risk for anorexia nervosa. The parents' overprotectiveness retards the child's development of autonomy and competence (Minuchin et al., 1978). *Rigidity* refers to families that are heavily committed to maintaining the status quo and find change difficult. Conflict is avoided, and a strong ethical code or religious orientation is usually the rationale.

The family, often unwittingly, can transmit unrealistic attitudes about weight, shape, and size. Adolescents are particularly sensitive to comments about their bodies because this is the stage for body image formation. Parental attitudes about weight have been found to influence body dissatisfaction and dieting; parental comments about weight or shape or even parents' worrying about their own weight can influence adolescents in much the same way as the media does. See [Box 32.5](#).

Hurtful weight-related comments by family members and significant others have been associated with disordered eating in both females and males. Adolescents' perceived family functioning and the quality of their relationship with each parent have been shown to positively influence body image dissatisfaction and disordered eating. Therefore, healthy family relationships are believed to be a protective factor for developing an eating disorder and support research findings linking parental-focused treatment programs to positive

outcomes for those with eating disorders (Wallis et al., 2018).

Box 32.5

Mothers, Daughters, and Body Image

Handford, C. M., Rapee, R. M., Fardouly, J. (2018). The influence of maternal modeling on body image concerns and eating disturbances in preadolescent girls. Behaviour Research and Therapy, 00:17-23. doi: 10.1016/j.brat.2017.11.001.

THE QUESTION: Do maternal attitudes and behavior about their daughter's weight and eating habits influence body esteem, body satisfaction, eating attitudes, and eating behaviors of young girls?

METHODS: Fifty mother-daughter pairs were recruited from the community and allocated to one of two conditions: maternal modeling (self-critical remarks about their own weight, shape, and diet) or no modeling. Daughters were then asked to complete body esteem, body satisfaction, and eating attitudes questionnaires (pre- and postmaternal modeling).

FINDINGS: Girls whose mothers made self-critical comments about their own appearance and diet reported lower body esteem, lower body satisfaction, more problematic eating attitudes, and ate significantly fewer sweets than girls whose mothers had not made self-critical comments.

IMPLICATIONS FOR NURSING: Families should be cautioned that self-critical statements can lead to daughters' lower esteem, body dissatisfaction, and more problematic eating attitudes.

RECOVERY-ORIENTED CARE FOR PERSONS WITH ANOREXIA NERVOSA

Teamwork and Collaboration: Working Toward Recovery

Treatment for the patient with anorexia nervosa focuses on initiating nutritional

rehabilitation to restore the individual to a healthy weight, resolving psychological conflicts around body image disturbance, increasing effective coping, addressing the underlying conflicts related to maturity fears and role conflict, and assisting the family with healthy functioning and communication. Several methods are used to accomplish these goals during the stages of illness and recovery.

The medical complications presented in [Table 32.1](#) influence the decision to hospitalize an individual with an eating disorder. Suicidality is another reason for hospitalization. The criteria for hospital admission vary, and there is a lack of evidence-based studies determining when adolescents with anorexia nervosa should be hospitalized. The APA criteria are outlined in [Box 32.6](#).

After an acceptable weight (at least 85% of ideal) is established, the patient is discharged to a partial hospitalization program or an intensive outpatient program. The intensive therapies needed to help patients with their underlying issues (e.g., body distortion and maturity fears) and to help families with communication and enmeshment usually begin after refeeding because concentration is usually impaired in severely undernourished patients with anorexia.

Family therapy typically begins while the patient is still hospitalized. Recently family-based therapies and caregiver-based approaches have shown promise in the treatment of eating disorders. These assist in improving overall communication within the family and helps members understand the disorder (Wong et al., 2019).

Interpersonal therapy (IPT) is a type of treatment that focuses on uncovering and resolving the developmental and psychological issues underlying the disorder. Role transitions and negative social evaluations typically are the focus (Miniati et al., 2018). IPT and family-based therapies are sometimes combined.

TABLE 32-1: COMPLICATIONS OF EATING DISORDERS

Body SystemSymptoms

From Starvation to Weight Loss

Musculoskeletal	Loss of muscle mass, loss of fat (emaciation), osteoporosis
Metabolic	Hypothyroidism (symptoms include lack of energy, weakness, intolerance to cold, and bradycardia), hypoglycemia, decreased insulin sensitivity
Cardiac	Bradycardia; hypotension; loss of cardiac muscle; small heart; cardiac arrhythmias, including atrial and ventricular premature contractions, prolonged QT interval,

	ventricular tachycardia, sudden death
Gastrointestinal	Delayed gastric emptying, bloating, constipation, abdominal pain, gas, diarrhea
Reproductive	Amenorrhea, low levels of luteinizing hormone and follicle-stimulating hormone, irregular periods
Dermatologic	Dry, cracking skin and brittle nails caused by dehydration, lanugo (fine, baby-like hair over the body), edema, acrocyanosis (bluish hands and feet), thinning hair
Hematologic	Leukopenia, anemia, thrombocytopenia, hypercholesterolemia, hypercarotenemia
Neuropsychiatric	Abnormal taste sensation (possible zinc deficiency) Apathetic depression, mild organic mental symptoms, sleep disturbances, fatigue

Related to Purging (Vomiting and Laxative Abuse)

Metabolic	Electrolyte abnormalities, particularly hypokalemia, hypochloremic alkalosis; hypomagnesemia; increased blood urea nitrogen
Gastrointestinal	Salivary gland and pancreatic inflammation and enlargement with increase in serum amylase, esophageal and gastric erosion (esophagitis) rupture, dysfunctional bowel with dilation, superior mesenteric artery syndrome
Dental	Erosion of dental enamel (perimylolysis), particularly of the frontal teeth, with decreased decay
Neuropsychiatric	Seizures (related to large fluid shifts and electrolyte disturbances), mild neuropathies, fatigue, weakness, mild organic mental symptoms
Cardiac	Ipecac cardiomyopathy arrhythmias

Box 32.6

Criteria for Hospitalization of Patients with Eating Disorders

MEDICAL

- Acute weight loss, <85% below ideal
- Heart rate near 40 beats/min
- Temperature, <36.1°C
- Blood pressure, <80/50 mm Hg
- Hypokalemia
- Hypophosphatemia
- Hypomagnesemia
- Poor motivation to recover

PSYCHIATRIC

- Risk for suicide
- Severe depression
- Failure to comply with treatment

- Inadequate response to treatment at another level of care (outpatient)

Adapted from American Psychiatric Association (2006). Treatment of patients with eating disorders, third edition. *American Journal of Psychiatry*, 163(7 suppl), 4–54.

Dialectic behavioral therapy specifically designed for patients with anorexia nervosa has shown positive results. This skills training type of intervention focuses on emotional dysregulation, viewed as a key symptom in anorexia nervosa (Accurso et al., 2018).

Safety Issues

Mortality is high among patients with anorexia nervosa, especially when compared with other mental illnesses, and is reported to be 3% to 7% with a longer duration of the disorder predicting the higher range of the mortality rate (Chidiac, 2019). Suicide and cardiopulmonary arrest are the leading cause of death for individuals with anorexia nervosa (Goldstein & Gvion, 2019). These individuals tend to die by suicide with highly lethal means in which rescue is unlikely. Nurses need to pay special attention to the risk of suicide with these individuals (see [Chapter 21](#)). A significant number of individuals with eating disorders also self-injure without suicide attempts (Sagiv & Gvion, 2020).

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH ANOREXIA NERVOSA DISORDER

Mental Health Nursing Assessment

Physical Health Assessment

A thorough evaluation of body systems is important because many systems are compromised by starvation. A careful history from both the patient with anorexia nervosa and the family, including the length and duration of symptoms, such as

fasting, avoiding meals, and over-exercising, is necessary to assess altered nutrition. Nursing management involves various biopsychosocial assessments and interventions.

Patients with longer durations of these maladaptive behaviors typically have more difficult and prolonged recovery periods.

NCLEXNOTE Eating disorders are serious psychiatric disorders that threaten life. Careful assessment and referral for treatment are important nursing interventions.

The patient's weight is determined using the BMI and a scale. Currently, criteria for discharge require patients to be at least 85% of ideal weight according to height and weight tables. BMI, thought to reflect weight most accurately because exact height is used, is calculated by dividing weight in kilograms by height in meters squared. An acceptable BMI is between about 19 and 25.

Menses history also must be explored in that it provides information about possible estrogen depletion. However, it is often difficult to conclude that amenorrhea is present due to starvation because females in this age group often have irregular periods, and some are on oral contraceptives. However, if menses was regular prior to anorexia nervosa, a return to regular menses after treatment can signify substantial body fat restoration. Fat and weight restoration have been hypothesized to aid in the loss of bone mineral density (Karageorgiou et al., 2020).

Psychosocial Assessment

Mental Status and Appearance

Behavioral Responses

The psychological symptoms that patients with anorexia experience are listed in [Box 32.1](#). The classic symptoms of body distortion—fear of weight gain, unrealistic expectations and thinking, and ritualistic behaviors—are easily noted during a clinical interview. Often, people with anorexia nervosa avoid conflict and have difficulty expressing negative emotions, such as anger. Other conflicts,

such as sexuality fears and feelings of ineffectiveness, may underlie this disorder. These symptoms may not be apparent during a clinical interview; however, a variety of instruments is available to clinicians and researchers for determining their presence and severity. There is a high rate of nonsuicidal self-injury in patients with eating disorders, and the type and frequency of these behaviors should be assessed (Sagiv & Gvion, 2020).

The Eating Attitudes Test is frequently used in community samples (Garner et al., 1982). There is also a child version of this test, the CHEAT. The results of these paper-and-pencil tests can help identify the most significant symptoms for an individual patient and indicate a focus for interventions, especially therapy. In clinical settings, the Eating Disorder Examination Questionnaire (EDEQ) is most often used (Hilbert et al., 2012).

Self-Concept

Individuals with eating disorders are usually struggling with their self-concept. It is important to determine their self-concept and self-esteem. In many instances, these individuals appear to be very competent, but when queried about their views, they often feel that they are not good enough and will describe their perceived faults in great detail.

Stress and Coping Patterns

Individuals with an eating disorder are often coping with stress and anxiety through controlling eating. In times of perceived stressful events, the dysfunctional eating pattern often becomes worse. An assessment of the stress the person is experiencing and coping patterns is important because a part of successful treatment is developing healthy coping skills.

Social Assessment

The assessment should also focus on family interaction, influence, and peer relationships. The role of the patient in the family and community should be considered, as well as the person's ability to cope in social situations. For adolescents who are attending school, a conference with the teacher or counselor provides information regarding the amount and frequency of social contacts.

Quality of Life

Persons with anorexia nervosa have a lowered quality of life than others with psychiatric disorders or those without psychiatric disorders. Behaviors associated with AN such as low body mass index, depression, anxiety, and purging are associated with lower quality of life. Individuals with AN often recall selective events and focus on negative aspect of the event, which, in turn, contributes to a low quality of life (Hamatani et al., 2017).

Strengths Assessment

Strengths such as motivation to eat differently and have a more normal life may emerge during the interview. The following questions could be asked to elicit personal strengths:

- Do you remember a time when you did not have to worry about what you ate? If so, how old were you and what did you like to do?
- Have you found any strategy that prevented you from worrying about what you hate?
- Are you ready to change your eating patterns? What do you think will help you change your eating patterns?
- When you are successful in other areas (school, athletics), how do you reward yourself?

CLINICAL JUDGMENT

Medical complications and suicide ideation are the two top priorities. Bradycardia and hypotension are well-established responses to starvation. Cardiac issues should be treated before the psychological issues can be meaningfully addressed. Normal electrolyte balance should be restored. Suicidality is also a high priority of nursing care and should be carefully assessed.

THERAPEUTIC RELATIONSHIP

Establishing a therapeutic relationship with individuals with anorexia nervosa may be difficult initially because they tend to be suspicious and mistrustful, especially of authority figures and health personnel, who they believe will intervene to disrupt their restricting and starvation behaviors, placing them in a position of extreme fear of becoming fat. At the time they are hospitalized, mistrust can almost reach a state of paranoia. Because of their low body weight and starvation, they are often impatient and irritable. A firm, accepting, and patient approach is important in working with these individuals. Providing a rationale for all interventions helps build trust, as does a consistent, nonreactive approach. Power struggles over eating are common, and remaining nonreactive is a challenge. During such power struggles, the nurse should always think about their own feelings of frustration and need for control.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Mental Health and Wellness Goals

The mental health and wellness goals are very closely aligned for people with eating disorders. Successful recovery from an eating disorder involves establishing positive wellness habits of nutrition, physical activity, sleep, coping with stress, and developing a support system. The nurse and patient should prioritize long- and short-term goals. For example, a long-term goal is to maintain a normal weight through healthy eating and exercise. A short-term goal is to increase food intake by 300 calories per day.

NCLEXNOTE Setting realistic eating goals is one of the most helpful interventions for patients with eating disorders. Because individuals with anorexia nervosa are often perfectionistic, they often set unrealistic goals.

One of the most helpful skills the nurse can teach is to set realistic goals around food and around other activities or tasks. Because of perfectionism, patients with anorexia often set unrealistic goals and end up frustrated. The nurse

can help them establish smaller, more realistic, and attainable goals.

Physical Care

The person with anorexia can usually perform self-care activities. They may actually be overly perfectionistic regarding daily self-care activities. If symptoms become severe, hospitalization may be necessary to re-establish a healthy body weight.

Nutritional Rehabilitation

Refeeding, the most important intervention during the hospital or initial stage of treatment, is also the most challenging. In anorexia nervosa, there is a shift from carbohydrate to fat and protein utilization, placing the body in a catabolic state. In this state, there is an altered insulin response and increased glucagon secretion. As nutritional balance is re-established, anabolic metabolism is restored and the body switches back to carbohydrate metabolism leading to lower levels of phosphate.

The refeeding protocol typically starts with 1,500 calories a day and is increased slowly until the patient is consuming at least 3,500 calories a day in several meals. The higher the initial number of calories prescribed has been demonstrated to influence a shorter length of hospital stay and recovery (Garber et al., 2016). The usual plan for patients with very low weights is a weight gain of between 1 and 2 lb. a week. In severe malnourished adolescents, and especially those resisting refeeding, nasogastric tube feeding of supplements alone, or combined with meals, may be instituted (Garber et al., 2016).

There is controversy regarding aggressive refeeding. To prevent further weight loss, rapid increase of calories provides the best result. However, food anxiety is commonly experienced by people with AN, especially if there is a co-morbid disorder such as depression, obsessive-compulsive disorder, or PTSD. Increased anxiety can exacerbate the symptoms, making recovery more difficult. It is important that benefits of refeeding be weighed against the risk of increasing anxiety (Levinson et al., 2019).

The person will be fearful of weight gain and may refuse to eat. The nurse must monitor and record all intake carefully as part of the weight gain protocol.

Weight-increasing protocols usually include behavioral plans using positive reinforcements (i.e., excursion passes) and negative reinforcements (i.e., returning to bed rest) to encourage weight gain. The nurse should help patients to understand that these actions are not punitive. When all staff members agree on a clear protocol for behaviors related to eating and weight gain, reactivity of the staff to the patient is greatly reduced. These protocols provide ready-made, consistent responses to food-refusal behaviors and should be carried out in a caring and supportive context. On rare occasions when the patient is unable to recognize or accept their illness (denial) and their malnutrition is life-threatening, nasogastric tube feedings may be necessary.

Electrolytes may be completely depleted in anorexia nervosa, so nursing care involves stabilizing electrolyte balance. Potassium depletion usually results from use of diuretics, diarrhea, and vomiting. Calcium depletion is related to large intake of dietary fiber, which decreases calcium absorption. Many individuals also need phosphorus replacement (Peebles et al., 2017). During hospitalization, these electrolytes, if warranted, are replaced through oral or intravenous therapy.

A complication of refeeding is the development of **refeeding syndrome** (severe electrolyte disturbances). This condition can develop during the refeeding process and include circulatory fluid overload, respiratory failure, and cardiac failure. Hypophosphatemia is a precursor to refeeding syndrome, which can result in sudden death (Parker et al., 2020).

Promotion of Sleep

Sleep disturbance is also common, and these individuals are viewed as hyperkinetic. They sleep little, but they usually awaken in an energized state. A structured, healthy sleep routine must be established immediately to conserve energy and calorie expenditure because of low weight. To further conserve energy, patients are often relegated to bed rest until a certain amount of weight is regained. Exercise is generally not permitted during refeeding and only with caution after this phase. Inpatients must be closely supervised because they are often found exercising in their rooms, running in place, and doing calisthenics.

Medication Interventions

Selective serotonin reuptake inhibitors (SSRIs) are useful in the treatment of AN, especially regarding comorbid influences and symptoms such as OCD. The SSRI fluoxetine (Prozac) is approved by the Food and Drug Administration for the treatment of anorexia nervosa. Of course, comorbid conditions such as depression or OCD should be treated with appropriate medication. The nurse may be responsible for administering medications or providing patient and family teaching. See [Box 32.7](#).

Box 32.7

Fluoxetine Hydrochloride (Prozac)

DRUG CLASS: Selective serotonin reuptake inhibitor

RECEPTOR AFFINITY: Inhibits central nervous system neuronal uptake of serotonin with little effect on norepinephrine; thought to antagonize muscarinic, histaminergic, and α -adrenergic receptors

INDICATIONS: Treatment of depressive disorders, obsessive-compulsive disorder, bulimia nervosa, and panic disorder

ROUTES AND DOSAGE: Available in 10- and 20-mg capsules and 20-mg/5-mL oral solution

Adults: 20 mg/d in the morning, not to exceed 80 mg/d. Full antidepressant effect may not be seen for up to 4 weeks. If no improvement, dosage is increased after several weeks. Dosages greater than 20 mg/d are administered twice daily. For eating disorders: typically, 60 mg/d is recommended.

Geriatric: Administer at lower or less frequent doses; monitor responses to guide dosage.

Children: Safety and efficacy have not been established.

HALF-LIFE (PEAK EFFECT): 2 to 3 days (6 to 8 hours)

SELECTED ADVERSE REACTIONS: Headache, nervousness, insomnia, drowsiness, anxiety, tremors, dizziness, lightheadedness, nausea, vomiting, diarrhea, dry mouth, anorexia, dyspepsia, constipation, taste changes, upper respiratory infections, pharyngitis, painful menstruation, sexual dysfunction, urinary frequency, sweating, rash, pruritus, weight loss, asthenia, and fever

BOXED WARNING: Increased risk of suicidal thoughts and behaviors in children, adolescents, and young adults.

WARNINGS: Avoid use in pregnancy and while breastfeeding. Use with caution in patients with impaired hepatic or renal function and diabetes mellitus. Possible risk for toxicity if taken with tricyclic antidepressants.

SPECIAL PATIENT AND FAMILY EDUCATION

- Be aware that the drug may take up to 4 weeks to get a full antidepressant effect.
- Take the drug in the morning or in divided doses, if necessary.
- Families and caregivers of pediatric patients being treated with antidepressants should monitor patients

for agitation, irritation, and unusual changes in behavior.

- Report any adverse reactions.
- Avoid driving a car or performing hazardous activities because the drug may cause drowsiness or dizziness.
- Eat small, frequent meals to help with complaints of nausea and vomiting.

Management of Complications

Anorexia nervosa has the highest mortality rate of any mental illness. Every organ system can be adversely affected by AN—metabolic, cardiopulmonary, endocrine, gastrointestinal, and hematological. Laboratory tests that are typically ordered include CBC, calcium, magnesium, and phosphorus, liver function and albumin, vitamin D, serum BUN, creatinine, blood glucose, and TSH. Other tests usually included are stool examination for occult blood, ECG, bone densitometry, and abdominal x-ray. Results of all tests should be monitored frequently.

Some patients may have dysphagia as a result of malnutrition and will need to modify diet texture. Low fiber diets that are soft and easy to digest are recommended to reduce the feeding volume and the symptoms of early satiety. The patient may need tube feedings.

SMA (superior mesenteric artery) syndrome is a rare disorder in which acute angulation of the SMA causes compression of the third part of the duodenum between the SMA and the aorta. SMA syndrome can lead to obstruction of the duodenum and can occur in AN, causing patients to have epigastric abdominal pain and a need for a liquid diet or tube feeding.

Multiple musculoskeletal complications are associated with AN, including sarcopenia, which can result in functional weakness and balance impairments that increase fall risks. Physical therapy evaluation and treatment are important when bone mineral density is decreased. Even though falls are not usually associated with a young age group, fall risk evaluation should be conducted for a person with AN.

Psychosocial Interventions

Therapeutic Interactions

Identifying feelings, such as anxiety and fear, and especially negative emotions, such as anger, is the first step in helping patients to decrease conflict avoidance and develop effective strategies for coping with these feelings.

Do not attempt to change distorted body image by merely pointing out that the patient is actually too thin. This symptom is often the last to resolve itself, and some individuals may take years to see their bodies realistically. However, although this symptom is difficult to abate, patients can continue to fear becoming fat but not be driven to act on the distortion by starving. The fear of becoming fat eventually lessens with time.

Enhancing Cognitive Functioning

The nurse can help individuals with cognitive distortions and unrealistic assumptions to restructure the way they view the world, especially relative to food, eating, weight, and shape. Faulty ways of viewing these situations result in ineffective coping. [Table 32.2](#) lists some distortions commonly experienced by individuals with eating disorders and some typical restructuring responses or statements that challenge the distortion, which the nurse can present as more realistic ways of perceiving situations. Imagery and relaxation are often used to overcome distortions and to decrease anxiety stemming from a distorted body image.

TABLE 32-2: COGNITIVE DISTORTIONS TYPICAL OF PATIENTS WITH EATING DISORDERS, WITH RESTRUCTURING STATEMENTS

Distortion	Clarification or Restructuring
<i>Dichotomous or All-or-Nothing Thinking</i>	
“I’ve gained 2 lb., so I’ll be up to 100 lb. soon.”	“You have never gained 100 lb., but I understand that gaining 2 lb. is scary.”
<i>Magnification</i>	
“I binged last night, so I can’t go out with anyone.”	“Feeling bad and guilty about a binge are difficult feelings, but you are in treatment, and you have been monitoring and changing your eating.”

Selective Abstraction

“I can only be happy 10 lb. lighter.”

“When you were 10 lb. lighter, you were hospitalized. You can choose to be happy about many things in your life.”

Overgeneralization

“I didn’t eat anything yesterday and did okay, so I don’t think not eating for a week or two will harm me.”

“Any starvation harms the body, whether or not outward signs were apparent to you. The more you starve, the more problems your body will encounter.”

Catastrophizing

“I purged last night for the first time in 4 months—I’ll never recover.”

“Recovery includes up and downs, and it is expected you will still have some mild but infrequent symptoms.”

Using Behavioral Intervention

Many of the same behavioral interventions used in the care of persons who are depressed or anxious are also implemented in the care of persons with AN. See [Chapter 7](#). Reinforcing and rewarding positive eating behaviors and avoiding reinforcement of perfectionistic and ritualistic behaviors can help the patient refocus on meaningful, healthy behaviors.

Psychoeducation

When weight is restored and concentration is improved, patients with anorexia nervosa can benefit from psychoeducation. Although these individuals have a wealth of knowledge about food and calories, they also have misinformation that needs clarifying. For example, they are often unclear about the role of “fats” in a healthy diet and try to be as “fat free” as possible. A thorough assessment of their knowledge is important because they seem to be “walking calorie books” with little information on the role of all of the nutrients and the importance of including them in a healthy diet. There are several topic areas that should be included in a teaching plan. See [Box 32.8](#).

Teaching Strategies

Several factors influence the outcome of treatment for individuals with anorexia nervosa. Particularly long duration of symptoms and low weight when treatment begins predict poor outcomes, but family support and involvement generally improve outcomes. Comorbid conditions and their severity also influence recovery, especially anxiety disorders. Although patients are discharged from the hospital when their weight has reached 85% of what is considered ideal, restoration of healthy eating and changes in maladaptive thinking may not have yet occurred. Individuals often continue to restrict foods. Therefore, without intensive outpatient treatment, including nutritional counseling and support, they are unlikely to recover fully. Distorted thinking and eating patterns can set the stage for a relapse and later for the possible development of bulimia nervosa.

Box 32.8

Anorexia Nervosa

When caring for a patient with anorexia nervosa, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents, if used, including drug, action, dosage, frequency, and possible adverse effects
- Nutrition and eating patterns
- Effect of restrictive eating or dieting
- Weight monitoring
- Safety and comfort measures
- Avoidance of triggers
- Self-monitoring techniques
- Trust
- Realistic goal setting
- Resources

Wellness Challenges and Strategies

Individuals with AN are very aware of wellness recommendations related to nutrition and exercise. Since they focus on nutrition, exercise, and weight control, their real challenge is to focus less on nutrition and exercise and more

on developing positive self-concept and emotional wellness. They often ignore the other wellness dimensions, such as developing positive coping skills for stress management, developing a sense of connection with others, and searching for meaning or a purpose in life. See [Box 32.9](#).

Providing Family Education

Denial, guilt, and subsequent greater overprotectiveness are common reactions of the family, especially when hospitalization has been necessary. In addition to family therapy with a skilled therapist, the nurse can help family members express their feelings, increase effective communication, decrease protectiveness, and resolve guilt. Often, siblings become resentful of the patient with an eating disorder because of the significant amount of attention they get from their parents. Having siblings discuss these feelings and the effect the illness has had on them is helpful. Families and friends are eager to help the patient with anorexia but often need direction. [Box 32.10](#) provides a list of strategies that may assist them.

Box 32.9

Wellness Challenges and Strategies

- Recognizing the need for moderate physical activity, healthy foods, and sleep
- Strategies: Limit physical activity to a reasonable schedule
- Practice increasing amounts of healthy food
- Track sleep and increase amount of sleep (if needed) and engage sleep hygiene techniques
- Coping effectively with drive for thinness.
- Strategies: Identify times when the need to restrict diet occurs; Examine other strategies in dealing with the situation
- Stress management
- Strategies: Practice meditation, use cognitive strategies to examine beliefs and thoughts
- Increase self-concept
- Strategies: Keep a list of accomplishments, help others; keep busy; counseling or therapy
- Developing a sense of connection, belong, and a support system
- Strategies: Develop a plan to increase social contact
- Expanding a sense of purpose and meaning in life

- Strategies: Pray, meditate, help others, volunteer

Box 32.10

What Family and Friends Can Do to Help Those with Eating Disorders

- Tell the person you are concerned, you care, and you would like to help. Suggest that the person seek professional help from a physician or therapist.
- If the person refuses to seek professional help, encourage reaching out to an adult, such as a teacher, school nurse, or counselor.
- Do not discuss weight, the number of calories being consumed, or particular eating habits.
- Do try to talk about things other than food, weight, counting calories, and exercise.
- Avoid making comments about a person's appearance. Concern about weight loss may be interpreted as a compliment; comments regarding weight gain may be felt as criticism.
- It will not help to become involved in a power struggle. You cannot force the person to eat.
- You can offer support. Ultimately, however, the responsibility and the decision to accept help and to change rest with the person.
- Read and educate yourself regarding these disorders.

Promoting Safety

If hospitalized, the patient's systems are monitored closely because at the time of admission, most patients are severely malnourished (see [Table 32.1](#)). Patients usually are placed on a privilege-earning program in which privileges, such as having visitors and receiving passes to go outside the hospital, are earned based on weight gain. See [Chapter 10](#).

Developing Recovery-Oriented Rehabilitation Strategies

Recovery of persons with anorexia nervosa focuses on physical, psychological, and social aspects. Maintaining a normal weight and nutrition will require resisting urges to diet and overexercise. Motivation to continue to work toward

recovery should be supported throughout recovery. Development of cognitive strategies to address these issues will need to be reinforced through attending support groups and maintaining a treatment alliance with a provider.

Relapse prevention plays a major role in recovery. The patient and family should work closely with a clinician to understand the patient's individual relapse process. Together, they identify the triggers and early warning signs of relapse and agree upon a relapse prevention plan that responds to the triggers (Berends et al., 2018).

Evaluation and Treatment Outcomes

Short-term outcomes for individuals with anorexia nervosa after hospitalization are generally poor. Poor outcomes are related to lower body mass indices (BMI) at the beginning of treatment, the level of impulsivity, self-induced vomiting, and higher trait anxiety purging (vomiting and laxative use). Long-term outcomes are more positive than short-term outcomes, but remission rates vary from 20% to 70%, depending on the criteria used in the studies. Many individuals do recover, but recovery often takes years and can be characterized by residual symptoms (Fichter et al., 2017).

Continuum of Care

Emergency Care

Emergency care is not usually needed for individuals with anorexia nervosa. Family members and peers usually notice the weight loss and emaciation before patients' systems are compromised to the degree that they require emergency treatment. If systems are compromised enough to warrant emergency treatment, patients usually are admitted immediately for medical-surgical inpatient care.

Inpatient

Hospitalization is required based on criteria noted in [Box 32.6](#). Because of its life-threatening nature, anorexia nervosa in its very acute stage is unlikely to be

manageable in outpatient settings.

Community Care

After refeeding, treatment of anorexia nervosa takes place on an outpatient basis and involves individual and family therapy, nutrition counseling to reinforce healthy eating patterns and attitudes, and physician visits to monitor weight and evaluate somatic recovery. Support groups, which are often suggested, should not be substituted for therapy. Following an inpatient treatment program, many anorexia nervosa patients are referred for intensive outpatient therapy or day treatment programs prior to the usual outpatient therapy of 1 or 2 hourly sessions a week. In intensive outpatient therapy, patients may return to school but participate four to five evenings a week in a 4- to 5-hour structured program that includes group therapy, meeting with a dietician, and individual therapy. After full recovery, support groups are useful in maintaining recovery.

School Interventions

Younger patients with anorexia nervosa may have lost some school time because of hospitalization. Integrating back into a school and classroom setting is difficult for most. Shame and guilt about having an eating disorder and being hospitalized must be addressed. Because these patients typically have isolated themselves before hospitalization and treatment, renewing friendships and relationships with peers may provoke anxiety. Involving school nurses and teachers in the reentry process may help.

Prevention and early detection strategies for parents and schoolteachers are often the focus of school nurses and mental health nurses who work in the community. Some of these strategies appear in [Box 32.11](#) and are based on the research on risk factors and protective factors.

National eating disorder awareness and advocacy groups work toward educating the general public, those at risk, and those who work with groups at risk, such as teachers and coaches. They also monitor the media and work to remove unhealthy advertisements and articles that appear in magazines appealing to young girls. Policies, both health and social, can decrease the prevalence of eating disorders. Strategies include improving school-based curriculum to include content on prevention of Eds, implementing school-based

anti-bullying policies that protect students from being bullied about their weight, and training educators including coaches and health providers on prevention and early identification.

Box 32.11

Eating Disorder Prevention Strategies for Parents and Children

EDUCATION FOR PARENTS

- Real versus ideal weight
- Influence of attitudes, behaviors, teasing
- Ways to increase self-esteem
- Role of media: TV, magazines
- Signs and symptoms
- Interventions for obesity
- Boys at risk also
- Observe for rituals
- Supervision of eating and exercise

STRATEGIES FOR CHILDREN

Education

- Peer pressure regarding eating, weight
- Menses, puberty, normal weight gain
- Strategies for obesity
- Ways to develop or improve self-esteem
- Body image traps: media, retail clothing
- Adapting and coping with problems
- Reporting friends with signs of eating disorders

Screening: Screen for risk factors

Assessment: Assess for treatment

Follow-up: Monitor for relapse

Virtual Mental Health Care

Virtual mental health care is available through electronic applications available for downloading on a cell phone from national helplines such as the National

Eating Disorders Association and the National Association of Anorexia and Associated Disorders. Virtual applications are also being used in treatment of distorted body image to help the person receive realistic representation of body size (Irvine et al, 2020).

Integration With Primary Care

Persons with eating disorders are frequently treated in primary care for medical issues related to their eating disorder. Care in the mental health and primary care services should be coordinated with the mental health service providing care focusing on mental health issues and primary care treating the medical issues. When there are few psychiatric services available, eating disorders are treated and monitored by the primary care provider. The patient should have access to a therapist and dietitian in any treatment setting. Due to the fast-paced nature of primary care, eating disorders are not as easily recognized in a general health care setting and are often missed.

BULIMIA NERVOSA

Bulimia nervosa was once thought to be a type of anorexia nervosa. However, findings from extensive investigations have identified its characteristics as a separate entity. It is more prevalent than anorexia nervosa. Individuals with bulimia nervosa are usually older at onset than are those with anorexia nervosa. The disorder generally is not as life threatening as anorexia nervosa. The usual treatment is outpatient therapy. Outcomes are better for bulimia nervosa than for anorexia nervosa, and mortality rates are lower.

Clinical Course

Few outward signs are associated with bulimia nervosa. Individuals binge (eating an excessive amount, usually at one sitting) and purge (purposeful initiation of stomach or bowel evacuation through artificial means such as vomiting or laxatives) in secret and are typically of normal weight; therefore, it

does not come to the attention of parents and peers as readily as does anorexia nervosa. Treatment consequently can be delayed for years as individuals attempt on their own to get their eating under control. Patients usually initiate their own treatment when control of their eating becomes impossible. When treatment is undertaken and completed, patients typically recover completely, except in cases in which personality disorders and comorbid serious depression are also present.

Patients with bulimia nervosa present as overwhelmed and overly committed individuals, “social butterflies” who have difficulty with setting limits and establishing appropriate boundaries. They have an enormous number of rules regarding food and food restriction, and they feel shame, guilt, and disgust about their binge eating and purging. They may also be impulsive in other areas of their lives, such as spending.

Diagnostic Criteria

Bulimia nervosa involves eating a large amount of food within a discrete period of time (e.g., 2 hours) and engaging in recurrent episodes of binge eating and compensatory purging in various forms such as vomiting or using laxatives, diuretics, or emetics or in nonpurging compensatory behaviors, such as fasting or over-exercising in order to avoid weight gain. These episodes must occur at least once a week for a period of at least 3 months to meet the *DSM-5* criteria. Self-evaluation is excessively and inappropriately influenced by body weight and shape. Unlike anorexia nervosa, there is little or no weight loss. See [Box 32.1](#) for characteristics related to bulimia nervosa.

Remember Ellen?

She is of normal weight but has been vomiting one to two times a week for several months after bingeing. She has callouses on her hands from her teeth when she gagged herself. She sees herself as very overweight.

Does Ellen have characteristics of bulimia nervosa? If she did not know that these behaviors were symptoms of bulimia, how would you explain to her what her symptoms might mean?

Binge eating is defined as rapid, episodic, impulsive, and uncontrollable ingestion of a large amount of food during a short period of time, usually 1 to 2 hours. Eating is followed by feelings of guilt, remorse, and often self-contempt, leading to purging. To assuage the out-of-control feeling, severe dieting is instituted, and these restrictions, referred to as *dietary restraint*, precipitate the next binge. The restrictions are viewed as “rules,” such as no sweets, no fats, and so forth. The rules may be about what one can and cannot eat. Each binge sets up an out-of-control feeling, and thus the individual then sees the need for even stricter rules about what can and cannot be consumed, leading to more frequent binge eating. This cycle has prompted clinicians to focus treatment primarily on interventions related to dietary restraint. When dietary restraint is resolved, binge eating is decreased, and generally the purging that follows binge eating also is decreased. Feeling out of control with food is often the major complaint when individuals seek treatment for bulimia nervosa.

KEYCONCEPT **Dietary restraint** has been described by researchers in the field of eating disorders as a way to explain the relationship between dieting and binge eating.

Dieters’ deprivation, or restraint, whether real or imagined, contributes to

overeating and bingeing. Genetic predisposition for binge eating and deprivation may make dieters more prone to feel distressed over their dietary “failures,” especially if dieting has become a way to overcome body dissatisfaction and to compensate for distress through dietary restraint that leads to overeating (Castillo & Weiselberg, 2017). Whether the eating is influenced by the attraction of forbidden foods or by internal needs to assuage failure, there is significant evidence that restraining one’s intake is a precondition for bouts of overeating.

Bulimia Nervosa Across the Lifespan

Bulimia nervosa occurs in all age groups. It is not as common in children as in adolescents and adults; children appear more likely to have BED, discussed later. This finding has only recently been reported, and more data are needed to substantiate this finding.

Epidemiology and Risk Factors

Recent epidemiologic data report the lifetime prevalence of bulimia nervosa to be as high as 2.3% depending on whether clinical or community populations are sampled, but it is estimated that less than one third of the cases have been detected. Strict criteria are used when clinical groups are studied as opposed to self-reported symptoms in community surveys, making the community sample prevalence rates higher (Wade, 2019).

Age of Onset

Typically, the age of onset is between 15 and 24 years, which is later than the typical onset of anorexia nervosa. Some women older than the typical age of onset have developed bulimia nervosa and symptom cases have been identified as subsequent to life stressors such as a loss (Silén et al., 2020).

Gender Differences

As with anorexia nervosa, females are 10 times more likely than males to experience bulimia nervosa. [Box 32.2](#) highlights boys and men with eating disorders.

Ethnicity and Culture

Bulimia nervosa is related to culture in the same way as anorexia nervosa. In western cultures and those becoming westernized in their norms, the focus on achieving a thin body ideal underlies the dieting and dietary restraint that set up the trajectory toward a diagnosable eating disorder. Any ethnic differences have to do with the degree to which individuals from specific cultural backgrounds internalize the thin ideal.

Comorbidity

The most common comorbid conditions are anxiety disorders, mood disorders, self-harm, and substance use. If a comorbid condition occurs before the eating disorder develops, it may actually have a role in precipitating the disorder (Wade, 2019). The suicide rate for bulimia is around 7.5%, with suicide attempts and ideation ranging from 15% to 40%.

There are several medical complications affecting those with bulimia. Electrolyte imbalance can lead to cardiac arrhythmia, seizure, and death. Self-induced vomiting with loss of stomach acid can result in hyperchloremic alkalosis and hypokalemia. Chronic vomiting can result in subconjunctival hemorrhages, esophageal damage, acid reflux, and dental lesions (Castillo & Weiselberg, 2017).

Risk Factors

There are numerous risk factors associated with bulimia nervosa, including genetic risk, female gender, obstetric complication and perinatal factors, higher body mass index, frequent dieting, over-exercising, and concern about body weight. Childhood sexual abuse and/or neglect has often been suggested as a risk

factor for eating disorders. The beginning of puberty and the start of early adulthood are high-risk periods when adverse life events or peer teasing about appearance may trigger bulimic behavior, particularly if there is genetic susceptibility (Wade, 2019).

Etiology

As with anorexia nervosa, theories do not individually explain the development of bulimia nervosa. Rather, the convergence of many of these factors at a vulnerable stage of individual development best explains causality.

Some of the predisposing or risk factors for anorexia nervosa and bulimia nervosa overlap with theories of causality. For example, dieting puts an individual at risk for the development of bulimia nervosa. The dieting can turn into dietary restraint, a symptom that leads to binge eating and purging. However, not all individuals who diet experience bulimia nervosa. The interplay of other risk factors (e.g., body dissatisfaction and separation–individuation issues) most likely explains the development of this disorder.

Biologic Theories

Some progress has been made in understanding the biologic changes in bulimia nervosa. Dieting and bingeing can affect brain function. Dieting is believed to affect serotonergic regulation, and bingeing affects the dopamine (DA), acetylcholine (ACh), and opioid reward-related systems. The changes are the result of eating dysregulation rather than the cause. As with anorexia nervosa, these changes often disappear when symptoms such as dietary restraint, binge eating, and purging remit (Wade, 2019).

Genetic and Familial Predispositions

Bulimia nervosa runs in families, with an increased risk for individuals if family members are diagnosed with this disorder. Although anorexia and bulimia are both strongly related to genetics, it is believed that only bulimia has genetic specificity—that is, if one twin has bulimia nervosa, the other twin is at higher

risk for developing that disorder (Bulik et al., 2019).

Psychosocial Theories

Symptoms of bulimia nervosa develop when psychological, sociocultural, or environmental events occur. Because the age of onset for bulimia nervosa is late adolescence—going away to college, for example—may represent the first physical separation for some adolescents, who are unprepared for the emotional separation. In addition, an inability to set limits and develop healthy boundaries leads to a sense of being overwhelmed and “drained.” Overwhelming feelings often lead to binge eating, either to avoid or to distract oneself from feelings such as resentment, or binge eating can serve to assuage emptiness or to fill up a “drained” self with food.

Cognitive Theory

Many experts view bulimia nervosa as a disorder of thinking in that distortions are the basis for behaviors such as binge eating and purging. Psychological triggering mechanism models explain that cues such as stress, negative emotions, and even environmental cues (e.g., the presence of attractive food) play a role in etiology. However, today these cognitive and triggering theories are viewed as an explanation for maintaining the binge eating after it has been established rather than an explanation of causality.

The same sociocultural factors that underlie anorexia nervosa play a significant role in the development of bulimia nervosa.

Ellen's Triggers

Some of Ellen's triggers are anxiety, boredom, alcohol use, exhaustion, anger, and social situations where food is readily available.

What are the theoretical explanations that relate her triggers to bulimia behavior? What interventions would you suggest for these triggers?

Family Factors

Dysfunctional family relationships of persons with eating disorders have been implicated for years. Current research indicates that perceived lack of cohesion in a family relates to depressive and bulimic behaviors. That is, if a person is depressed and views family members as less cohesive, close, or supportive, the individual would be more likely to have depression and/or bulimia (Kluck et al., 2017).

RECOVERY-ORIENTED CARE FOR PERSONS WITH BULIMIA NERVOSA

Teamwork and Collaboration: Working Toward Recovery

Individuals with bulimia nervosa benefit from a comprehensive multimodal treatment approach. The goals for treatment for individuals with bulimia nervosa focus on stabilizing and then normalizing eating, which means stopping the binge-purge cycles; restructuring dysfunctional thought patterns and attitudes, especially about eating, weight, and shape; teaching healthy boundary setting;

and resolving conflicts about separation–individuation. Treatment usually takes place in an outpatient setting except when the patient is suicidal or when past outpatient treatment has failed (see [Box 32.6](#)).

Pharmacologic interventions paired with cognitive behavioral therapy (CBT) or interpersonal psychotherapy are also effective. Antidepressants demonstrate effectiveness in treating binge eating and purging even without comorbid depression. Nutrition counseling is an important part of outpatient treatment to stabilize and normalize eating. Some mental health professionals, psychologists, advanced practice psychiatric nurses, and social workers specialize in treating eating disorders, often working with nutritionists who also have expertise with this population. Group psychotherapy and support groups are also used. Family therapy is not usually a part of the treatment because many people with bulimia nervosa live on college campuses away from home or are older and live on their own. Usually, treatment becomes less intensive as symptoms remit. Therapy focuses on psychological issues, such as boundary setting and separation–individuation conflicts and on changing problematic behaviors and dysfunctional thinking using CBT.

Safety Issues

Bulimia nervosa is associated with a high risk of suicide, independent of other comorbid disorders. Individuals with bulimia nervosa are also often at risk for self-harm. Because they display high levels of impulsivity, shoplifting, and overspending, financial and legal difficulties have been associated with this disorder (Wade, 2019).

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH BULIMIA NERVOSA DISORDER

Mental Health Nursing Assessment

Physical Health and Functioning

Even though most individuals with bulimia nervosa maintain normal weights,

the physical ramifications of this disorder may be similar to those of anorexia nervosa. Hypokalemia can contribute to muscle weakness and fatigability, as well as to the development of cardiac arrhythmias, palpitations, and cardiac conduction defects. Patients who purge as well as abuse laxatives risk fluid and electrolyte abnormalities that can further compromise cardiac status. Tooth enamel erosion because of frequent purging is also a consequence of bulimia nervosa. Neuropsychiatric disturbances, such as poor concentration and attention, and sleep disturbances, are common.

The nurse should assess current eating patterns, determine the number of times a day the individual binges and purges, and note dietary restraint practices. Sleep patterns and exercise habits are also important.

Psychosocial Assessment

For the individual with bulimia nervosa, psychological assessment focuses on cognitive distortions—cues or stimuli that lead to dysfunctional behavior affecting symptom development—and knowledge deficits. The psychological characteristics typical of patients with bulimia nervosa are presented in [Box 32.1](#).

Individuals with bulimia nervosa display a significant number of cognitive distortions, examples of which are found in [Table 32.2](#). These thought patterns form the basis for “rules” and lead the way to destructive eating patterns. During routine history taking, patients relate many of these erroneous assumptions. Situations that produce feelings of being overwhelmed and powerless need to be explored, as does the patient’s ability to set boundaries, control impulsivity, and maintain quality relationships. These underlying issues precipitate binge eating. Body dissatisfaction should be openly explored. Mood is an important area for evaluation because many people with bulimia nervosa also have depression. Symptoms of depression should be thoroughly explored (see [Chapter 23](#)). See Nursing Care Plan 32.1—which sets forth a plan of care for Ellen, the case study patient in this chapter.

Quality of Life

Quality of life is negatively impacted by bulimia nervosa as well as AN. In

bulimia nervosa, bingeing and purging are related to poor quality of life and are associated with alcohol bingeing (Escrivá-Martínez et al., 2020; van Hoeken & Hoek, 2020).

Strengths Assessment

Persons with bulimia can usually identify periods of time when they were able to resist bingeing and purging. They are usually motivated to reduce or eliminate the bingeing and purging. The following questions can be used if the strengths do not emerge during the assessment interview.

- How have you curtailed the bingeing and purging behavior in the past?
- What do you do to reduce your anxiety (instead of bingeing)?
- Is there anyone in your life that you feel understands your situation?
- How motivated are you to change your eating behaviors and work on body image issues?

NURSING CARE PLAN 32.1

The Patient With Bulimia Nervosa

Ellen is a 20-year-old female admitted to the inpatient eating disorders unit for treatment of bulimia nervosa. She was discharged from a medical unit where she was treated for electrolyte imbalance and dehydration. She started bingeing and purging when she left home for college. She was introduced to Ipecac but found that she could force herself to vomit through sticking her hand in her throat. She has agreed to admission in order to learn how to change her behavior.

Setting: Inpatient Psychiatric Unit

Baseline Assessment: Ellen wants to maintain a normal weight but believes that she is overweight. She has been bingeing and purging for 2 years. When she is dieting, she becomes very hungry and binges on as many as 10,000 calories at once. She then becomes angry with herself and purges through vomiting. She feels better temporarily, but soon feels out of control, guilty, and remorseful. She does not use laxatives or diuretics to lose weight. She has dental problem, bilateral parotid enlargement, and tenderness. Her menstrual periods are irregular; cardiac arrhythmias related to electrolyte imbalance noted in chart. BP 110/60; P 70, R 16, Ht. 5 ft 3 in, Wt. 125, BMI 22.9.

Associated Psychiatric Diagnosis Medications

Bulimia Nervosa

None

Priority of Nursing Care: Body Image Disturbance

Important Characteristics

Considers herself too fat and unattractive despite contrary evidence

Associated Considerations

Inaccurate perceptions of body size
Believes that she is too fat despite evidence that she is normal weight.

Outcomes

Initial

Verbalizes feelings related to changing body shape and weight. Identifies beliefs about controlling body size.

Long Term

Identifies positive aspects of her body and its ability to function.

Interventions

Interventions Rationale

Explore Ellen's beliefs and feelings about body. Maintain a nonjudgmental approach.

Assist patient in identifying positive physical characteristics.

Clarify patient's views about an ideal body.

Provide education

Rationale

To help patient gain a more positive understanding of her own views is important.

In anorexia, the body is viewed negatively. By focusing on parts of the body that are positive, such as eyes or hands, the patient can begin to experience a positive image of her body.

Many societal cues idealize an unrealistically thin female body.

Providing education will help in reinforcing a broader view

Providing education will help in reinforcing a broader view

Ongoing Assessment

Monitor for statements that identify perceptions of her body. Is her view *distorted or dissatisfied?*

Observe for patient's reaction to her body. Which areas are viewed positively? Observe for negative statements related to body size and self-esteem.

Monitor for statements indicating external pressures to lose weight, experiences of teasing about body changes, or evidence of sexual abuse from others.

Assess patient's willingness to learn

related to of the importance of a healthy information.
 normal growth body.
 of women's
 bodies, role of
 fat in protection
 of body.

Evaluation

Outcomes

Ellen revealed that she believes that she is too fat but does have positive physical traits—eyes. She believes that those who are overweight have lost control of their lives. She knows some models who are 6 ft and weigh barely 100 lb.

Willing to read information about normal body functioning.

Revised Outcomes

Accept alternative beliefs related to her own body.

Accept a new view of body functioning as a complex phenomenon.

Interventions

Gradually, focus on other positive physical aspects of Ellen's body. Discuss grooming that encourages a more attractive look. Challenge her beliefs about body weights of models.

Discuss the biologic aspect of the development of body weight. Emphasize multiple factors determine body weight.

Priority of Care: Motivated for change

Important Characteristics

Expresses willingness to change
 bingeing and purging behavior

Associated Considerations

History of dieting and purging.
 Wanting to resume normal eating

Choices of daily living are appropriate patterns without purging.
for meeting treatment goals.

Outcomes

Initial

Desires to move to a higher level of wellness.
Identify two new strategies to enhance
management of bulimia nervosa.

Long Term

Develop positive eating
patterns.

Interventions

Interventions

Rationale

Ongoing Assessment

Encourage Ellen to
discuss her strategies to
meet higher wellness
goals.

Patient needs to identify specific
goals to meet wellness goals.

Determine if she
is able to
articulate
realistic goals.

Help Ellen identify two
new strategies to avoid
dieting and purging.

Identification of specific, realistic
plans to meet needs increases
possibility of carrying out
strategies.

Determine if
goals are doable.

Evaluation

Evaluation

Revised Outcomes

Interventions

Met new wellness goals.

Completed

Able to use new strategies to resist
dieting and purging.

Completed

CLINICAL JUDGMENT

The first priority is to address emerging medical problems such as electrolyte imbalances. Suicide or self-harm behaviors should also be addressed.

THERAPEUTIC RELATIONSHIP

Individuals with bulimia nervosa experience a great deal of shame and guilt. They also often have an intense need to please and be liked and may approach the nurse–patient relationship in a superficial manner. They are too ashamed to discuss their symptoms but do not want to disappoint others, so they may discuss more social or unrelated issues in an attempt to engage the nurse ([Box 32.12](#)). A nonjudgmental, accepting approach, stressing the importance of the relationship and outlining its purpose, is important at the outset. Explaining the nature of the relationship and the goals of therapy will help clarify the boundaries.

BOX 32.12 • THERAPEUTIC DIALOGUE: THE PATIENT WITH AN EATING DISORDER

INEFFECTIVE APPROACH

Nurse: Ellen, I am glad to see that you ate your lunch.

Ellen: Thanks, I feel so fat after I eat.

Nurse: I will lock the bathroom so you are not tempted to purge.

Ellen: What, don't you trust me?

Nurse: It is not about trust, but I don't feel comfortable leaving you alone with bathroom access.

Ellen: Really? You have your nerve.

Nurse: We are just trying to help.

Ellen: Some help you are. I know you don't trust me.

Nurse: Now, Ellen that is not what I said.

Ellen: No, but that is what you meant.

EFFECTIVE APPROACH

Nurse: Ellen, how was your lunch.

Ellen: I was ok. I always feel so fat after I eat.

Nurse: That is understandable. How long does that feeling last.

Ellen: Well, it depends on how much I have eaten. Since I didn't eat much, it will last for about an hour?

Nurse: Oh, I see. For many people with bulimia, the urges to purge are strongest after a meal? Is this a hard time for you?

Ellen: Sometimes it is.

Nurse: How can I help you resist the urges? Would you like me to stay with you until group time?

Ellen: That would be great.

CRITICAL THINKING CHALLENGE

- What effect did the first interaction have on Ellen's behavior? Why?
- In the second interaction, what theories and interventions regarding eating disorders did the nurse use in her approach to Ellen?

Consider This

Ellen feels shame and guilt over her bingeing and purging. She does not like to talk about it and is very reluctant to talk to the nurse about the behavior.

Which interventions would be helpful to help Ellen deal with her guilt?
Would she be a candidate for a support group?

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

Important goals for a person with bulimia are to establish a normal eating/elimination pattern and to develop positive self-esteem and positive body image. Since these individuals are not likely to be over-exercising, helping them normalize physical activities and develop healthy sleep patterns are two possible wellness goals.

Physical Care

If the patient is admitted to the hospital, meals and all food intake are strictly monitored to normalize eating. Bathroom visits may also be supervised to prevent purging. Outpatients are asked to record their intake, binges, and purges.

Because individuals with bulimia nervosa have chaotic lifestyles and are often overcommitted, sleep may be a low priority. Sleep-deprived individuals may assume that food would be helpful, and they begin to eat, triggering a binge. To encourage regular sleep patterns, sleep hygiene strategies are implemented.

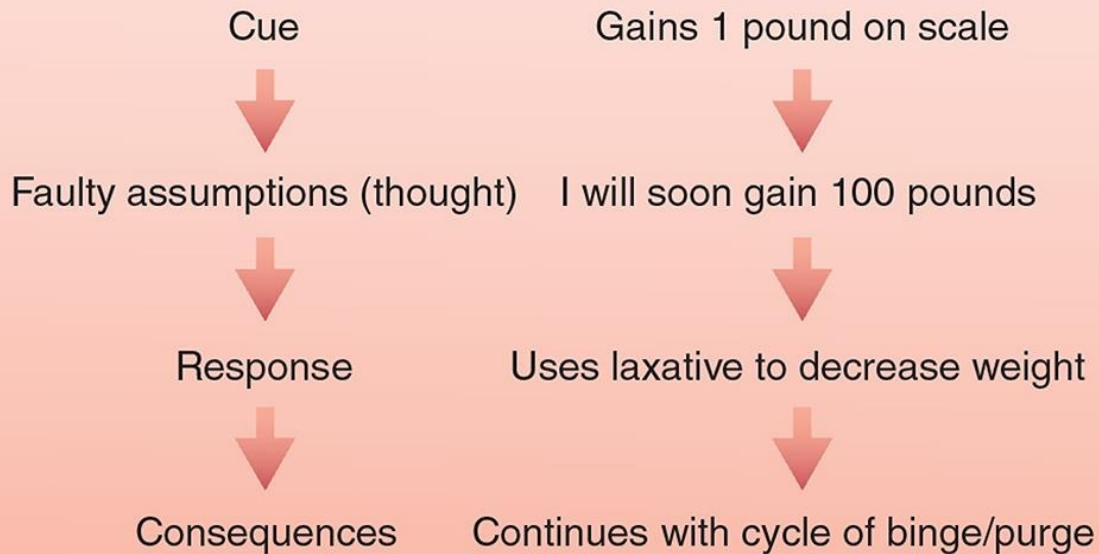

Medication Interventions

Fluoxetine is approved by the FDA for treating bulimia nervosa. This SSRI has been shown to reduce vomiting and bingeing episodes (Bello & Yeomans, 2018).

Using Cognitive and Behavioral Interventions

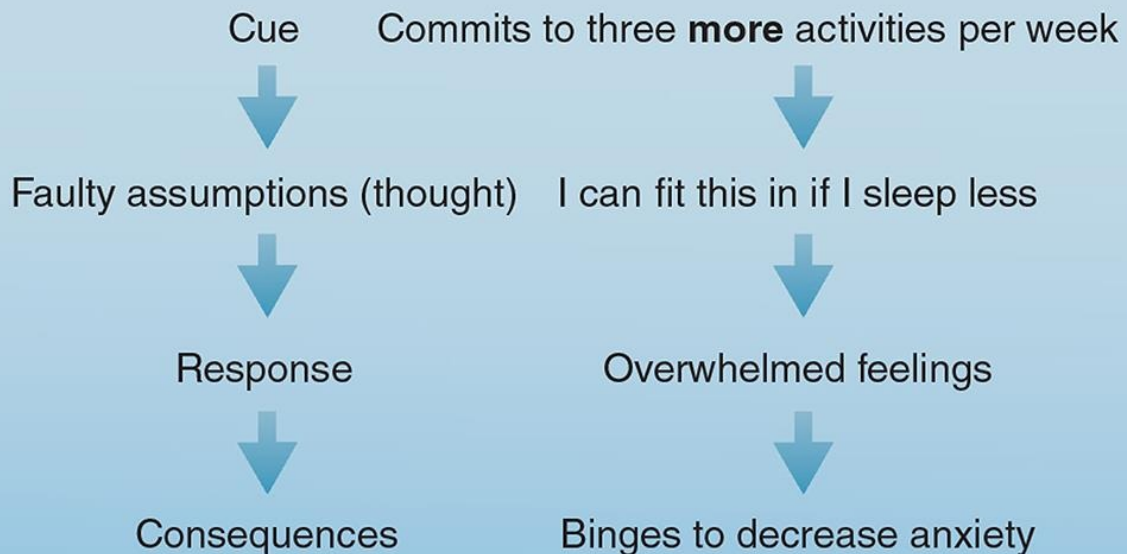

The behavioral techniques, such as cue elimination and response prevention, require self-monitoring to individualize the therapy. Self-monitoring is accomplished using a diary in which the patient records binges and purges and precipitating emotions and environmental cues. Emotional and environmental cues are identified, and alternative responses are suggested, tried, and reinforced. When a cue or stimulus leads to a dysfunctional or unhealthy response, the response can be eliminated or an alternate, healthier response to the cue can be substituted, tried, and then reinforced. [Figure 32.2](#) gives two examples of behavioral interventions. In Example 1, for the patient with anorexia nervosa, the response is modified or altered to a healthier one; in Example 2, for the patient with bulimia nervosa, the cue is changed to produce a different, healthier response. Other techniques, such as postponing binges and purges through distraction, a technique to interrupt the cycle, are also effective.

1. Patient With Anorexia Nervosa

Nursing Intervention: Help patients with **alternative** responses to normal weight gain such as relaxation, distraction.

2. Patient With Bulimia Nervosa

Nursing Intervention: Help patient **eliminate cues** to binge eating by setting limits on her free time.

FIGURE 32.2 Examples of the relationship of cues, thoughts, responses, and behavioral interventions.

NCLEXNOTE Cognitive interventions within the context of a therapeutic relationship are a priority in the nursing care of patients with eating disorders.

Psychoeducation

Teaching Strategies

In addition to cognitive and behavioral techniques, educational strategies are also incorporated into treatment. For individuals with bulimia nervosa, psychoeducation focuses on setting boundaries and healthy limits, developing assertiveness, learning nutritional concepts related to healthy eating, and clarifying the many misconceptions they have about food and its influence on weight. Rules that result from dichotomous thinking must also be addressed because of their role in dietary restraint and resulting binge eating.

Teaching About Symptoms

The nurse can assist patients in understanding the binge–purge cycle and the role of rigid rules in contributing to this cycle. The value of eating meals regularly to ward off hunger and reduce the possibility of a binge is also important. Patients who abuse laxatives must be taught that although these drugs produce water-weight loss, they are ineffective for true, lasting weight loss because they work on the colon and not the small intestine or stomach where food is absorbed. Patients also need information about potassium depletion, electrolyte imbalances, dehydration, and the medical consequences of binge eating and purging. Other topics for psychoeducation are included in [Box 32.13](#).

Box 32.13

Bulimia Nervosa

When caring for the patient with bulimia nervosa, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents, if used, including drug, action, dosage, frequency, and possible adverse effects
- Binge–purge cycle and effects on the body
- Nutrition and eating patterns
- Hydration
- Avoidance of cues
- Cognitive distortions
- Limit setting
- Appropriate boundary setting
- Assertiveness
- Resources
- Self-monitoring and behavioral interventions
- Realistic goal setting

Convening Support Groups

Group interventions are cost effective and increase learning more effectively than does individual treatment because patients learn from each other as well as from the nurse, therapist, or leader. Some experts have recommended 12-step programs for treating bulimia nervosa. However, many clinicians who work in this specialty have noted that these programs, with their strict rules, can be counterproductive for patients with bulimia nervosa, who already have rigid rules and are “abstinent” in many ways that lead to binge eating. Broad parameters regarding food choices (e.g., all foods allowed in moderation), in combination with knowledge about healthy eating, should be encouraged instead.

After symptoms subside, patients can concentrate on interpersonal issues in therapy, such as a fused relationship with their mothers or feelings of inadequacy and low self-esteem, which often underlie their lack of assertiveness.

Developing Recovery-Oriented Rehabilitation Strategies

Strategies used for AN can also be applied to BN. There is emerging research that shows that physical exercise and dietary therapy may be a realistic approach that supports recovery (Mathisen et al., 2020).

Evaluation and Treatment Outcomes

Most people recover from bulimia nervosa over time. Rates of recovery from bulimia peak within the first 10 years. Patients with bulimia nervosa have better and quicker recovery than do those with anorexia nervosa (Eddy et al., 2017).

Continuum of Care

Emergency and Inpatient-Focused Care

Although patients with bulimia nervosa are less likely than those with anorexia nervosa to require hospitalization, those with extreme dehydration and electrolyte imbalance, depression and suicidality, or symptoms that have not remitted with outpatient treatment need hospitalization.

However, most treatment takes place in outpatient settings. After treatment, referrals to recovery groups and support groups are important to prevent relapse. Rarely do patients with bulimia nervosa require emergency care.

Community Care

As with anorexia nervosa, preventing bulimia nervosa requires effort on the part of teachers, school nurses, parents, and society as a whole. Because many of the risk factors are seen early in children attending elementary school, educating school nurses and teachers is an important focus for psychiatric-mental health nurses working in the community. Protective factors that mediate between risk

factors and the development of an eating disorder must be emphasized and developed. [Box 32.11](#) covers important prevention strategies for parents and their children or adolescents.

Society has begun to engage in an effort to help young girls. The federal government has developed a website called *girlshealth* that is devoted to areas such as body changes, body image, relationships, and self-confidence.

BINGE EATING DISORDER

BED is characterized by episodes of consuming large amounts of foods in a short period of time. These individuals binge in the same way as those with bulimia nervosa do, but they do not purge or compensate for binges through other behaviors. BED differs from other eating disorders in that there are few severe impairments. It can result from psychological, social, and cultural factors. Some risk factors include childhood obesity, loss of controlled eating in childhood, intestinal microbiota alteration, distorted body image, perfectionism, conduct problem, and substance use. In the United States, the prevalence of BED is estimated to be 2.6% (Iqbal & Rehman, 2020).

The diagnostic criteria for BED consist of binge eating, which includes both the ingestion of a large amount of food in a short period of time and a sense of loss of control during the binge, distress regarding the binge; eating until uncomfortably full, and feelings of guilt or depression after the binge. As mentioned, purging or other compensatory behavior does not follow the binge. The prevalence of BED is estimated to be 1.6% for females and 0.8% for males in the United States (APA, 2013).

Because this is a newly recognized disorder, additional research is needed to clarify its symptoms, etiology, and treatment. Its etiology is believed to be similar to that of bulimia nervosa. The treatment of individuals with BED includes psychotherapy, pharmacotherapy, and weight loss treatment (Iqbal & Rehman, 2020).

OTHER EATING DISORDERS

A complete discussion of all the eating disorders is outside the scope of this text.

Purging disorder and night eating are briefly described here.

Purging Disorder

In purging disorder, there is frequent purging, but not bingeing. Individuals with this disorder purge at least once a week and have an intense fear of gaining weight or becoming fat (APA, 2013). They restrict their dietary intake and purge after eating normal amounts of food due to the fear of eating, gaining weight, and/or appearing “fat.” These individuals have increased levels of body image disturbance, higher levels of general psychopathology, distress, eating pathology, and personality disorders when compared to a comparable group of persons without purging disorder. While individuals with this disorder do not overeat as those with bulimia nervosa, they do report more dietary restraint, greater fear of losing control, and greater guilt over eating than control groups. On a continuum of bulimic symptomatology, purging disorder may be the midpoint with bulimia nervosa the more severe (Forney et al., 2020).

Night Eating Syndrome

In night eating syndrome, the individual eats after awakening from sleep or consumes an excessive amount of food after the evening meal (APA, 2013). The person is aware of overeating, which causes significant distress or impairment to the individual. There is a feeling of loss of control over consumption, sleep fragmentation, and morning anorexia. Night eating syndrome is conceptualized as a disorder of circadian modulation of food intake and sleep. It is mainly attributed to an endocrine metabolic or psychological trigger factor. These individuals typically experience insomnia and nighttime awakenings (Haraguchi et al., 2019).

SUMMARY OF KEY POINTS

- Anorexia nervosa and bulimia nervosa have some common symptoms but are classified as discrete disorders.

- Eating disorders are best viewed along a continuum that includes subclinical or partial-syndrome disorders; because these disorders occur more frequently than full syndromes, they are often overlooked but, after they are identified, they can be prevented from worsening.
- Similar factors predispose individuals to the development of anorexia nervosa and bulimia nervosa, and these factors represent a biopsychosocial model of risk. These disorders are preventable, and identifying risk factors assists with prevention strategies.
- Etiologic factors contribute in combination to the development of eating disorders; no one factor provides an explanation.
- Treatment of anorexia nervosa frequently includes hospitalization for refeeding; bulimia nervosa is treated primarily on an outpatient basis.
- Cognitive-behavioral therapy and medications improve the symptoms. Individual and group interpersonal psychotherapy are also effective in self-evaluation and communication.
- The outcomes for bulimia nervosa are better than those for anorexia nervosa. The type and severity of comorbid conditions and the length of the illness influence outcomes.
- BED is characterized by periods of binge eating not followed by purging or any other compensating behaviors.

CRITICAL THINKING CHALLENGES

1. Discuss the potential difficulties and risks in attempting to treat a patient with anorexia nervosa in an outpatient setting.
2. Parents are often in need of support and suggestions for how to help prevent eating disorders. Develop a teaching program and include the topics and rationale for suggestions chosen.
3. Identify the important nursing management components of a refeeding

program for a hospitalized patient with anorexia nervosa.

- i. Bulimia nervosa is often described as a closet disorder with secretive binge eating and purging. Identify the signs and symptoms of each system involved for someone with this disorder.
- j. Positive outcomes for the recovery of bulimia nervosa and anorexia nervosa depend on many factors. Identify the factors that promote positive outcomes and those related to poorer outcomes and prognosis.

Somatic Symptom and Dissociative Disorders

Nursing Care of Persons with Somatization

Mary Ann Boyd and Victoria Soltis-Jarrett

KEYCONCEPTS

- somatization

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of somatization in somatic symptom and related disorders in people with mental health problems.
2. Delineate the clinical symptoms and course of somatic symptom disorder (SSD).
3. Analyze the prevailing theories related to somatic symptoms and related disorders.
4. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with somatization and cognitive distortions.
5. Apply a person-centered, recovery-oriented nursing process for persons with somatic symptoms and related disorders.

5. Identify the role of medications for people with SSD.
7. Develop wellness strategies for persons with SSD.
8. Differentiate the type of mental health care provided in emergency care, inpatient-focused care, community care, and virtual mental health care.
9. Discuss the importance of integrated health care for persons with SSD.
10. Describe other disorders related to somatic symptom and dissociative disorders.

KEY TERMS

- Alexithymia
- Conversion disorder
- Factitious disorder
- Factitious disorder imposed on another
- Illness anxiety disorder
- Pseudologia fantastica
- Psychosomatic
- Somatic symptom disorder (SSD)

Case Study

Carol is a 48-year-old woman with obesity who is very angry at being forced to see a mental health care provider. She has had multiple surgeries, including hysterectomy, gastric bypass, and carpal tunnel release. She suffers from shoulder and neck pain and from vertigo. She takes multiple medications.

INTRODUCTION

The connection between the “mind” and “body” has been hypothesized and described for centuries. The term psychosomatic has been traditionally used to

describe, explain, and predict the psychological origins of illness and disease. Unfortunately, this notion perpetuates the stigma that certain disorders are purely “psychological” in nature and thus are not real or valid. For example, it was formerly believed that people with asthma were behaviorally “acting out” their anger, fear, or emotional pain and were seeking attention rather than experiencing an alteration in their respiratory status.

In contrast, the concept of *somatization* acknowledges and respects that bodily sensations and functional changes are expressions of health and illness, and, even though they may be unexplained, they are not imaginary or “all in the head” (Marek et al., 2020).

KEYCONCEPT Somatization (from *soma*, meaning body) is the manifestation of psychological distress as physical symptoms that may result in functional changes, somatic descriptions, or both.

Whereas some evidence suggests that somatization is a result of abnormally high levels of physiologic response (Guo et al., 2019), other evidence supports the idea that somatization is the physical expression of personal problems or the internalization and expression of stress through physical symptoms (Astill Wright et al., 2020). For example, a woman quits her job because of chronic fatigue syndrome rather than recognizing that she is emotionally stressed from the constant harassment of a coworker.

Historically, the concept of somatization was linked to women and was related to a woman’s body, mind, or even her soul. For example, the term *hysteria*, frequently associated with somatization, actually comes from ancient times when it was believed that a woman’s unfounded physical symptoms were related to her “wandering or discontented uterus.” Because *hystera* is the Greek word for “uterus,” the terms *hysteria* and *hysterical* were used to describe a woman whose physical or emotional symptoms could not be substantiated by physicians at that time.

We now understand that somatization is not linked to the uterus, nor is it just a problem for women. Men also are affected by somatization. Much research is still needed in this area to be able to make any valid and reliable conclusions about gender and somatization (Shangguan et al., 2020). Somatization also crosses all cultures and is recognized in almost every society (de la Torre-Luque et al., 2020). In many cultures, the expression of physical discomfort is more acceptable than acknowledging psychological distress. The disruption of routine body cycles, such as digestion, menstruation, or sleep, is more socially

acceptable than having emotional responses related to interpersonal relationships, economic crises, adjustment to marriage, infertility, or the death of a spouse.

SOMATIC SYMPTOM AND RELATED DISORDERS OVERVIEW

This chapter explores the holistic evidence-based nursing care for people experiencing the *DSM-5* group of disorders with the prominent symptom of somatization (American Psychiatric Association [APA], 2013). SSD is highlighted and illness anxiety disorder, conversion disorder, and factitious disorders are discussed.

SOMATIC SYMPTOM DISORDER

Nurses in primary care and medical–surgical settings are more likely than mental health nurses to encounter persons with these problems. It must be noted that the term *somatoform* is no longer used in the *DSM-5* to describe these disorders (APA, 2013).

Clinical Course

Somatic symptom disorder (SSD) is one of the most difficult disorders to manage because its symptoms tend to change, are diffuse and complex, and vary and move from one body system to another. For example, initially gastrointestinal (e.g., nausea, vomiting, diarrhea) and neurologic (e.g., headache, backache) symptoms may be present that change to musculoskeletal (e.g., aching legs) and sexual issues (e.g., pain in the abdomen, pain during intercourse). Physical symptoms may last for more than 5 years (D’Souza & Hooten, 2020).

Individuals with SSD perceive themselves as being “sicker than the sick” and report all aspects of their health as poor. Many eventually become disabled and unable to work. They typically visit health care providers many times each month and quickly become frustrated because their primary health care providers

do not understand their level of suffering and are unable to validate that a particular problem accounts for their extreme discomfort. Consequently, individuals with SSD tend to “provider shop,” moving from one to another until they find one who will give them new medication, hospitalize them, or perform surgery. Because the source of worrisome physical symptoms cannot be determined through medical or laboratory tests, medical or psychiatric interviews, or medical imaging, they repeatedly seek a medical reason for their discomfort and ask for relief from suffering. Depending on the severity, these individuals undergo multiple surgeries and even develop iatrogenic illnesses. People with SSD often evoke negative subjective responses in health care providers, who usually wish that the patient would go to someone else.

The following are the most common characteristics:

- Reporting the same symptoms repeatedly
- Receiving support from the environment that otherwise might not be forthcoming (e.g., gaining a spouse’s attention because of severe back pain)
- Expressing concern about the physical problems inconsistent with the severity of the illness (being “sicker than the sick”)

NCLEXNOTE Patients with SSD seek health care from multiple providers but often avoid mental health specialists.

Diagnostic Criteria

The diagnostic criteria of SSD include one or more symptoms that cause persistent distress or significant disruption in daily lives for at least 6 months and excessive thoughts about the seriousness of the symptoms, feelings (such as anxiety about the symptoms or overall health), or behaviors related to the symptoms or health concerns (e.g., spending excessive time and energy focusing on these symptoms or health) (APA, 2013). These symptoms may or may not be explained by medical evidence. The expression of the symptoms varies from population to population.

SSD Across the Life Span

SSD is found in most populations and cultures even though its expression may vary from population to population. In cultures that highly stigmatize mental illness, somatic symptoms are more likely to appear (Horsfield et al., 2020).

Children and Adolescents

Although many children have somatic symptoms, SSD is not usually diagnosed until adolescence. However, when children have medical symptoms, further evaluation is needed so they are often referred to specialists to rule out physical, sexual, or emotional abuse or a comorbid psychiatric illness, such as depression or anxiety. In children, the most common symptoms are frequent abdominal pain, headache, fatigue, and nausea. Expression of somatic symptoms in children tend to be overlooked or minimized when it needs to be identified as a risk factor for follow-up (Boerner et al., 2020). In adolescents, initial symptoms are typically menstrual difficulties, and pelvic or abdominal pain. Risk factors for both children and adolescents need to be taken seriously. Research has shown a link between childhood sexual abuse and somatization, substance use, and depression in adults (Ibeziako et al., 2020).

Older Adults

SSD can involve a lifelong pattern of symptoms that persists into old age. The symptoms of SSD, however, are often unrecognized by health care providers who tend to accept and minimize them as a part of the natural aging process after no medical cause is found.

Epidemiology and Risk Factors

The estimated prevalence of SSD ranges from 5% to 7% (APA, 2013). Millions of dollars of lost revenue and the increased use of short- and long-term disability

have prompted employers to study this unique population of employees. This disorder is believed to be higher than reported. In persons with fibromyalgia syndrome, nearly 35% meet the criteria for SSD (Axelsson et al., 2020).

Age of Onset

SSD usually begins before the age of 30 years, with the first symptom often appearing during adolescence. Rarely diagnosed until several years later, seeking help can last for many years, with the individual frequently going from one health care provider to another to no avail. The use of specific assessment instruments is increasing the likelihood of earlier diagnosis and treatment (Toussaint et al., 2019).

Gender, Ethnic, and Cultural Differences

Epidemiologic studies have reported that SSD occurs primarily in non-White, less educated women, particularly those with a lower socioeconomic status and high emotional distress (Granot et al., 2018). Men are less likely to be diagnosed with SSD, partly because of stereotypic male traits, such as a disinclination to admit discomfort or seek help for their symptoms (APA, 2013).

Familial Differences

SSD tends to run in families, and children of parents with multiple unexplained somatic complaints are more likely to have somatic problems. Individuals with a tendency toward heightened physiologic arousal and a tendency to amplify somatosensory information have a greater risk of developing this disorder. Data have also confirmed a strong association between sexual trauma exposure and somatic symptoms, illness attitudes, and health care utilization in women (Granot et al., 2018).

Comorbidity

SSD frequently coexists with other psychiatric disorders, most commonly depression and anxiety. Others include post-traumatic stress disorder, panic disorder, social phobia, obsessive-compulsive disorder (OCD), psychotic disorders, and personality disorders (Newby et al., 2017). Older adults are at particularly high risk for comorbid depression (Johnson et al., 2017).

Ultimately, numerous unexplained medical problems also coexist with this disorder because many patients have received medical and surgical treatments, often unnecessarily, and are plagued with side effects. A disproportionately high number of women who eventually receive diagnoses of SSD have been treated for irritable bowel syndrome (IBS), polycystic ovary disease, and chronic pain.

Etiology

Biologic Theories

The cause of SSD is unknown. General agreement exists that somatization has a biopsychosocial basis, with the possibility of biologic dysfunction common in depression and chronic fatigue syndrome. There are data to support the presence of anatomical and functional deficits in the cortico-limbic-cerebellar circuit (Li et al., 2018).

Although SSD has been shown to run in families, the exact transmission mechanism is unclear. Strong evidence suggests an increased risk for SSD in first-degree relatives, indicating a familial or genetic effect. Because many individuals with SSD live in chaotic families, the high prevalence in first-degree relatives could be explained by environmental influence.

Psychological Theories

Somatization has been explained as a form of social or emotional communication, meaning that the bodily symptoms express an emotion that cannot be verbalized by the individual. An adolescent who experiences severe abdominal pain after her parents argue or a wife who receives nurturing from her

husband only when she has back pain are two examples. From this perspective, somatization may be a way of communicating and maintaining relationships. Following this line of reasoning, an individual's physical problems may also become a way of controlling relationships, so somatization becomes a learned behavior pattern. With time, physical symptoms develop automatically in response to perceived threats. Finally, SSD develops when somatizing becomes a way of life (Davoodi et al., 2018).

Consistent with a communication explanation, cognitive behaviorists explain somatization symptoms as an interaction of negative views of the world with physical factors (e.g., pain, discomfort). In this model, individuals have a heightened response based on their experiences with a stressor, especially if the stressor is uncontrollable and unpredictable. Over time, their exaggerated responses become an automatic pattern, resulting in “sick role” behavior, which in turn provokes either a negative or positive response in others (Bilsky et al., 2018; Mik-Meyer & Obling, 2012).

Another theoretical explanation for somatization is the personality trait alexithymia, which is associated with SSD. Individuals with alexithymia have difficulty identifying and expressing their emotions. They have a preoccupation with external events and are described as concrete externally oriented thinkers (de Vroeghe et al., 2018). Credible evidence suggests a link between a history of childhood sexual abuse, rape, and domestic violence, and subsequent lifetime sequelae of somatic symptoms and somatic disorders (Granot et al., 2018).

Social Theories

SSD has been reported globally even though its conceptualization is primarily Western. The symptoms may vary from culture to culture. For example, studies in China have identified and discussed the notion of somatization as a moral issue rather than a medical problem. Somatization is a more socially acceptable way to express behavior in lieu of being diagnosed as depressed because in China, where mental illness is perceived as a character flaw. In many non-Western societies, where the mind–body distinction is not made and symptoms have different meanings and explanations, these physical manifestations are not labeled as a psychiatric disorder (Zhou et al., 2016) (Box 33.1). In Latin American countries, depression is more likely described in somatic symptoms, such as headaches, gastrointestinal disturbances, or complaints of “nerves,”

rather than sadness or guilt (Schantz et al., 2017).

Box 33.1

Somatization in Chinese Culture

In Chinese tradition, the health of the individual reflects a balance between positive and negative forces within the body. Five elements at work in nature and in the body control health conditions (e.g., fire, water, wood, earth, metal), five viscera (e.g., liver, heart, spleen, kidneys, lungs), five emotions (anger, joy, worry, sorrow, fear), and five climatic conditions (e.g., wind, heat, humidity, dryness, cold). All illness is explained by imbalances among these elements. Because emotion is related to the circulation of vital air within the body, anger is believed to result from an adverse current of vital air to the liver. Emotional outbursts are seen as results of imbalances among the natural elements rather than the results of behavior of the person.

The stigma of mental illness in the Chinese culture is so great that it can have an adverse effect on a family for many generations. If problems can be attributed to natural causes, the individual and family are less responsible, so that stigma is minimized. The Chinese have a culturally acceptable term for symptoms of mental distress—the closest translation of which would be *neurasthenia*—which comprises somatic complaints of headaches, insomnia, dizziness, aches and pains, poor memory, anxiety, weakness, and loss of energy (Bhola & Chaturvedi, 2020).

Family Response to Disorder

Family dynamics are shaped by all members, including the person with SSD. When one member has several ongoing chronic health issues, family members' activities and interactions are affected. The physical symptoms of the individual become the focus of family life, so activities are planned around that person. Because so much time and so many resources are used trying to discover an underlying illness, resources to other family members are reduced. Because the person is always sick, expressing anger about the situation is difficult. The family members need support as they learn to understand the seriousness and

difficulty of experiencing an SSD.

RECOVERY-ORIENTED CARE OF PERSONS WITH SSD

Teamwork and Collaboration: Working Toward Recovery

The care of patients with SSD involves three approaches:

- Providing long-term supportive general management of the chronic condition
- Treating symptoms of comorbid psychiatric and physical problems
- Providing care in special settings, including individual and group treatment and the use of complementary and alternative medicine.

The cornerstones of management are trust and believing. Ideally, the patient should see only one health care provider at regularly scheduled visits. During each primary care visit, the provider should conduct a holistic assessment, including a partial physical examination of the organ system, focusing on the areas where the patient has complaints. Physical symptoms are treated conservatively using the least intrusive approach. The provider should also assess for any stressors, life changes, and/or a history of trauma that has been linked to the excessive expression of somatic symptoms. In the mental health setting, the use of cognitive-behavioral therapy (CBT) can be effective (Liu et al., 2019).

Safety Issues

SSD and related disorders are associated with a risk of suicide. If depression and anxiety are present, the risk is greater. Safety becomes even more of a concern because these individuals are not usually treated in a mental health setting where suicide assessments are routine (Torres et al., 2021).

EVIDENCE-BASED MENTAL HEALTH NURSING

CARE OF THE PERSON WITH SSD

Mental Health Nursing Assessment

During the assessment interview, the nurse should allow enough time for the patient to explain all medical problems; a hurried assessment interview blocks communication. Nursing Care Plan 33.1—which sets forth a plan of care for Carol, the case study patient in this chapter.

NCLEXNOTE Encourage and allow patients with SSD to discuss their physical problems before focusing on psychosocial issues.

Physical Health Assessment

Psychiatric–mental health nurses typically see these patients for problems related to coexisting psychiatric disorders, such as depression, not SSD. While taking the patient’s history, the nurse may discover that the individual has had multiple surgeries or medical problems, making SSD a strong possibility. If the patient has not already received a diagnosis of SSD, the nurse should screen for it by determining the presence of the most commonly reported problems associated with this disorder, which include dysmenorrhea, a lump in the throat, vomiting, shortness of breath, burning sensation in the sex organs, painful limbs, and amnesia. If the patient has these symptoms, they should be seen by a mental health provider qualified to make the diagnosis. [Box 33.2](#) presents the Health Attitude Survey, which can be used as a screening test for somatization.

Review of Systems

Although these patients’ symptoms have usually received considerable attention from the medical community, a careful review of systems is important because the appearance of physical problems is usually related to psychosocial problems. Even as the patient continues to be seen for mental health problems, an ongoing awareness of biologic symptoms is important, particularly because these symptoms are de-emphasized in the overall case management.

Pain is the most common finding in people with this disorder. Because the pain is usually related to symptoms of all the major body systems, it is unlikely that a somatic intervention such as an analgesic will be effective on a long-term basis. Remember that although no medical explanation exists for the pain, the patient's pain is real and has serious psychosocial implications. A careful assessment should include the following questions:

NURSING CARE PLAN 33.1

The Patient with Somatic Symptom Disorder

Carol is a 48-year-old woman who is making her weekly visit to her primary care physician for unexplained multiple somatic problems. This week, her concern is reoccurring abdominal pain that fits no symptom pattern. Upon physical examination, a cause for her abdominal pain could not be found. She is requesting a refill of alprazolam (Xanax), which is the only medication that relieves her pain. She is in the process of applying for disability income because of being completely disabled by neck and shoulder pain. The physician and office staff avoid her whenever possible. The physician will not refill the prescription until Carol is evaluated by the consulting mental health team that provides weekly evaluations and services.

Setting: Primary Care Office

Baseline Assessment: Forty-eight-year-old White woman with obesity who

appears very angry. She resents being forced to see a mental health provider for the only medication that works. She denies any psychiatric problems or emotional distress. Carol is wearing a short black top and slacks. Her hair is in curlers, and she says that it is too much trouble to comb her hair. Her mental status is normal, but she admits to being slightly depressed and takes alprazolam for her nerves. She says that sometimes she feels like going to sleep and not waking up, but denies any thoughts of killing herself. She depends on her children for everything and feels very guilty about doing so. She spends most of her waking hours going to various doctors and taking combinations of medications to relieve her pains. She has no friends or nonfamily social contacts because they would not be able to stand her. BP 144/80, P 80, R 18, Ht. 5'2"; Wt. 190; BMI 34.7.

Associated Psychiatric Diagnosis

Medications

R/O depression; SSD S/P hysterectomy S/P gastric bypass S/P carpal tunnel release Chronic shoulder, neck pain, vertigo	Premarin, 0.625 mg every day Alprazolam (Xanax), 25 mg tid Ranitidine HCL (Zantac), 150 mg with meals Simethicone, 125 mg four times daily with meals Calcium carbonate, 1,200 mg every day Multiple vitamin, every day Zolpidem tartrate (Ambien), 10 mg at bedtime PRN Ibuprofen, 600 mg q 4 h PRN pain Simethicone 125 mg, PRN for indigestion phenylephrine topical suppositories PRN for hemorrhoid pain
---	---

Priority of Care: Negative Self-Esteem

Important Characteristics

Associated Considerations

Slight depressions

Feels she is a burden to family

Dependency on others	Thinks about going to sleep and not waking up
Expresses guilt	Constant physical problems that interfere with normal social activities
Expresses feelings of helplessness	

Outcomes

Initial

Identify need to increase self-esteem

Long-term

Participate in individual or group therapy for esteem building

Interventions

Interventions

Establish rapport with patient.

Rationale

Individuals with low self-esteem are reluctant to discuss true feelings.

Ongoing Assessment

Examine feelings provoked by patient (discuss with supervisor if interfering with care). Determine whether patient is beginning to engage in a relationship.

Encourage patient to spend time dressing and grooming appropriately.

Confidence and self-esteem improve when a person looks well-groomed.

Monitor response to suggestions.

Encourage patient to discuss various somatic problems but allow some

Patients with SSD need time to express their physical problems. It helps them feel valued. The best way

Monitor time that patient spends explaining physical symptoms.

time to discuss psychological and interpersonal issues.	to build a relationship is to acknowledge physical symptoms.	
Explore opportunities for Carol will meet other people with similar, nonmedical interests.	Focusing Carol on meeting others will improve the possibilities of increasing contacts.	Observe willingness to identify other interests besides physical problems.

Evaluation

Outcomes	Revised Outcomes	Interventions
Carol admitted to having low self-esteem but was very reluctant to consider meeting new people.	Focus on building self-esteem.	Identify activities that will enhance personal self-esteem.

Priority of Care: Using Medication Inappropriately

Important Characteristics	Associated Considerations
Lack of medication effectiveness. Verbalizes difficulty with prescribed regimens.	Uses medication for other conditions than prescribed.

Outcomes

Initial	Long-term
---------	-----------

Discuss the use of medications honestly.	Use nonpharmacologic means for stress reduction, especially avoiding continued use of antianxiety medications.
--	--

Interventions

Interventions	Rationale	Ongoing Assessment
Clarify the frequency and purpose of taking alprazolam.	Unsupervised polypharmacy is very common with these patients. Further clarification is usually needed.	Carefully track self-report of medication use; determine if patient is disclosing the use of all medications.
Educate patient about the effects of combining medications, emphasizing side effects.	Education about combining medication is the beginning of helping patient become effective in medication regimen.	Observe patient's ability and willingness to consider negative effects.
Recommend that patient gradually reduce number of medications and problem-solve other means of managing physical symptoms.	Giving patients clear directions about managing health care regimens needs to be followed up with specific strategies to change behavior.	Evaluate patient's ability to solve problems.

Evaluation

Outcomes	Revised Outcomes	Interventions
----------	------------------	---------------

Carol disclosed use of medications but was unwilling to consider changing ineffective use of medication.	Identify next step if primary care physician does not refill prescription.	Discuss the possibility of not being able to obtain alprazolam. Refer patient to mental health clinic for further evaluation.
--	--	---

Box 33.2

Health Attitude Survey

On a scale of 1 to 5, please indicate the extent to which you agree (5) or disagree (1).

DISSATISFACTION WITH CARE

1. I have been satisfied with the medical care I have received. (R)
2. Doctors have done the best they could to diagnose and treat my health problems. (R)
3. Doctors have taken my health problems seriously.
4. My health problems have been thoroughly evaluated. (R)
5. Doctors do not seem to know much about the health problems I have had.
6. My health problems have been completely explained. (R)
7. Doctors seem to think I am exaggerating my health problems.
8. My response to treatment has not been satisfactory.
9. My response to treatment is usually excellent. (R)

FRUSTRATION WITH ILL HEALTH

10. I am tired of feeling sick and would like to get to the bottom of my health problems.
11. I have felt ill for quite a while now.
12. I am going to keep searching for an answer to my health problems.
13. I do not think there is anything seriously wrong with my body. (R)

HIGH UTILIZATION OF CARE

14. I have seen many different doctors over the years.
15. I have taken a lot of medicine recently.
16. I do not go to the doctor often. (R)
17. I have had relatively good health over the years.

EXCESSIVE HEALTH WORRY

18. I sometimes worry too much about my health.
19. I often fear the worst when I develop symptoms.
20. I have trouble getting my mind off my health.

PSYCHOLOGICAL DISTRESS

21. Sometimes, I feel depressed and cannot seem to shake it off.
22. I have sought help for emotional or stress-related problems.
23. It is easy to relax and stay calm. (R)
24. I believe the stress I am under may be affecting my health.

DISCORDANT COMMUNICATION OF DISTRESS

25. Some people think that I am capable of more work than I feel able to do.
26. Some people think that I have been sick just to gain attention.
27. It is difficult for me to find the right words for my feelings.

(R) indicates items reversed for scoring purposes. Scoring—The higher the score, the more likely somatization is a problem.

Reprinted from Noyes, R., Jr, Langbehn, D. R., Happel, R. L., Sieren, L. R., & Muller, B. A. (1999). Health Attitude Survey: A scale for assessing somatizing patients. *Psychosomatics*, 40(6), 470–478. Copyright © 2011 The Academy of Psychosomatic Medicine. With permission.

- What is the pain like?
- What is the extent of the pain?
- What helps the pain get better?
- When is the pain at its worst?
- What has worked in the past to relieve the pain?

Physical Functioning

The actual physical functioning of these individuals is often marginal. They usually have problems with sleep, fatigue, activity, and sexual functioning. Assessment of these areas generates data to be used in planning interventions. The amount and quality of sleep are important, as are the hours when the individual sleeps. For example, an individual may sleep a total of 6 hours each diurnal cycle but only from 2:00 to 6:00 AM plus an afternoon nap.

Fatigue is a constant problem for many people with SSD, and because various physical problems interfere with normal activity. These patients report an overwhelming lack of energy, which makes maintaining usual routines or accomplishing daily tasks impossible. Fatigue is accompanied by the inability to concentrate on simple functions, leading to decreased performance and disinterest in surroundings. Patients tend to be lethargic and listless and often have little energy ([Box 33.3](#)).

Female patients with this disorder usually have had multiple gynecologic problems, so that the physical manifestations of SSD often lead to altered sexual behavior. Symptoms of dysmenorrhea and painful intercourse may indicate a history of sexual abuse and sexual trauma. Physiologic indicators, such as those produced by laboratory tests, are not available. However, a careful assessment of the patient's menstrual history, gynecologic problems, and sexual functioning is important. It is also important to assess whether abuse or trauma has occurred in the past or continues in the present, and whether such abuse is sexual, physical, or emotional.

Nutrition

Nutrition assessment is important because gastrointestinal disorders are highly comorbid with psychiatric disorders, especially SSD. Psychological distress and poorer psychosocial functioning associated with SSD contribute to the severity of IBS (Porcelli et al., 2020). In IBS, there is a disordered communication between the gut and brain that results in motility disturbances, visceral hypersensitivity, and altered CNS processing. The primary treatment of IBS includes dietary changes, soluble fiber, and antispasmodic drugs (Ford et al., 2020).

BOX 33.3 CLINICAL VIGNETTE

Somatic Symptom Disorder and Stress

Ms. J, age 42 years, has been coming to the mental health clinic for 2 years for her nerves. She has seen only the physician for medication but now has been referred to the nurse's new stress management group because she is experiencing side effects to all the medications that have been tried. The psychiatrist has diagnosed SSD and wants her to learn to manage her "nerves" without medication.

At the first meeting with the nurse, Ms. J was preoccupied with chest pain and bloating that had lasted for the past 6 months. Her chest pain is constant and sharp at times. The pain does not prevent her from going to her job as a waitress but does interfere with meal preparation at night for her family and her ability to have sexual intercourse. She has numerous other physical

problems, including allergies to certain perfumes, dysmenorrhea, ovarian polycystic disease (ovarian cysts), chronic urinary tract infections, and rashes. She is constantly fatigued and has frequent leg cramps. She states that she is too tired to fix dinner for her family. On days off from work, she takes a nap in the afternoon, sleeping until evening. She is unable to fall asleep at night.

She believes that she will soon have to have her gallbladder removed because of occasional referred pain to her back and nausea that occurs a couple hours after eating. She is not enthusiastic about a stress management group and does not believe it will help her problems. However, she has agreed to consider it for as long as the psychiatrist will continue prescribing diazepam (Valium).

What Do You Think?

- How would you prioritize Ms. J's physical symptoms?
- What are some possible explanations for Ms. J's fatigue?

Furthermore, the quality of the diet is associated with medically unexplained gastrointestinal symptoms. Diet patterns loaded with fruits, vegetables, low-fat dairy, dried fruits, and whole grains have fewer reported gastrointestinal disturbances than diets loaded with vegetable oil, meat, salt, french fries, hydrogenated oils, onions, egg, poultry, fish, and refined grains or diets loaded with processed meats, sweet deserts, high-fat dairy (Haghighatdoost et al., 2020).

Medication

A medication assessment of these patients can be challenging. Patients with SSD frequently seek help from numerous providers because they do not feel that they are believed, or they think that providers don't care about their suffering. Because they often receive medications from each provider, they usually take a large number of drugs. A medication assessment is needed not only because of the number of medications but also because these individuals frequently experience unusual side effects, or they report that they are "sensitive" to medications. Because of their somatic sensitivity, they often overreact to

medication. Developing a therapeutic relationship promotes trust and can minimize these patients' search for a health care professional who believes their symptoms and suffering.

Substance Use

These patients spend much of their lives trying to find out what is wrong with them. When one health care provider after another can find little if any explanation for their symptoms, many patients become anxious and/or depressed. To alleviate their symptoms of anxiety, they sometimes self-medicate with over-the-counter (OTC) medications and/or substances of abuse (e.g., alcohol, marijuana), or they seek a health care provider who prescribes a benzodiazepine such as alprazolam. Because symptoms associated with their disorder cannot be treated within a few weeks with a benzodiazepine, they can become dependent on medication that should not have been prescribed in the first place.

Although benzodiazepines have a place in therapeutics, they are not recommended for long-term use and only complicate the treatment of individuals with SSD. These medications should also be avoided because of their addictive qualities, which place patients at risk of addiction. Unfortunately, by the time patients with SSD see a mental health provider, they often have already begun taking the medications for anxiety. Many times, they only agree to see a mental health provider because the last provider would no longer prescribe an anxiolytic without a psychiatric evaluation.

Remember Carol?

Carol has been taking alprazolam for stress for years. Her primary health care provider is refusing to prescribe it again until she has a complete mental health examination. No other health care providers will prescribe alprazolam for her.

Psychosocial Assessment

The mental status of individuals with SSD can be within normal limits, although most patients report frustration, depression, and hopelessness about their situation. What is most noticeable is their intense focus on their bodies and the physical symptoms that are causing them distress and disability.

Cognitive and Behavioral Responses

Generally, cognition is not impaired in people with SSD, but it may be distorted, such as believing the pain means a life-threatening condition. These individuals seem preoccupied with the signs and symptoms of their illnesses and may even keep a record of their experiences. Living with illness, diseases, and suffering truly becomes a way of life.

Self-Concept

People with SSD usually have a negative self-concept of physical weakness and illness-related symptom evaluation. The self-concept can be determined by physical appearance, affect, and explanation of the current situation. Negative self-concept usually begins in childhood or adolescence when the child begins to see themselves as ill and cannot participate in normal school or recreational activities. Parents who focus on protecting children from illness can inadvertently reinforce the self-concept of being ill.

Stress and Coping Patterns

Some individuals with SSD have intense emotional reactions to life stressors and have led or are leading traumatic or chaotic lives. These patients usually have had a series of personal crises beginning at an early age. Examples include severe sexual and physical abuse and psychological trauma. Typically, a new symptom or medical problem develops during times of emotional stress, as well as during anniversaries of losses or traumas that have occurred in the patient's lifetime. It is critical that the link between the physical assessment data and the patient's psychological and social history are considered. A thorough history of major psychological events should be compared with the chronology of physical problems. Special attention should be paid to any history of sexual abuse or trauma in the patient's younger years. Early sexual abuse may also prevent the individual from being able to perform sexually or to endure chronic abdominal pain or discomfort during sexual relations.

The individual's mood is usually labile, often shifting from extremely excited or anxious to being depressed and hopeless. Response to physical symptoms is usually magnified, such as interpreting a simple cold as pneumonia or a brief chest pain as a heart attack. Family members may not believe the physical symptoms are real and may view them as attention-getting behavior because symptoms often improve when the patient receives attention. For example, a woman who has been in bed for 3 weeks with severe back pain may suddenly feel much better when her children visit her.

Social Network

People with this disorder spend excessive time seeking medical care and treating their multiple illnesses. Because they believe themselves to be very sick, they also believe that they are disabled and cannot work. Many are unemployed, so frequently these individuals have changed jobs, had multiple positions over their lifetimes or careers, or have had absences or gaps in employment (Sharma & Manjula, 2013).

Because their symptoms are often inconsistent with any identifiable medical diagnosis, these individuals are rarely satisfied with their health care providers, who can find nothing wrong. However, their social network often consists of a series of health care providers, rather than peers or family members, who can also become weary of the individual's constant complaints of physical problems. Identifying a support network requires sorting out the health care providers from family and friends.

Consider Carol's Limited Social Network

Carol has no friends and spends her time going from provider to provider. Her anxiety about her symptoms has impacted her ability to maintain friendships and other close relationships.

Family Issues

Individuals with SSD sometimes live in chaotic families with multiple problems.

In assessing the family structure, other members with psychiatric disorders must be identified. Women may be married to abusive men who have antisocial personality disorders; substance use disorders are common. Identifying the positive and negative relationships within the family is important.

SSD is particularly problematic because it disrupts the family's social life. Changes in routine or major life events often precipitate the appearance of a symptom. For example, a person may be planning a vacation with the family but at the last minute decides they cannot go because the back pain has returned, and they will be unable to sit in the car. These family disruptions are common. In addition, as already noted, employment history for the person with SSD may be erratic.

Quality of Life

SSD has a negative impact on the quality of life. Since many of the physical symptoms (25% to 50%) are unexplained, the person is continually told that there are no medical explanations, which leads to frustration and seeking out additional medical opinions. The pain or discomfort interferes with daily activities and prevents the person from participating fully with family and friends (van Westrienen et al., 2020).

Strengths Assessment

A person with SSD may have difficulty identifying *any* personal strengths. The nurse should help the person focus on daily activities and suggest strengths that emerge. For example, some strengths might be that the person has a place to live, has a caring family, or some educational attainment. The nurse also elicits motivation to feel better.

CLINICAL JUDGMENT

The physical issues dominate the individual's concern and should not be dismissed. They may have a variety of health issues to discuss, including fatigue,

pain, and insomnia. Psychologically, depression and suicidal behavior should always be considered. Social isolation may be an outward expression of depression.

THERAPEUTIC RELATIONSHIP

The most difficult aspect of nursing care is developing a sound, positive, nonjudgmental nurse–patient relationship, yet this relationship is crucial. Without it, the nurse is just one more provider who fails to meet the patient’s expectations. Developing this relationship requires time and patience. Therapeutic communication techniques should be used to refocus the patient on psychosocial problems related to the physical manifestations ([Box 33.4](#)).

During periods when symptoms of other psychiatric disorders surface, additional interventions are needed. For example, if depression occurs, additional supportive or cognitive approaches may be needed.

Carol’s Behavior on the Mental Health Unit

Carol felt she was tricked into agreeing to be admitted to a mental health unit for medication evaluation. She believes she should be on a medical unit for her constant pain.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

Establishing recovery and wellness goals may seem to be out of the question with individuals who defines themselves as “ill,” “sick,” and/or in “chronic pain.” However, helping such individuals define their symptoms and validate them is a start to recovery. Nurses are poised to educate individuals with multiple somatic problems to better understand their symptoms (e.g., what triggers them) and to define short-term goals for recovery. The notion of recovery itself is patient centered and focused on what the patient believes is realistic and possible. For example, some patients with this disorder may choose to learn to live with their symptoms (e.g., pain) and find alternative ways of coping. Nursing interventions can focus on individuals learning the triggers in their lives that worsen their symptoms as well as those activities that lessen them. Even though a patient may suffer from multiple somatic symptoms and/or this chronic illness, together the nurse and the patient can work toward setting short- and long-term goals that promote health and wellness.

Physical Health Interventions

Nursing interventions that focus on physical health become especially important because medical treatment must be conservative; aggressive pharmacologic treatment must be avoided. Each time a nurse sees the patient, some of that time should be spent respectfully discussing physical complaints and validating the patient’s distress. During the discussion, it is important that the nurse project the belief that the patient is truly experiencing the symptoms. Several physically focused interventions, including pain management, activity enhancement, nutrition regulation, relaxation, and pharmacologic interventions, may be useful in caring for patients with SSD.

Pain Management

In pain management, a single approach rarely works. Pain is a primary issue and was previously considered a separate disorder. Nursing care focuses on helping patients identify strategies to relieve pain and to examine stressors in their lives. After a careful assessment of the pain, nonpharmacologic strategies should be developed to reduce it. If gastrointestinal pain is frequent, eating and bowel habits should be explored and modified as needed. For back pain, exercises and consultation from a physical therapist may be useful. Headaches are a challenge. Self-monitoring and tracking them engages the patient in the therapeutic process and helps to identify psychosocial triggers. In addition, suggesting or referring the individual for complementary and alternative treatments may be useful. Relaxation techniques, identifying thoughts and feelings about pain or discomfort, and including family members in the intervention have also been shown to be useful.

Activity Enhancement

Helping the patient establish a daily routine may alleviate some of the difficulty with sleep but doing so may be difficult because most of these patients are not employed. Encouraging the patient to get up in the morning and go to bed at night at specific times can help the patient to establish a routine. These patients should engage in regular exercise to improve their overall physical state, although they often have numerous reasons why they cannot. This is where the nurse's patience is tested; the nurse ultimately needs to remember that the patient's symptoms are an expression of suffering. Agreeing that daily exercise is difficult but continuing to emphasize the importance of exercise can counter some of the reluctance to exercise.

BOX 33.4 • THERAPEUTIC DIALOGUE: ESTABLISHING A RELATIONSHIP

INEFFECTIVE APPROACH

Nurse: Good morning, Carol.

Carol: I'm in so much pain. Take that breakfast away.

Nurse: You don't want your breakfast?

Carol: Can't you see? I hurt! When I hurt, I can't eat!

Nurse: If you don't eat now, you probably won't be able to have anything until lunch.

Carol: Who cares? I have no intention of being here at lunchtime. I don't belong here.

Nurse: Carol, I don't think that your doctor would have admitted you unless there were a problem. I would like to talk to you about why you are here.

Carol: Nurse, I'm just here. It's none of your business.

Nurse: Oh.

Carol: Please leave me alone.

Nurse: Sure, I will see you later.

EFFECTIVE APPROACH

Nurse: Good morning, Carol.

Carol: I'm in so much pain. Take that breakfast away.

Nurse: (Silently removes tray. Pulls up chair and sits down.)

Carol: My back hurts.

Nurse: Oh, when did the back pain start?

Carol: Last night. It's this bed. I couldn't get comfortable.

Nurse: These beds can be pretty uncomfortable.

Carol: My back pain is shooting down my leg.

Nurse: Does anything help it?

Carol: Sometimes, if I straighten out my leg it helps.

Nurse: Can I help you straighten out your leg?

Carol: Oh, it's OK. The pain is going away. What did you say your name is?

Nurse: I'm Susan Miller, your nurse while you are here.

Carol: I won't be here long. I don't belong in a psychiatric unit.

Nurse: While you are here, I would like to spend time with you.

Carol: OK, but you understand, I do not have any psychiatric

problems.

Nurse: We can talk about whatever you want. But because you want to get out of here, we might want to focus on what it will take to get you ready for discharge.

CRITICAL THINKING CHALLENGE

- What communication mistakes did the nurse in the first scenario make?
- What communication strategies helped the patient feel comfortable with the nurse in the second scenario?
- How is the first scenario different from the second?

Nutrition Regulation

Patients with SSD often have gastrointestinal problems and may have special nutritional needs. The nurse should discuss the nutritional value of foods with the patient. Discussing the use of whole healthy food sources rather than processed or “junk” food is a strategy nurses can use to assist the patient with gastrointestinal distress to consider dietary changes. The act of talking with patients about ways that they can exert some control of their bodies can have a positive effect and assist them with managing some of their symptoms. If patients are being prescribed medications that promote weight gain, weight control strategies may be discussed, including exercise or increasing movement with physical therapy.

Relaxation

Patients taking anxiety-relieving medication can be taught relaxation techniques to alleviate stress. It is a challenge to help these patients really use these strategies. The nurse should consider various techniques, including simple relaxation techniques, distraction, and guided imagery (see [Chapter 11](#)).

Wellness Challenges

Individuals with SSD focus on signs of illness, not behaviors supporting wellness. Because these individuals have intense bodily sensations that are associated with illness, it is difficult to help them re-focus on wellness.

Medications Interventions

No medication is specifically recommended for patients with SSD; however, psychiatric symptoms of comorbid disorders, such as depression and anxiety, should be treated pharmacologically as appropriate. Usually, patients who are depressed or anxious take an antidepressant to treat their symptoms (see [Chapter 25](#)).

Multiple antidepressants have been shown to be effective for treating pain and the symptoms of depression. Duloxetine—a serotonin and norepinephrine (NE) reuptake inhibitor that is indicated for neuropathy, depression, and anxiety—is also used to manage pain (Brammer, 2018). See [Box 33.5](#).

Patients who report symptoms of anxiety are treated pharmacologically, similar to those with depression. The first line of treatment for all anxiety disorders is with an SSRI. Doses for SSD are usually higher than those prescribed for depression to relieve and manage the symptoms of the anxiety disorders, including panic, social phobia, generalized anxiety, OCD, and post-traumatic stress disorder.

Box 33.5

Drug Profile: Duloxetine

DRUG CLASS: Serotonin and norepinephrine reuptake inhibitor (SNRI)

RECEPTOR AFFINITY: Binds selectively and has a high affinity to both NE and serotonin (5-HT) transporters yet lacks affinity for monoamine receptors within the central nervous system.

INDICATIONS: Treatment of depression, generalized anxiety disorder, chronic musculoskeletal pain, diabetic peripheral neuropathic pain, fibromyalgia

ROUTE AND DOSAGE: Available as capsules: 30 mg, 60 mg

Adults: Initially, 60 mg daily and increasing to 90 mg/d consistent with patient tolerance. Therapy at 120 mg/d may be necessary before response occurs. Can be given in divided doses for individuals who are

used to taking pain medication twice a day.

Geriatric: Adjust dosage as needed because older patients—particularly those on other medications—are more prone to develop side effects. May initiate dose of 30 mg daily for 2 weeks.

Pediatric: Not recommended for children younger than 18 years of age

HALF-LIFE (PEAK EFFECTS): Duloxetine has an elimination half-life of about 12 hours (the range is 8 to 17 hours). Steady state is usually achieved after 3 days.

SELECTED SIDE EFFECTS: Nausea, dry mouth, constipation, diarrhea, fatigue, difficulty sleeping, and dizziness. Increased blood pressure can occur and should be monitored. Seizures have been reported. Sexual dysfunction (decreased sex drive and delayed orgasm and ejaculation) has been associated with duloxetine.

BOXED WARNING: Suicidal thoughts and behaviors

WARNINGS: Screen for bipolar disorder, monitor for serotonin syndrome; monitor blood pressure before and after dosage is initiated (e.g., weekly for one month), screen for medication-to-medication interactions.

SPECIFIC PATIENT/FAMILY EDUCATION

- Take drug exactly as prescribed; do not stop taking it abruptly or without consulting your health care provider.
- If patients wish to stop the medication, they need to consult with their provider about tapering the dose due to discontinuation syndrome, a cluster of physical and emotional symptoms that are associated with decreasing SNRIs and SSRIs too quickly. Symptoms of abrupt discontinuation can include the following: Symptoms of withdrawal include dizziness, anxiety, nausea, vomiting, nervousness, and diarrhea.
- Families and caregivers of patients should be advised to observe for the emergence of anxiety, agitation, panic attacks, insomnia, irritability, hostility, aggressiveness, impulsivity, hypomania, mania, other unusual changes in behavior, worsening of depression, and suicidal ideation. Such symptoms should be reported to the patient's prescriber or health professional, especially if side effects are severe, abrupt in onset, or were not part of the patient's presenting symptoms.
- Report any signs and symptoms of side effects.
- Combining duloxetine with aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin (Coumadin), or other drugs that are associated with bleeding may increase the risk of bleeding.

Nonpharmacologic approaches, such as biofeedback and relaxation, are also quite useful in conjunction with pharmacologic treatment. Benzodiazepines may be used initially in the treatment of those with anxiety but should be slowly decreased and discontinued because of the psychological and physiologic dependence associated with these medications. Buspirone (BuSpar), a nonbenzodiazepine, does not lead to tolerance or withdrawal and may be useful for relief of acute anxiety. BuSpar should be used cautiously with other serotonin-related medications (such as SSRIs) because of its high affinity for serotonin receptors. If panic disorder is present, it should be treated aggressively with SSRIs and frequently at higher doses.

Pain medication should be prescribed conservatively. If mood disorders are also present, some mood stabilizers not only treat the depression but also may treat the pain. An example is gabapentin, another frequently prescribed medication for neuropathic pain experienced during and after herpes zoster (also commonly known as shingles).

Administering and Monitoring Medications

In SSD, patients are usually treated in the community, where they commonly self-medicate. Carefully question patients about self-administered medicine and determine which medicines or substances they are currently using to relieve their pain and/or discomfort (including OTC, herbal supplements, and/or illicit substances). Also listen carefully to determine any side effects the patient attributes to the medication. This information should be documented and reported to the rest of the team. The patient should be encouraged to continue taking only prescribed medication and to seek approval before taking any additional OTC or other prescribed medications. SSD patients are at high risk for prescription drug misuse and abuse, as well as for purchasing substances illicitly. The recent trends of prescription drug misuse have been linked to opioid use disorder and overdose.

Managing Side Effects

These individuals often have atypical reactions to their medications. Side effects should be assessed, but the patient should be encouraged to compare the benefits of the medication with any problems related to side effects. Patients should also be encouraged to give the medications enough time to be effective because many medications require up to 6 weeks before the patient has a response or experiences a relief of symptoms. This is especially true for patients who are prescribed some of the antidepressants that have been in use the longest, such as fluoxetine.

Management of Complications

In working with patients with SSD, always be on the lookout for drug–drug interactions. Medications these patients take for physical problems could interact with psychiatric medications. Patients may be taking alternative medicines, such as herbal supplements, but they usually willingly disclose doing so. The patient should be encouraged to use the same pharmacy for filling all prescriptions so possible interactions can be checked and monitored.

Psychosocial Interventions

The choice of psychosocial intervention depends on the specific problem the patient is experiencing. The most important and ongoing intervention is the maintenance of a therapeutic relationship.

Therapeutic Interactions

Nursing care should include listening to the patient’s report of symptoms and fears, validating it by acknowledging that the fears may be real, asking the patient to monitor symptoms in a journal, and encouraging the patient to bring the journal to the next visit. By reviewing the symptom pattern, it is possible to continue to educate the patient and assess for significant symptoms. The outcome of this approach should be a decrease in fears and better control of the symptoms.

Using Cognitive Behavioral Interventions

Several interventions are effective in reducing patients’ fears of experiencing serious illnesses. Cognitive-behavioral therapy (CBT), stress management, and group interventions can decrease the intensity and increase the control of symptoms (Wortman et al., 2018). Whether the positive outcomes result from the intervention itself or from the symptom validation and increased attention given to the patient remains unknown.

Counseling

Counseling with a focus on problem-solving is needed from time to time. These patients often have chaotic lives and need support through the multitude of crises. Although they may appear fascinating and at times self-assured, they can easily irritate others because of their constant complaints. The consequences of their impaired social interaction with others must be examined within a counseling framework. It will become evident that the patient's problem-solving and decision-making skills could be improved. Identifying stresses and strengthening positive coping responses helps the patient deal with a chaotic lifestyle.

Psychoeducation

Teaching About Symptoms

Health teaching is useful throughout the nurse–patient relationship. These patients have many questions about illnesses, symptoms, and treatments. Emphasize positive health care practices and minimize the effects of serious illness. Because of problems in managing medications and treatment, the therapeutic regimen needs constant monitoring, resulting in ample opportunities for teaching. (Box 33.6).

Wellness Strategies

Wellness strategies should be included in the discussion of the interventions. The same interventions that were discussed in reducing the symptoms of SSD are also used as wellness strategies. Patients with SSD should focus on “staying healthy” instead of focusing on their illnesses. For these individuals, approaching the topic of health promotion usually has to be within the context of preventing further problems. Setting aside time for themselves and identifying activities that meet their psychological and spiritual needs, such as going to church or synagogue, are important in maintaining a healthy balance.

Social Relationships

Patients with SSD are usually isolated from their families and communities. Strengthening social relationships and activities often becomes the focus of nursing care. The nurse should help the patient identify individuals with whom contact is desired, ask for a commitment to contact them, and encourage them to reinitiate the relationship. The nurse should counsel patients about talking too much about their symptoms with these individuals and emphasize that medical information should be shared with the nurse instead. The nurse must also ensure that patients know when their next appointments are scheduled.

Box 33.6

Somatic Symptom Disorder

When caring for a patient with SSD, be sure to include the following topic areas in the teaching plan:

- Psychopharmacologic agents (anxiolytics) if ordered, including drug, action, dosage, frequency, and possible side effects
- Nonpharmacologic pain relief measures
- Exercise
- Nutrition
- Social interaction
- Appropriate health care practices
- Problem-solving
- Relaxation and anxiety-reduction techniques
- Sexual functioning

Providing Family Education

The results of a family assessment often reveal that families of these individuals need education about the disorder, helpful strategies for dealing with the multiple complaints of the patient, and usually help in developing more effective

communication patterns. Because of the chaotic nature of some of the families and the lack of healthy problem solving, physical, sexual, and psychological abuse may be evident. It is important to be particularly sensitive to any evidence of current physical or sexual abuse because this may lead to a need for additional interventions.

Promoting Safety

Individuals with SSD can benefit from a crisis safety plan that could be used during times of stress or depression. The safety plan would list triggers for anxiety, suicidal ideation, and mood changes with specific behavioral strategies for each trigger. See [Chapters 11](#) and [22](#).

Group Interventions

Although these patients may not be candidates for insight group psychotherapy, they do benefit from cognitive-behavioral groups that focus on developing coping skills for everyday life (Liu et al., 2019). Because most are women, participation in groups that address feminist issues should be encouraged to strengthen their assertiveness skills and improve their generally low self-esteem.

When leading a group that has members with this disorder, redirection can keep the group from giving too much attention to a person's illness. However, these individuals need reassurance and support while in a group. They may say that they do not fit in or belong in the group. In reality, they are feeling insecure and threatened by the situation. The group leader needs to show patience and understanding to engage the individual effectively in meaningful group interaction.

Evaluation and Treatment Outcomes

Recovery outcomes for patients with SSD should be realistic. Because this is a lifelong disorder, small successes should be expected. Specific outcomes should be identified, such as gradually increasing social contact. Over time, a gradual reduction in the number of health care providers the individual contacts should

occur and a slight improvement in the ability to cope with stresses should follow.

Continuum of Care

Emergency Care

The emergencies these individuals experience may be physical (e.g., chest pain, back pain, gastrointestinal symptoms) or stress responses related to a psychosocial crisis. Occasionally, these individuals become suicidal and require an intensive level of care. Generally speaking, nonpharmacologic interventions should be tried first, with very conservative use of antianxiety medications. All attempts should be made to retrieve records from other facilities.

Inpatient Care

Ideally, individuals with SSD spend minimal time in the hospital for treatment of their medical or comorbid mental disorders. While an inpatient, the patient should have consistency in providers who care or oversee all nursing care. Therapeutic interactions and relationships are very important and can help move the individual toward recovery.

Community Care

Patients with SSD can spend a lifetime in the health care system and still have little continuity of care. Switching from one health care provider to others is detrimental to their long-term care. Most are outpatients. When they are hospitalized, it is usually for evaluation of medical problems or to receive care for comorbid disorders.

Virtual Mental Health Care

Digital applications provide immediate access to self-health programs such as relaxation, stress reduction, sleep, and imagery. Using these tools can reduce the intensity of the distress and discomfort. Virtual primary care visits and health education sessions provide opportunities for patient–clinician interactions within a safe environment.

Integration with Primary Care

Primary care is the main treatment setting for persons with SSD. With the exception of a severe depression or comorbid mental health disorder, mental health specialists serve primarily as supportive consultants to primary care clinicians. The role of the mental health clinician is to validate the diagnosis in order to avoid unnecessary treatments. SSD will most likely be diagnosed if the primary care provider is aware of the patient medical and social history, recognizes a discrepancy between the symptoms presented by the patient and objective findings, and identifies the lack of clarity about the nature of the patient symptoms (Patel et al., 2020).

Health education in a familiar environment can help protect the patient from unnecessary procedures and use of resources. Education can improve perceptions of pain, views of health, and decrease feelings of loneliness (Johnson et al., 2020). See [Box 33.7](#).

Box 33.7

Psychoeducational Intervention in Primary Care

Johnson, K. K., Bennett, C., & Rochani, H. (2020). Significant improvement of somatic symptom disorder with brief psychoeducational intervention by PMHNP in primary care. Journal of the American Psychiatric Nurses Association, 1078390320960524. Advance online publication. <https://doi.org/10.1177/1078390320960524>

THE QUESTION: Does a psychoeducation intervention by a psychiatric mental health nurse practitioner that explains the HPA axis response to acute and chronic stress reduce anxiety and stress in persons diagnosed with SSD?

METHOD: Thirty-four primary care patients (24 females, 9 males)

participated in a 30-minute psychoeducational intervention following their medical visit. A visual analog scale consisting of SSD symptoms and the Patient Health Questionnaire (PHQ-15) were used pre- and post-intervention. The intervention included open-ended questions about their visit to establish rapport, education on the release of the cortisol hormone by the HPA axis, stress responses, symptom pathways, benefits of wellness strategies, problem-solving strategies, and information about other psychotherapeutic interventions.

FINDINGS: Following the brief intervention, the participants rated the overall health significantly better than prior to the intervention. Anxiety, fearfulness, and worry about their health, loneliness, and pain were significantly less at the completion of the intervention. At 3-week follow-up, the participants continued to experience less distress about their health.

IMPLICATIONS FOR NURSING: Persons with SSD can benefit from early intervention in a primary care setting. A psychoeducational intervention can significantly reduce the anxiety and distress associated with health concerns.

OTHER DISORDERS

Illness Anxiety Disorder

Illness anxiety disorder is a new classification in the *DSM-5*. Previously, the term *hypochondriasis* (or *hypochondria*) was used to designate this disorder. Most of the persons with hypochondriasis were also diagnosed with SSD. However, there are some individuals who either do not have somatic symptoms or have only very mild symptoms, but who remain preoccupied with having or developing a medical illness (APA, 2013). These individuals would receive the diagnosis of illness anxiety disorder and would be encouraged to seek mental health treatment for their anxiety and preoccupation.

Individuals with illness anxiety disorder are fearful about developing a serious illness based on their misinterpretation of body sensations. The fear of having an illness continues despite medical reassurance and interferes with psychosocial functioning. They spend time and money on repeated examinations looking for

feared illnesses. For example, an occasional cough or the appearance of a small sore results in the person making an appointment with an oncologist. An illness anxiety disorder sometimes appears if the person had had a serious childhood illness or if a family member has a serious illness.

It is important to understand that the lack of physical sensation and movement is real for the patient. In approaching this patient, the nurse treats conversion symptoms as real symptoms that may have distressing psychological aspects. Acknowledging the symptoms helps the patient deal with them. As trust develops within the nurse–patient relationship, the nurse can help the patient develop problem-solving approaches to everyday problems.

Conversion Disorder (Functional Neurologic Symptom Disorder)

Conversion disorder is a psychiatric condition in which severe emotional distress or unconscious conflict is expressed through physical symptoms (APA, 2013). Patients with conversion disorder have neurologic symptoms that include impaired coordination or balance, paralysis, aphonia (i.e., inability to produce sound), difficulty swallowing or a sensation of a lump in the throat, and urinary retention. They may also have loss of touch, vision problems, blindness, deafness, and hallucinations. In some instances, they may have seizures (Peeling & Muzio, 2020). However, laboratory, electroencephalographic, and neurologic test results are typically negative. The symptoms, different from those with an organic basis, do not follow a neurologic course but rather follow the person's own perceived conceptualization of the problem. For example, if the arm is paralyzed and will not move, reflexes and muscle tone may still be present.

Some evidence suggests that there are neurobiologic changes in the brains of people with this disorder that may be responsible for the loss of sensation or control of movement. Stress may also be a contributing factor. Published reports state that childhood trauma (e.g., sexual abuse) is associated with the later development of conversion disorder (Hailes et al., 2019).

It is important to understand that the lack of physical sensation and movement is real for the patient. In approaching the patient, the nurse treats conversion symptoms as real symptoms that may have distressing psychological aspects. Acknowledging the symptoms helps the patient deal with them. As trust develops within the nurse–patient relationship, the nurse can help the patient

develop problem-solving approaches to everyday problems.

Factitious Disorders

Factitious disorders are very different from SSDs. Persons with factitious disorders intentionally cause an illness or injury to receive the attention of health care workers. These individuals are motivated solely by the desire to become a patient and develop a dependent relationship with a health care provider. There are two types of factitious disorders: factitious disorder and factitious disorder imposed on another.

Factitious Disorder

Although feigned illnesses have been described for centuries, it was not until 1951 that the term *Münchhausen's* [sic] *syndrome* was used to describe the most severe form of this disorder, which was characterized by fabricating a physical illness, having recurrent hospitalizations, and going from one health care provider to another (Asher, 1951). This disorder is now called *factitious disorder* and is differentiated from malingering, in which the individual who intentionally produces symptoms of illness and is motivated by another specific self-serving goal, such as being classified as disabled or avoiding work.

Clinical Course and Diagnostic Criteria

Unlike people with borderline personality disorder, who typically injure themselves overtly and readily admit to self-harm, patients with factitious disorder injure themselves covertly. The illnesses are produced in such a manner that the health care provider is tricked into believing that a true physical or psychiatric disorder is present (Carnahan & Jha, 2020).

The self-produced physical symptoms appear as medical illnesses and involve all body systems. They include seizure disorders, wound-healing disorders, the abscess processes (i.e., introduction of infectious material below the skin surface), and feigned fever (rubbing the thermometer). These patients are

extremely creative in simulating illnesses. They tell fascinating but false stories of personal triumph. These tales are referred to as pseudologia fantastica and are a core symptom of the disorder. Pseudologia fantastica are stories that are not entirely improbable and often contain a mixture of truth and falsehood. These patients falsify blood, urine, and other samples by contaminating them with protein or fecal matter. They self-inject anticoagulants to receive diagnoses of “bleeding of undetermined origin” or ingest thyroid hormones to produce thyrotoxicosis. They also inflict injury on themselves by inserting objects or feces into body orifices, such as the urinary tract, open wounds, or even intravenous tubing. They produce their own surgical scars, especially abdominal, and when treated surgically, they delay wound healing through scratching, rubbing, or manipulating the wound and introducing bacteria into the wound. These patients put themselves in life-threatening situations through actions such as ingesting allergens known to produce an anaphylactic reaction.

Patients who manifest primarily psychological symptoms produce psychotic symptoms such as hallucinations and delusions, cognitive deficits such as memory loss, dissociative symptoms such as amnesia, and conversion symptoms such as pseudoblindness or pseudoparalysis. These individuals often become psychotic, depressed, or suicidal after an unconfirmed tragedy. When questioned about details, they become defensive and uncooperative. Sometimes these individuals have a combination of both physical and psychiatric symptoms.

Epidemiology and Risk Factors

The prevalence of factitious disorder is unknown because diagnosing it and obtaining reliable data are difficult. The prevalence was reported to be high when researchers were actually looking for the disorder in specific populations. Within large general hospitals, factitious disorders are diagnosed in about 1% of patients with whom mental health professionals consult. The age range of patients with the disorder is between 19 and 64 years. The median age of onset is the early 20s. Formerly thought to occur predominantly in men, this disorder is now reported predominantly in women. No genetic pattern has been identified, but it does seem to run in families. The presence of comorbid psychiatric disorders, such as mood disorders, personality disorders, and substance-related disorders, is common. Health care professionals, nurses, pharmacists, and physicians are over-represented in the occurrence of this disorder (Jimenez et al.,

2019).

Etiology

Many people with factitious disorder have experienced severe sexual abuse, trauma, and/or distress before the development of the disorder. The psychodynamic explanation is that these individuals, who were often abused as children, received nurturance only during times of illness; thus, they try to recreate illness or injury in a desperate attempt to receive love and attention. During the actual self-injury, the individual is reported to be in a trance-like, dissociative state. Many patients report having an intimate relationship with a health care provider, either as a child or as an adult, and then experiencing rejection when the relationship ended. The self-injury and subsequent attention is an attempt by the individual to re-enact those experiences and gain control over the situation and the other person (Jimenez et al., 2019).

These patients are usually discovered in medical–surgical settings. They are hostile and distance themselves from others. Their network is void of friends and family and usually consists only of health care providers, who change at regular intervals. In factitious disorder, the patient fabricates a detailed and exaggerated medical history. When the interventions do not work and the fabrication is discovered, the health care team feels manipulated and angry. When the patient is confronted with the evidence, they become enraged and often leave that health care system, only to enter another. Eventually, the person is referred for mental health treatment. The course of the disorder usually consists of intermittent episodes.

Evidence-Based Nursing Care for Persons with Factitious Disorder

The overall goal of treatment for a patient with factitious disorder is to replace the dysfunctional attention-seeking behaviors with positive behaviors. To begin treatment, the patient must acknowledge the deception. Because the pattern of self-injury is well established and meets overwhelming psychological needs, giving up the behaviors is difficult. The treatment is long-term psychotherapy.

The psychiatric–mental health nurse will most likely care for the patient during or after periods of feigned illnesses.

Mental Health Nursing Assessment

A nursing assessment should focus on obtaining a history of medical and psychological illnesses. Physical disabilities should be identified. Early childhood experiences, particularly instances of abuse, neglect, or abandonment, should be identified to understand the underlying psychological dynamics of the individual and the role of self-injury. Family assessment is important because family relationships become strained as the members become aware of the self-inflicted nature of this disorder.

Clinical Judgment

The consequences of self-injury are the first priority. Medical treatment may be needed. The patient is at high risk for self-abuse as discovery unfolds. Any nursing intervention must be implemented within the context of a strong nurse–patient relationship. A nonjudgmental attitude is imperative. Desired outcomes include decreased self-injurious behavior and increased positive coping behaviors.

Mental Health Nursing Interventions

The fabrications and deceptions of patients with factitious disorder provoke anger and a sense of betrayal in many nurses. To be effective with these patients, it is important to be aware of these feelings and resolve them by developing a better understanding of the underlying psychodynamic issues. Confronting the patient has been reported to be effective only if the patient feels supported and accepted and if there is clear communication among the patient, the mental health care team, and family members. All care should be centralized within one facility. The patient should see health care providers regularly even when not in active crisis. Offering the patient a tactful way of giving up the behaviors is often

crucial. Behavioral techniques that shape new behaviors help the patient move forward toward a new life.

The health care team that knows the patient, agrees on a treatment approach, and follow-up is crucial to the patient's eventual recovery. For this to happen, the medical, psychiatric, inpatient, and outpatient teams need to communicate with each other on a regular basis. Family members must also be aware of the need for consistent treatment.

Factitious Disorder Imposed on Another

A rare but dramatic disorder, **factitious disorder imposed on another** (previously *factitious disorder by proxy* or *Munchausen's* [sic] *by proxy*), involves a person who inflicts injury on another person. It is commonly a mother, who inflicts injuries on her child to gain the attention of the health care provider through her child's injuries. These actions include inducing seizures, poisoning, or smothering. This most severe form of child abuse is usually identified in the emergency department. The mother rarely admits injuring the child and thus is not amenable to treatment; the child is frequently removed from the mother's care. This form of child abuse is distinguished from other forms by the routine unwitting involvement of health care workers, who subject the child to physical harm and emotional distress through tests, procedures, and medication trials. Some researchers suspect that children who are abused in this way may later experience factitious disorder themselves (Abeln & Love, 2018).

SUMMARY OF KEY POINTS

- Somatization is affected by sociocultural and gender factors. It occurs more frequently in women than men and in those who are less educated. It also has been strongly associated with individuals who have been sexually abused as children.
- SSD is a chronic relapsing condition characterized by multiple physical symptoms of unknown origin that develop during times of emotional distress.
- Conversion disorder is a condition of neurologic symptoms (e.g., impaired voluntary muscles or sensory stimulation) that is associated with severe emotional distress.
- Factitious disorders include two types, factitious disorder and factitious disorder imposed on another. In factitious disorder, physical or psychological symptoms (or both) are fabricated to assume the sick role.

In factitious disorder imposed on another, the intentional production of symptoms is in others, usually children.

- Identifying SSDs is very complex because patients with these disorders refuse to accept any psychiatric basis to their health problems and often go for years moving from one health care provider to another to receive medical attention and avoid psychiatric assessment.
- These patients are often seen on the medical–surgical units of hospitals and go years without receiving a correct diagnosis. In most cases, they finally receive mental health treatment for comorbid conditions, such as depression, anxiety, and panic disorder.
- The development of the nurse–patient relationship is crucial to assessing these patients and identifying appropriate interventions. Because these patients deny any psychiatric basis to their problem and continue to focus on their symptoms as being medically based, the nurse must take a flexible, relaxed, and nonjudgmental approach that acknowledges the symptoms but focuses on new ways of coping with stress and avoiding recurrence of symptoms.
- Health teaching is important to help the individual develop positive lifestyle changes in place of somatization responses. Identifying personal strengths and supporting the development of positive skills improve self-esteem and personal confidence. Teaching the use of stress management provides the patient with positive coping skills.

CRITICAL THINKING CHALLENGES

1. A depressed young woman is admitted to a psychiatric unit in a state of agitation. She reports extreme abdominal pain. Her admitting provider tells you that she has a classic case of somatization disorder and to de-emphasize her physical symptoms. Under no circumstances can she have any more pain medication. Conceptualize the assessment process and how you would approach this patient.
2. Develop a continuum of “self-injury” for patients with borderline personality disorder, SSD, factitious disorder, and factitious disorder imposed on another.
3. Develop a teaching plan for an individual who has a long history of somatization but who recently received a diagnosis of breast cancer. How will the patient be able to differentiate the physical symptoms of somatization from those associated with the treatment of her breast cancer?
4. A Chinese American patient was admitted for panic attacks and numerous

somatic problems, ranging from dysmenorrhea to painful joints. The results of all medical examinations have been negative. She truly believes that her panic attacks are caused by a weak heart. What approaches should the nurse use in providing culturally sensitive nursing care?

- i. A person with depression is started on a regimen of phenelzine, 15 mg three times a day. She believes that she is allergic to most foods but insists on having wine in the evenings because it helps digest her food. Develop a teaching plan that provides the knowledge that she needs to prevent a hypertensive crisis caused by excessive tyramine but that is sensitive to the patient's food preferences.

Movie Viewing Guides

Safe: 1995. This is a story of Carol White (Julianne Moore), a married stay-at-home mother who appears to have everything. She begins having headaches that lead to a grand mal seizure. As the movie unfolds, she becomes sicker and sicker as she reports she is allergic to environmental toxins. She seeks help from an allergist and psychiatrists. She eventually leaves her husband for a retreat that is actually a scam.

SIGNIFICANCE: The film depicts the pain and suffering that is characteristic of somatization and its impact on the family. It also shows how desperate a person can be to seek out relief of symptoms.

VIEWING POINTS: Identify the mistakes in recognizing and treating the somatic disorder.

Sleep–Wake Disorders

Nursing Care of Persons with Insomnia and Sleep Problems

Sheri Compton-McBride

KEYCONCEPTS

- sleep
- sleep–wake cycle
- insomnia
- rhythm

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the role of the sleep–wake cycle in mental disorders.
2. Delineate the clinical symptoms and course of insomnia disorder.
3. Analyze the primary theories of insomnia disorder.
4. Develop strategies to establish a patient-centered, recovery-oriented therapeutic relationship with a person with insomnia disorder.
5. Apply a person-centered, recovery-oriented nursing process for persons with insomnia disorder.

6. Identify medications used to treat people with insomnia disorder and evaluate their effectiveness.
7. Develop wellness strategies for persons with insomnia disorder.
8. Discuss the treatment setting for insomnia disorder.
9. Discuss the importance of integrated health care for persons with insomnia disorder.
10. Describe other sleep–wake disorders.

KEY TERMS

- Chronotherapy
- Circadian rhythm
- Insomnia disorder
- Non–rapid eye movement (NREM)
- Rapid eye movement (REM) sleep
- Sleep architecture
- Sleep debt
- Sleep diary
- Sleep efficiency
- Sleep homeostasis
- Sleep–wake disorders
- Sleep latency
- Slow-wave sleep
- Somnambulism

Case Study

Michael is a 20-year-old student who is majoring in nursing. He presents himself at Student Health Services with a complaint of insomnia. In assessing his problem, the nurse ascertains that he falls asleep 2 to 3 hours after turning lights out.

INTRODUCTION

Sleep is a recurrent, altered state of consciousness that occupies nearly one third of our lives and occurs for sustained periods. Unlike a coma, sleep can be disrupted and reversed quite easily. Sleep is usually preceded by a period of sleepiness or the urge to fall asleep.

KEYCONCEPT Sleep, which is necessary for human survival, is a state of decreased awareness of environmental stimuli and a relative state of unconsciousness with no memory of the state.

Sleep is important to our development, functioning, and health. Sleep has identifiable cycles and a variety of cognitive experiences, ranging from memory recall to feeling energetic. The consequences of disturbed sleep include impaired alertness and performance.

This chapter presents a discussion of normal sleep rhythms and patterns, sleep–wake disorders, and nursing care for persons with sleep problems. Insomnia disorder is highlighted.

SLEEP AND WELLNESS

Adequate sleep is a critical aspect of wellness. Sleeping less than the recommended 7 hours per night is associated with obesity, diabetes, high blood pressure, coronary heart disease, stroke, and mental distress (Centers for Disease Control and Prevention [CDC], 2017). More than one third of Americans report sleeping less than 7 hours per night (CDC, 2017), with the average sleep duration of U.S. adults being between 6 and 6.5 hours from a high of 8.5 hours in 1960. Sleepiness has been linked to catastrophic disasters, such as the Exxon Valdez oil spill, the nuclear meltdown at Chernobyl in Ukraine, the space shuttle *Challenger* accident, and the Three Mile Island disaster in the United States (Mitler et al., 1988; Rajaratnam & Arendt, 2001).

Biologic Theories

The biology of sleep appears to involve dopamine, gamma-aminobutyric acid

(GABA), adenosine, histamine, hypocretin, melatonin, and cortisol, which play roles in changing sleep states (Herrera-Solis et al., 2019). Wakefulness is maintained by the reticular activating system in the brain. As the cycle of the reticular activating system dwindles, neurotransmitters that promote sleep take over (see [Chapter 8](#)).

Psychosocial Theories

Sleep is also related to psychosocial factors, such as lifestyle, stress, and work- and school-related factors. Underrepresented groups have short sleep duration (Johnson et al., 2019). Short sleep duration is associated with lower socioeconomic groups and the unemployed (Guglielmis et al., 2019).

Pattern of Sleep

Sleep is a patterned activity and is one component of the biphasic 24-hour sleep–wake cycle.

KEYCONCEPT The **sleep–wake cycle** is an endogenously generated rhythm close to 24 to 25 hours synchronized with the day–night cycle. The sleep–wake cycle is regulated by circadian rhythms and sleep homeostasis (Zisapel, 2018).

Sleep latency, the amount of time it takes to fall asleep, is measured from “lights out,” or bedtime, to initiation of sleep. Sleep architecture is the pattern of non–rapid eye movement (NREM) and rapid eye movement (REM) that are in about a 90- to 110-minute cycle. Sleep occurs in stages, and the timing of sleep is regulated by circadian rhythms. Sleep efficiency is the ratio of total sleep time to time in bed.

Circadian Rhythms

KEYCONCEPT **Rhythm** is movement with a cadence, a measured flow that occurs at regular intervals, with a cycle of coming and going, ebbing and rising, to return at the start point and begin again.

Nearly all physiologic and psychological functions fluctuate in a pattern that repeats itself in a 24-hour cycle, called circadian rhythms (Fig. 34.1). The biologic clock that regulates our circadian rhythms is located in the *suprachiasmatic nucleus*, an area of the hypothalamus that lies on top of the optic chiasm. However, it is now recognized that almost all cells and tissues in the body are circadian clocks (Reinke & Asher, 2019). When two or more rhythms reach their peak at the same time, they are synchronized; if they reach their peak at different times, they are desynchronized.

FIGURE 34.1 Circadian rhythms fluctuate in patterns.

The peak is the point at which the rhythm reaches its maximum, and the trough is the point at which the rhythm reaches its minimum. The period is the time it takes to complete a cycle. The amplitude is the extent of the peak and is half the distance from peak to trough.

Most physiologic functions reach their lowest levels during the middle of the sleep period. For example, body temperature follows a predictable pattern from lowest, in the early morning, to highest, in the mid-evening. Manual dexterity, reaction time, and simple recognition appear to coincide with the circadian rhythm of body temperature. Most circadian rhythms continue even when humans are unaware of the time of day. Natural age-related changes in circadian sleep rhythms generally regulate people as they get older, toward morning alertness and productivity and sleepiness at night (Hood & Amir, 2017).

Sleep Homeostasis

The circadian rhythms are not the only processes that regulate sleep. Sleep homeostasis is an internal biochemical system that operates as a timer or counter that generates pressure to sleep and regulates sleep intensity. This process reminds the body to sleep after a certain time. The longer we have been awake, the stronger the desire and need for sleep becomes and the likelihood of falling asleep increases. The longer we sleep, the pressure to sleep decreases and we are more likely to wake (Frank & Heller, 2019).

Stages of Sleep

Sleep is biphasic, cycling between NREM and REM ([Fig. 34.2](#)). During an 8-hour sleep period, the cycle of NREM and REM repeats itself. This duration of the cycles may change as the night progresses. In the first cycle, the amount of REM sleep is brief. With each succeeding cycle, the amount of time spent in REM lengthens. Conversely, NREM is most prominent during the initial cycle but declines as total sleep time progresses ([Fig. 34.3](#)).

FIGURE 34.2 Brain activity during the sleep–wake cycle. The brain is as active in rapid eye movement (REM) or dreaming sleep as when awake but is metabolically less active in slow-wave or non-rapid eye movement (NREM) sleep. (Courtesy of Monte S. Buchsbaum, MD, *the Mount Sinai Medical Center and School of Medicine*, New York.)

Non–Rapid Eye Movement Sleep

NREM sleep occurs about 90 minutes after falling asleep and consists of four substages. Light sleep is characteristic of stages 1 and 2, in which the person is easily aroused. A person aroused from stage 1 sleep may even deny having been asleep, such as dozing while watching television and awakening minutes later during a loud commercial. Stage 1 accounts for only 2% to 5% of a night's sleep and is a transition between relaxed wakefulness and sleep. Stage 2 comprises about 45% to 55% of sleep. During phases 1 and 2, an electroencephalogram (EEG) shows an alpha rhythm gradually being replaced by a theta rhythm. Sleep spindles or “k complexes” occur in stage 2 (see [Fig. 34.3](#)).

Slow-wave sleep, or the deepest state of sleep, characterizes stages 3 and 4. Slow-wave sleep is believed to have a restorative function, although the exact mechanism for this is unclear. It may serve to conserve energy because metabolism and body temperature decrease during this part of sleep. These stages make up 10% to 23% of sleep. EEG findings show high-amplitude waves, slow waves, or delta waves. The difference between stages 3 and 4 is the amount of delta waves seen, with stage 3 demonstrating 20% to 50% of delta waves and stage 4 showing more than 50% of delta waves.

Rapid Eye Movement Sleep

Rapid eye movement (REM) sleep is a state characterized by bursts of rapid eye movements. REM sleep occurs in four to six separate episodes and makes up about 20% to 25% of a night's sleep. Although REM sleep is a deep sleep and muscles seem to be at rest, EEG findings demonstrate an active brain. Brain waves resemble a mixture of wakeful and drowsy patterns. Although vivid dreaming is the outstanding feature reported by adults when awakened out of REM sleep, people also report dreams when they awakened from NREM sleep.

FIGURE 34.3 Brain waves during wakefulness and stages. Brain waves during wakefulness and stages 1, 2, 3, and 4 sleep on the *left* and duration of wakefulness, rapid eye movement (REM), and non-rapid eye movement (NREM) sleep on the *right*. In typical sleep architecture in normal young adults, NREM and REM sleep stages cycle every 90 to 110 minutes through the night. Wakefulness accounts for less than 5% of the night's sleep pattern. Slow-wave sleep dominates the first third of the night during NREM stages 3 and 4. REM sleep occurs in four to six separate episodes throughout the night (20% to 25% of sleep) and dominates the last third of the night's sleep. Reprinted with permission from Norris, T. L.. (2019). *Porth's Pathophysiology: Concepts of altered health states* (10th ed.). Philadelphia, PA: Wolters Kluwer.)

During REM sleep, nerve impulses are blocked within the spinal cord. Muscle tone diminishes to the point of paralysis. Only stronger impulses are relayed, producing muscular twitches, eye movements, and impulses controlling heart

rate and respiration. Breathing and heart rate may become irregular.

This type of sleep has a circadian rhythm that closely coincides with the body temperature rhythm. The greatest amount of REM sleep is seen when the body temperature cycle is at its lowest. People do not sweat or shiver during REM sleep because temperature regulation is impaired. Patterns of hormone release, kidney function, and reflexes change. Women have clitoral engorgement and an increase in blood flow to the vagina. Men have penile erections.

Factors Affecting Sleep Pattern and Quality

Gender

Sleep problems and poorer quality sleep are reported more often by women than men. Disturbed sleep and daytime sleepiness have a cumulative effect on mental health (Thomas et al., 2017). Women are at greater risk for insomnia and other sleep problems. Sleep in women is influenced by the sex hormones, which vary throughout the life cycle (Perger et al., 2019). Socioeconomic factors contribute to poor sleep quality and daytime sleepiness in American women (Xiao & Hale, 2018). Sleep deprivation and sleep quality in transgender and gender nonconforming adults (TGNC) have been reported and are compounded when TGNC individuals experience sexual victimization (Kolp et al, 2020).

Age

Sleep patterns change dramatically over the course of the life span. Newborns need 17 to 18 hours of sleep each day, which occurs in 3- to 4-hour episodes throughout the day. By age 6 months, 12 hours of sleep at night and two 1- to 2-hour naps each day are needed. After age 5 years, children gradually need less sleep.

Preadolescents need about 10 hours of sleep each night, and napping is rare. A teenager's sleep need is only slightly less, at about 9 hours. During young adulthood, about 8 hours of sleep is needed. The amount of sleep required and sleep architecture typically remain unchanged during the middle-aged years. Poor sleep in women is associated with hormonal changes, such as during the menstrual cycle, pregnancy, and menopause.

For older adults, the need for sleep does not decrease, but the ability to sustain sleep changes. Older people spend more time in bed, sleep less, wake more often during the night, and take longer to fall asleep than younger adults. For some, sleep requirements are met by daytime napping. Furthermore, temperature rhythm in older people peaks earlier; early morning arousals may reflect early rise of body temperature. Older people are at higher risk for sleep disorders (Thomas et al., 2017).

Environment

Sleep-related problems have multiple factors that make up the clinical picture. Whereas some are external, such as the noise and temperature, others are internal (e.g., stress and pain). A person can be sleepy but may stay awake if in a stimulating environment with bright lights or a lot of activity. In contrast, a sleepy person in a quiet place or engaged in sedentary activity cannot resist the urge to fall asleep. Sleepiness is a physiologic state, and although a stimulating environment can temporarily forestall it, when these stimuli are removed, the urge to sleep will persist. Even when someone who is chronically sleep deprived does not feel sleepy, the tendency to fall asleep is much greater and may manifest by causing the person to doze off while sitting in lectures or during the monotonous operation of machinery or driving.

Lifestyles

Many factors can cause disrupted sleep patterns, such as travel across time zones, stress or anxiety, and changes in the sleep–wake pattern because of shift work. When traveling across time zones or working night shifts (and sleeping during the day), one’s regular sleepiness–alertness rhythm may persist for several days. Even when daytime sleep is improved with a pharmacologic agent, sleepiness in the early morning hours usually continues for the first 2 to 3 nights. This extreme sleepiness often decreases after a 4- to 6-day reversal of the sleep–wake cycle (see [Box 34.1](#)).

Box 34.1

Nurses' Sleep, Fatigue, and Sleepiness Impact on Cognitive Performance

Wolf, L. A., & Perhats, C. (2017). *The effect of reported sleep, perceived fatigue, and sleepiness on cognitive performance in a sample of emergency nurses. The Journal of Nursing Administration, 47*(1), 44–49.

THE QUESTION: Is there a relationship between the emergency nurses reported sleep, perceived fatigue and sleepiness, and cognitive performance?

METHODS: A quantitative correlational design was used in the study. In each of seven different statistical models, zero-order relationships between predictors and the dependent variable were examined with appropriate inferential tests.

FINDINGS: Participants reported high levels of sleepiness and chronic fatigue that impeded full functioning both at work and at home. Although high level of self-reported fatigue did not show any effects on cognitive function, others factors in the environment may contribute to delayed, missed, or inappropriate care.

IMPLICATIONS FOR NURSING: Nurses are at high risk for sleep deprivation and fatigue. Self-care and patient can be negatively impacted by fatigue associated with variable shifts, long work hours, and chaotic environments.

Changes in Normal Sleep

Normal sleep is sensitive to changes, and the body responds when deprived of certain phases of sleep, particularly REM sleep and slow-wave sleep. Certain activities, such as early rising, alcohol intake before bedtime, or consumption of certain medications, can suppress REM sleep. One example is the use of central nervous system (CNS)-acting medications. Fragmented sleep interrupts the restorative function of a good night's sleep. Not only does insufficient sleep cause daytime sleepiness, but disturbed sleep also affects daytime alertness and performance. A sleep debt occurs when there is recurrent long-term sleep deprivation.

When individuals are deprived of REM sleep, there is a subsequent “rebound effect,” wherein the lost REM sleep is made up during the next sleep period. The body makes up for this lost REM sleep by earlier occurrence of REM sleep during the next night. The presence of REM at sleep onset implies REM deprivation.

Slow-wave sleep does not appear to have a circadian determinant, but it is more sensitive to the amount of previous sleep obtained. When one is deprived of both REM and slow-wave sleep, the body prefers to make up the slow-wave before the REM sleep.

SLEEP–WAKE DISORDERS OVERVIEW

Sleep–wake disorders are diagnosed when an individual is dissatisfied about the quality, timing, and amount of their sleep, which is causing daytime distress and impairment. Sleep problems are more common in women, and prevalence increases with age in both genders. Sleep–wake disorders occur independently of the diagnosis of other mental disorders, but they are also seen in people with mental disorders. For example, a core feature of posttraumatic stress disorder (PTSD) is sleep disturbance.

An occasional change in sleep pattern becomes a sleep disorder when mental and physical health is compromised as a result of problems in the sleep–wake cycle. Sleep–wake disorders include insomnia, hypersomnolence, and narcolepsy. Other disorders include breathing-related sleep disorders (such as obstructive sleep apnea [OSA] and circadian rhythm disorders) and parasomnias.

INSOMNIA DISORDER

KEYCONCEPT **Insomnia**, which is Latin for “no sleep,” refers to difficulty falling asleep or maintaining sleep when opportunity and circumstances are adequate for sleep. Dissatisfaction with sleep quantity or quality may also be present (Khoury & Doghramji, 2015).

Clinical Course

Few studies describe the course of insomnia disorder, which can last for short periods in some patients and for decades in others. Since ancient times, physicians noted individuals having difficulty falling asleep, staying asleep, and early morning awakenings (Riemann et al., 2020). Acute insomnia is described as 3 or more nights per week with symptoms occurring in a 2- to 12-week timeframe, whereas chronic insomnia has a longer duration (Perlis et al., 2020).

Diagnostic Criteria

Insomnia disorder is characterized by dissatisfaction with sleep quantity or quality and difficulty initiating or maintaining sleep, or in waking early in the morning, and being unable to return to sleep (APA, 2013).

Children and Adolescents

Sleep issues in children can occur in the presence of attention deficit hyperactivity disorder (ADHD), epilepsy, and autism spectrum disorder or independently of a neurologic or psychiatric diagnosis (Maski & Owens, 2016). Up to 66% of children are experiencing anxiety disorders, such as separation anxiety disorder or specific phobias, including social anxiety disorder, and experience insomnia (Khurshid, 2018). Not unlike adults, cognition and emotional regulation are impacted when sleep quality and/or sleep quantity are impacted.

Older Adults

Cognitive impairment, depression, anxiety, and increased risk of falls are linked to insomnia in those 65 years and older. Increased rates of insomnia are seen in those residing in institutions versus those in a community setting. Older adults should be educated about the impact of poor quality sleep on daily functioning as well as vital organs, including cardiovascular, neurologic, and mental health implications (Berkley et al., 2020).

Epidemiology and Risk Factors

Age of Onset

Age of onset for insomnia varies and may be impacted by physical health issues and psychological and environmental experiences that impact sleep. Older adults and those with health problems are reportedly more likely to experience insomnia (Grewal & Doghramji, 2017).

Gender Differences

Women report a higher prevalence of insomnia as compared to men within the United States and across countries in Europe and Asia (Grewal & Doghramji, 2017).

Ethnicity and Culture

There is not an equal distribution of sleep disorders among race and ethnicity. Underrepresented groups experience less optimal sleep compared to those populations less impacted by health disparities. In addition to poor sleep quality and quantity, underrepresented groups are at increased risk for adverse mental and physical health outcomes, such as diabetes, hypertension, cardiovascular disease, mood disorders, and occupational accidents (Johnson et al., 2019).

Familial Differences

Fatal familial insomnia is characterized by not only insomnia but also dysautonomia, changes to motor function, neuropsychiatric disorders, and myoclonic limb activity. Rarely does clinical onset occur before the age 32, with the average at 51 years of age, with the majority of cases reported from Italy, Spain, and Germany. Genetically, the disorder is of autosomal dominant pattern (Llorens et al., 2017).

The most widely regarded predictor of a familial risk for insomnia is a

maternal history. It is challenging to distinguish differences among families and support systems due to the web of intricacies that can impact sleep, specifically insomnia. Known medical disorders and treatment regimens can impact sleep architecture whereby making it challenging to determine if insomnia is idiopathic or a consequence of another component of overall health wellness management or treatment.

Of all sleep-related problems, insomnia is the most prevalent. Thirty percent to 50% of the population experiences short-term, occasional insomnia (Sateia et al, 2017). The prevalence of chronic or severe insomnia (occurring for at least 3 months and a minimum of three times per week) is estimated to range from 10% to 15% (Chen et al., 2017). Insomnia is one of the most prevalent complaints in primary health care.

Insomnia has a greater prevalence among older people and among divorced, separated, and widowed adults. Increasing age, female sex, and comorbid disorders (e.g., medical, mental disorders, and substance use) are all risks for developing insomnia disorder.

Comorbidity

Sleep–wake disorders occur independently of the diagnosis of other mental disorders, but they are also seen in people with mental disorders, such as PTSD and depression. Insomnia often increases the risk for relapse of the mental disorder. Documented comorbid conditions include cardiovascular disorders, diabetes, musculoskeletal disorders (e.g., arthritis, chronic back/neck pain), respiratory disorders (e.g., chronic obstructive pulmonary disease [COPD], seasonal allergies, chronic bronchitis, emphysema), digestive disorders (e.g., gastroesophageal reflux disease, irritable bowel syndrome), pain conditions, and mental disorders including depression, PTSD, and other sleep disorders such as sleep apnea, and restless legs syndrome (RLS) (Kessler et al., 2012).

Etiology

Many factors affect sleep, but one of the major reasons for insomnia is depression, which accounts for most cases. However, most people with insomnia do not have a psychiatric diagnosis (Riemann et al., 2020).

Family Response to Disorder

Living with a family member with insomnia disorder is challenging. Irritability, complaints of sleeplessness, and chronic fatigue interfere with quality of interpersonal relationships. Family members become “exhausted” by living with someone who never sleeps.

RECOVERY-ORIENTED CARE FOR PERSONS WITH INSOMNIA

Teamwork and Collaboration: Working Toward Recovery

Sleep disorders are best treated by clinicians specializing in this area, but primary and mental health care professionals should be able to identify sleep disturbances and provide education and interventions for normalizing sleep. However, because sleep disorders are common in individuals with mental health problems, psychiatric–mental health nurses should be prepared to provide care for those with sleep disorders. Optimal management and treatment of insomnia have been linked to improved outcomes in those with coexisting psychiatric disorders (Khurshid, 2018).

Safety Issues

Safety is a priority for people with insomnia disorder. Sleep deprivation can lead to accidents, falls, and injuries, especially in older patients. Sedating medication could potentially increase falls (Kessler et al., 2012).

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH INSOMNIA

Nursing assessment for the patient with insomnia focuses on difficulty falling

asleep, staying asleep, and/or early morning awakenings. The following are examples of assessment questions.

- What time do you go to bed? In your estimation, how long does it take you to fall asleep?
- When did your symptoms begin? Did anything unusual or stressful precipitate the sleep disturbance pattern?
Does anyone in your family experience the same symptoms?
Do you find yourself awakening feeling sluggish or refreshed?
- Does your reported sleep issue impact your daily activities or ability to function?
- Do you nap? If so, what time and for how long?

Interventions stress the importance of sleep hygiene and helping the patient establish normal sleep patterns. If medications are given, the commonly prescribed over-the-counter (OTC) medications and supplements include diphenhydramine and melatonin. Prescription medications used for insomnia include Benzodiazepine Receptor Agonists (BzRAs), Melatonin Receptor Agonist, and Orexin Receptor Antagonist.

Mental Health Nursing Assessment

Assessment of a patient's sleep pattern is a part of every psychiatric nursing assessment (see [Chapter 11](#)). If a patient has a sleep disorder, a detailed sleep history should be included in the assessment process. See Nursing Care Plan 34.1.

Physical Health and Functioning

During the patient interview, the description, duration (when problem began), stability (every night?), and intensity (how bad is it?) should be determined ([Box 34.2](#)). A sleep history includes current sleeping patterns, medical problems, current medications (including OTC and dietary supplements), current life

events, use of alcohol and caffeine, and emotional and mental status that might be affecting sleep (see [Boxes 34.3](#) and [34.4](#)). A sleep diary is a person's subjective written account of their sleep experience (Short et al., 2017). The diary may cover a few days to several weeks. A simple diary is a record of the patient's daily, estimated bedtime, rise time, total sleep time, estimated time to fall asleep, number and length of awakenings, and naps. More complicated sleep diaries involve recording the amount and time of alcohol and caffeine ingestion, activity level, ratings of fatigue, medication, and stressful events.

NURSING CARE PLAN 34.1

Insomnia

Michael is a 20-year-old student who is majoring in nursing. He presents himself at Student Health Services with a complaint of insomnia. In assessing his problem, the nurse ascertains that Michael takes 2 to 3 hours to fall asleep. During this interim of wakefulness, he lies in bed, calm but somewhat restless. He has had no prior difficulty with insomnia. His problem falling asleep occurs 3 nights a week—Monday, Wednesday, and Friday. He exercises vigorously during his physical education class (7–9 PM) on these three evenings. He denies any sleep problems during spring break, when he took a trip. The patient drinks 1 cup of coffee in the morning and denies the use of other stimulants. He reports that as a consequence he has had some irritability and difficulty concentrating on the days following a “bad night.” He has tried an OTC sleep medication, but does not remember the name of it. When he took these sleeping pills, he was able to fall asleep better, but found them to be costly. He would like a prescription for sleeping medication that would be covered by student health insurance.

Setting: Outpatient Student Health Service

Baseline Assessment: A 20-year-old man who presents with difficulty initiating sleep. After vigorous evening exercise, he takes 2–3 hours to fall asleep. Strengths: intelligence, motivated for treatment, adequate insurance coverage, good physical health.

Associated Psychiatric Diagnosis Medications

Primary insomnia

None

Priority of Care: Insomnia

Important Characteristics

Difficulty falling asleep, estimated sleep latency of 2–3 hours, three nights a week
Changes in usual sleep environment
Poor sleep hygiene

Associated Considerations

Mood alterations
Poor concentration

Outcomes

Initial

Discharge

1. Describe factors that prevent or inhibit sleep.
2. Identify strategies to improve sleep hygiene.
3. Report an optimal balance of rest and activity.

Interventions

Interventions	Rationale	Ongoing Assessment
Teach patient good sleep hygiene habits.	Discussion of good sleep hygiene is the first treatment strategy.	Monitor Michael's reports of estimated sleep latency.
Instruct patient to keep a sleep diary for 1 week—including bedtime, sleep latency, rising time, naps, caffeine intake, time of exercise.	Keeping a sleep diary can give insight into insomnia problems by identifying alerting influences in relation to disturbed sleep. Exercise before sleep appears to be the primary factor that could be causing insomnia on Monday, Wednesday, and Friday.	Monitor other sleep hygiene issues.
Reassure patient that short-term insomnia will resolve when the factors that caused the problem are eliminated.	Anxiety about insomnia is a predisposing factor to the development of primary insomnia.	Determine Michael's level of anxiety about insomnia.
Determine whether it is possible to adjust schedule so that vigorous exercise occurs several	Physical exercise raises basal metabolism, which may interfere with sleep.	Determine whether it is possible to adjust course

hours before sleep.		schedule.
Problem solve with Michael how to adjust sleep schedule to avoid insomnia.	Problem-solving allows the patient to learn how to consider alternative strategies.	Evaluate whether strategies are reasonable.
Evaluation		
Outcomes	Revised Outcomes	Interventions
After readjustment of exercise schedule, Matthew was able to resume normal sleep.	None	None

BOX 34.2 • SLEEP ASSESSMENT

INEFFECTIVE APPROACH

Nurse: What time do you go to bed at night?

Michael: Oh, my bedtime varies between 10 PM and 2 AM.

Nurse: What time do you get up?

Michael: I get up anywhere between 6 AM and noon.

Nurse: How do you sleep during the night?

Michael: OK.

Nurse: OK?

Michael: Yeah, no problems sleeping.

EFFECTIVE APPROACH

Nurse: What time do you go to bed at night and what time do you get up?

Michael: Oh, my bedtime varies between 10 PM and 2 AM. I get up anywhere between 6 AM and noon.

Nurse: Let's be more specific. During a week's time, what time do you go to bed each night?

Michael: Well, this semester I have a morning clinical rotation Monday through Thursday. I'm usually up till 11 or midnight preparing for the next day. On Friday and Saturday nights, I typically go out with my friends and get to bed around 2 AM. On Sunday night, I get on to bed around 10 PM.

Nurse: What time do you get up each day of the week?

Michael: On the mornings that I have clinicals, I have to get up around 6 AM to be at the hospital by 6:45 AM. On Friday, I get up at 8 AM for a 9 o'clock class. Saturday morning, I get up around 8 AM so I can go to my part-time job. On Sunday, I get up by noon.

Nurse: How long do you take to fall asleep?

Michael: That's gotten much better. I fall asleep in 15 minutes or so.

Nurse: Do you take any naps?

Michael: Outside of class, I don't have time to nap. I'm just too busy with my classes, clinical, homework, job, and social life.

Nurse: Before this semester, how much sleep did you get?

Michael: That was last summer; I had a job that started at 1:30 PM, so I could sleep as late as I wanted. I bet I got 8 or even 9 hours of sleep every night. I don't remember being sleepy then.

CRITICAL THINKING CHALLENGE

- Compare the quality and quantity of elicited data in the two scenarios.
- What conclusions could be drawn from the first scenario?
- Are the conclusions different for the second scenario? Explain.

Sleep History

- Perception of sleep problem
- Sleep schedule (bedtime and rise time)
- Difficulty falling asleep or maintaining sleep
- Quality of sleep
- Daytime sleepiness and impact of the sleep disorder on daytime functioning
- General emotional and physical problems (e.g., stress)
- Sleep hygiene (e.g., consuming caffeine immediately before bed)
- Sleep environment (e.g., room temperature, noise, light)

Adapted from Kessler, T. A., & Kurtz, C. P. (2019). Sleep and sleep-wake disorders. In Norris, T. L (Ed.). *Porth's Pathophysiology: Concepts of altered health states*, 10th ed. (pp. 505–523). Philadelphia, PA: Wolters Kluwer.

Consider Michael

His problem falling asleep occurs three nights a week—on Mondays, Wednesdays, and Fridays. He exercises vigorously during his physical education class (7 to 9 PM) on these 3 evenings. He denies any sleep problems during a spring break trip.

Should Michael keep a sleep diary? How would exercise impact his sleep? What does it mean that he has no problem sleeping during spring break?

Substance Use and Medication

The bidirectionality of insomnia and substances must be acknowledged as substances impact the receptors and neurotransmitters directly involved with sleep–wake regulation. The development of sleep-related issues can be associated with the use of OTC products, such as nicotine and caffeine. Those who use products that are stimulating need to be informed about not only the effects on overall health but also the timing of consumption as it relates to initiating sleep and maintaining sleep and the impact on sleep quality. OTC and prescription medications that have a stimulating effect need to be avoided within 4 hours of sleep initiation. Though alcohol consumption may initially assist in helping individuals fall asleep, ultimately alcohol use impacts sleep architecture and leads to disrupted, poor sleep quality; increases the likelihood of snoring or sleep apnea; and due to the diuretic effects increases restroom visits (Krystal et al., 2019).

Psychosocial Assessment

The assessment also includes evaluating the behavioral and social factors related to sleep problems. Though we each respond differently, stressful life events impact the quality and quantity of our sleep. Factors to consider include gender, coping skills, timing and perception of the stressor, and substance use or misuse. Recent changes in relationships, particularly a divorce or death of a loved one, can interfere with sleep significantly. A recent move, travel, and addition of a new family member can impact sleep.

Fatigue and stress increase when individuals assume the role of a caregiver in their personal lives and in those with occupations as professional health care providers. A rotating or variable work schedule compromises the circadian rhythm and contributes to insomnia (Kalmbach et al., 2018).

Quality of Life

Health-related quality of life is decreased in adults who experience insomnia. There are numerous studies showing the quality of life is negatively impacted in

people with insomnia. While insomnia has a negative effect on quality of life in both genders, women report a lower quality of life than men (Lucena et al., 2020).

Box 34.4

Medications and Other Substances and Their Effects on Sleep

ALCOHOL

- Increases TST (total sleep time) during the first half of the night
- Decreases TST during the second half
- Decreases REM sleep during the first half of the night
- Withdrawal from long-term use of alcohol decreases TST, increased wakefulness after sleep onset, and REM rebound

AMPHETAMINES

- Disrupt sleep–wake cycle during acute use
- Decrease TST
- Decrease REM sleep
- Withdrawal may cause REM rebound

ANTIDEPRESSANTS (TRICYCLICS AND MAOIS)

- Sleep effects vary with sedative potential
- Increase slow-wave sleep (i.e., a recurrent period of very deep sleep, typically totaling 5 or 6 hours a night)
- Decrease REM sleep

BARBITURATES

- Increase TST
- Decrease WASO
- Decrease REM sleep
- Withdrawal may cause a decrease in TST and REM rebound

BENZODIAZEPINES

- Drugs vary in onset and duration of action
- Decrease SL
- Increase TST

- Decrease WASO
- Decrease REM sleep
- Daytime sedation may occur with long-acting drugs

BETA-ADRENERGIC BLOCKERS

- Decrease REM sleep
- Increase WASO, nightmares
- Daytime sedation may occur

CAFFEINE

- Increases SL
- Decreases TST
- Decreases REM sleep

L-DOPA

- Vivid dreams and nightmares

LITHIUM

- Increases slow-wave sleep
- Decreases REM sleep

OPIOIDS

- Effects vary with specific agents
- Increase WASO
- Decrease REM sleep
- Decrease slow-wave sleep

PHENOTHIAZINES

- Increase TST
- Increase slow-wave sleep

STEROIDS

- Increase WASO
- MAOI, monoamine oxidase inhibitor; REM, rapid eye movement; SL, sleep latency; TST, total sleep time; WASO, wake after sleep onset.

CLINICAL JUDGMENT

The primary concern is sleep deprivation or insomnia, which can result in depression, cognitive dysfunction, and suicide ideation. It is important to help the patient learn about sleep hygiene and the role that sleeps plays in maintaining health and well-being.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Recovery and Wellness Goals

Sleep problems impact all aspects of health and wellness. Helping a person examine current sleep patterns and their impact on any mental health issues is a beginning step in establishing wellness goals. Depending on the sleep problem, the nurse and patient should collaborate on establishing realistic goals. For example, going to bed at a regular hour each night or omitting caffeine after a set time of day could be a realistic goal.

Wellness Challenges

Wellness activities are especially challenging because of the negative impact lack of sleep has on daily life. Wellness can be severely compromised because the person is tired and irritable from lack of sleep. The lack of energy can lead to poor nutrition and inadequate performance at work or school. Coping with everyday stress can be difficult (see [Box 34.5](#)).

The nurse can help the patient develop bedtime rituals and good sleep hygiene. Bedtime should be at a regular hour, and the bedroom environment should be conducive to sleep. Preferably, the bedroom should not be where the individual watches television or does work-related activities. The bedroom should be viewed as a room for either resting or sleep (see [Box 34.6](#)).

Box 34.5

Wellness Challenges and Strategies

- Coping effectively with daily stresses when not getting adequate sleep.
 - Strategies: Reduce number of activities that require intense concentration
- Seeking pleasant environments that support well-being
 - Strategies: Arrange for short periods of “quiet time” throughout the day.
- Recognizing the need for physical activity, healthy foods, and sleep
 - Strategies: Encourage regular physical activity, discuss healthy diets, encourage establishing healthy sleep hygiene routines
- Developing a sense of connection, belong, and a support system
 - Strategies: Seek positive relationships and reduce number of unpleasant interactions.

Box 34.6

Sleep Hygiene Tips

Nurses are often involved in helping patients develop and maintain good sleep habits. Teaching tips include the following:

1. The most important healthy sleep habit is to *establish and maintain a regular bedtime and rising time*. Even if you awaken feeling unrefreshed, get up and out of bed at a regular, consistent time. “Sleeping in” can disturb sleep on the subsequent night. For most, time in bed should be limited to 8 hours.
2. Avoid naps.
3. Abstain from alcohol. Although alcohol may assist with sleep onset, there is an alerting effect when it wears off.
4. Refrain from caffeine after midafternoon. Avoid nicotine before bedtime and during the night. Caffeine and nicotine are strong stimulants and fragment sleep.
5. Exercise regularly, avoiding the 3 hours before bedtime. Exercising 6 hours before bedtime tends to strengthen the circadian rhythms of body temperature and sleepiness.
6. Use the bedroom only for sleep and sex. Promote the bedroom as a stimulus for sleep, not for studying, watching television, or socializing on the telephone.
7. Set a relaxing routine to prepare for sleep. Avoid frustrating or provoking activities before bedtime.
8. Provide for a comfortable environment. A cool room temperature, minimal light, and limiting noise are suggested.

Nonpharmacologic health-promoting interventions are the first choice before administering pharmacologic agents (Khouri & Doghramji, 2015). Sleep hygiene strategies can be effective and should be encouraged (Box 34.6). The goal is to normalize sleep patterns to improve well-being.

Activity, Exercise, Nutrition, and Thermoregulation

Interventions

With the emergence of smartphones and other portable devices, limiting screen time to within 1 hour of bedtime has been found to improve sleep quality and positively impact daytime vigilance (Perrault et al., 2019). Exercise promotes sleep, but regular exercise should be planned to end 3 hours before bedtime. Routines are important, especially when preparing your body to sleep. Engaging in a quiet relaxing activity, such as listening to soft music or reading nonstimulating material, is often suggested. Additional interventions include avoiding eating a heavy meal, and avoiding drinking alcohol or caffeinated beverages. Patients should be encouraged to evaluate the temperature of the room. Generally, a cooler environment enhances sleep.

Medication Interventions

Types of drugs used to treat symptoms of insomnia include benzodiazepine receptor agonists, melatonin receptor agonists, sedating antidepressants, and OTC medications and dietary supplements.

Remember Michael?

Michael has tried OTC sleep medication but does not remember the name of it. When he took these pills, he was able to fall asleep better but found the pills to be costly. He wants a medication that will be covered by his student

health insurance.

What nonpharmacologic interventions would you suggest before exploring less costly medications? Which sleeping medications requiring a prescription have the least side effects?

Benzodiazepine Receptor Agonists

The BzRA hypnotics have U.S. Food and Drug Administration (FDA) approval for insomnia. They include the benzodiazepines (e.g., triazolam, temazepam, estazolam, quazepam, and flurazepam) and the nonbenzodiazepines (e.g., zolpidem, zolpidem extended release, zaleplon, and eszopiclone) (Table 34.1). All these medications bind to benzodiazepine receptors and exert their effects by facilitating GABA effects. GABA, the most common inhibitory neurotransmitter, must be present at the benzodiazepine receptor for the BzRA to exert its effect. These medications are all absorbed rapidly and reduce sleep latency (the amount of time it takes to fall asleep after the lights have been turned off) with medication at recommended doses (Pillai et al., 2017). Nonbenzodiazepine hypnotics, which provide immediate relief, are often used for short-term treatment of insomnia. The most common side effects are headache, dizziness, and residual sleepiness (Box 34.7).

The BzRAs are Schedule IV–controlled substances by federal regulation, have abuse and dependence potential, and produce withdrawal signs and symptoms after abrupt discontinuation. The risk for residual sedation on the day after using hypnotic medication is determined by the dose and rate of elimination (Pillai et al., 2017). The recommended therapeutic dose for using zolpidem (immediate release) is 5 mg and zolpidem CR is 6.25 mg.

TABLE 34-1: HYPNOTICS: BENZODIAZEPINE RECEPTOR AGONISTS

	Dosage (mg)	Half-life (h)
Estazolam	1–2	10–24
Flurazepam	15–30	48–120
Temazepam (Restoril)	15–30	8–20

Triazolam (Halcion)	0.125–0.25	2.4
Quazepam (Doral)	7.5–15	48–120
Zolpidem (Ambien)	5–10	1.4–3.8
Zolpidem ER (Ambien)	6.25–12.5	2.8
Zaleplon (Sonata)	5–20	1
Eszopiclone (Lunesta)	1–3	6

Melatonin Receptor Agonist

Melatonin is a hormone, released from the pineal gland that aids in the regulation of the sleep–wake cycle through activation of MT₁ and MT₂ receptors. Melatonin has been shown to shift circadian rhythm, decrease body temperature, alter reproductive rhythm, enhance immune function, and decrease alertness. Normally, levels of melatonin increase with decreasing exposure to light. Ramelteon (Rozerem), indicated for insomnia, is a melatonin receptor agonist with high affinity for melatonin receptors MT₁ and MT₂. This pharmacologic activity is believed to be related to its sleep-promoting properties (Box 34.8). Ramelteon has a low abuse potential and is not a controlled substance (Neubauer et al., 2018).

Box 34.7

Zaleplon (Sonata)

DRUG CLASS: Sedative–hypnotic (pyrazolopyrimidine nonbenzodiazepine hypnotic). It is readily absorbed and metabolized with only about 1% of zaleplon eliminated in urine.

RECEPTOR AFFINITY: Zaleplon acts at the GABA–benzodiazepine receptor complex.

INDICATION: Treatment of onset or maintenance insomnia

ROUTES AND DOSING: Zaleplon is available in 5- and 10-mg capsules. It should be taken at bedtime or after a nocturnal awakening with difficulty falling back to sleep (but at least 4 hours before the desired rise time).

Adults: The recommended starting dose is 10 mg with a maximum of 20 mg. An initial dose of 5 mg should be considered in adults with low body weight. Doses of over 20 mg have not been sufficiently studied.

Geriatric: Initially, 5 mg is recommended as a starting dose. Older adults should not exceed a 10-mg dose.

HALF-LIFE (PEAK PLASMA CONCENTRATION): 1 hour

SELECTED SIDE EFFECTS: Abdominal pain, headache, dizziness, depression, nervousness, difficulty concentrating, back pain, chest pain, migraine, conjunctivitis, bronchitis, pruritus, rash, arthritis, constipation, and dry mouth

WARNINGS: Zaleplon should not be administered to patients with severe hepatic impairment. Zaleplon potentiates the psychomotor impairments of ethanol consumption.

Box 34.8

Ramelteon (Rozerem)

DRUG CLASS: Sedative–hypnotic. It is readily absorbed and metabolized with median peak concentrations occurring 0.5–1.5 hours after fasted oral administration.

RECEPTOR AFFINITY: Ramelteon is a melatonin receptor agonist with high affinity for MT1 and MT2. No appreciable affinity for the GABA receptor complex.

INDICATION: Treatment of insomnia characterized by difficulty with sleep onset.

ROUTES AND DOSING: The recommended dose is 8 mg. It should be taken 30 minutes before bedtime.

It should not be taken with or immediately after a high fat meal. Patients should be advised to use caution if they consume alcohol in combination with ramelteon.

Adolescents and Children: Ramelteon has been associated with an effect on reproductive hormones in adults, for example, decreased testosterone levels and increased prolactin levels.

Geriatric: No overall differences in safety or efficacy were observed between older and younger adult subjects.

HALF-LIFE (PEAK PLASMA CONCENTRATION): 1–2.6 hours

SELECTED ADVERSE REACTIONS: Somnolence, dizziness, nausea, fatigue, headache, and insomnia

WARNINGS: Ramelteon should not be used by patients with severe hepatic impairment. It should not be used in combination with fluvoxamine.

Orexin Receptor Antagonist

Orexins (also known as hypocretins) are neurotransmitters produced in the hypothalamus that trigger wakefulness, while low levels result in sleep. A deficiency is associated with narcolepsy. Suvorexant (Belsomra) is an orexin receptor antagonist approved for the treatment of insomnia. Blocking the binding

of orexins to receptors is thought to suppress the wake drive. This antagonism may also trigger signs of narcolepsy/cataplexy. There is emerging evidence that this group of medications is effective for other psychiatric disorders (Han et al., 2020).

Over-the-Counter Medications and Dietary Supplements

OTC sleeping pills are usually antihistamines. The most common agents are doxylamine and diphenhydramine. These histamine-1 antagonists have a CNS effect that includes sedation, diminished alertness, and slowing of reaction time. These drugs also produce anticholinergic side effects, such as dry mouth, accelerated heart rate, urinary retention, and dilated pupils. Drowsiness lasts from 3 to 6 hours after a single dose. Next-morning hangover can be a problem. Diphenhydramine decreases sleep latency and improves quality of sleep for those with occasional sleep problems but is not as effective as benzodiazepines for chronic sleep disturbances (Neubauer et al., 2018).

Melatonin has long been an available OTC and has been shown to have mild sleep-promoting properties when given outside the period of usual secretion. That is, melatonin can advance the sleep–wake cycle by making it easier to fall asleep earlier than usual. Some evidence suggests that in young and older individuals with insomnia, melatonin can be beneficial in ameliorating the symptoms (Neubauer et al., 2018).

Valerian, a dietary supplement, is used as a medicinal herb in many cultures. The mechanism of action is not fully understood and is believed to inhibit GABA reuptake. Valerian may be useful for sleeplessness, but not enough evidence from double-blind studies exists to confirm this. The American Academy of Sleep Medicine recommended against using valerian for chronic insomnia in adults. Mild side effects include headaches, dizziness, upset stomach, and tiredness the morning after its use (National Center for Complementary and Alternative Medicine, 2020b).

Administering and Monitoring Medication

Sleeping medications are commonly used in all settings. They are usually given nightly for a short period of time to establish a wake–sleep pattern. Rebound insomnia can occur if a drug is abruptly discontinued. This side effect can be minimized or prevented by giving the lowest effective dose and tapering before discontinuing. Nurses should assess for confusion, memory problems, excessive sedation, and risk of falls.

Monitoring for Drug-to-Drug Interactions

Sleep medications generally have increased depressive effects when given with other CNS depressants. Sleep medications can interact with oral contraceptives, isoniazid (an antibiotic), fluvoxamine (a serotonin reuptake inhibitor [SSRI]), and verapamil (a calcium channel blocker) (see [Chapter 12](#)). Grapefruit juice should be avoided when taking these drugs. Ramelteon should not be given with fluvoxamine.

Teaching Points

Pharmacologic agents should complement sleep hygiene practices. These medications can be useful on a short-term basis. Alcohol use should be avoided when taking sleeping medications. Patients should use these medications when time for sleeping is adequate (at least 8 hours). Most sleep-related medications should be taken at bedtime. Patients should be instructed about the safe use of these medications and possible side effects.

Psychosocial Interventions

Enhancing Cognitive Functioning

Cognitive-behavioral therapy (CBT) is useful in changing negative learned responses that perpetuate insomnia. This approach is especially helpful for those who also have comorbid depression or anxiety. The objective of CBT is to change the belief system that results in improvement of the self-efficacy of the

individual (Khoury & Doghramji, 2015) (see [Chapter 13](#)).

Using Behavioral Interventions

Stimulus control is a technique used when the bedroom environment no longer provides cues for sleep but has become the cue for wakefulness. Patients are instructed to avoid behaviors in the bedroom incompatible with sleep, including watching television, doing homework, and eating. This allows the bedroom to be reestablished as a stimulus for sleep.

Another behavioral intervention is *sleep restriction*. Patients often increase their time in bed to provide more opportunity for sleep, resulting in fragmented sleep and irregular sleep schedules. Patients are instructed to spend less time in bed and avoid napping.

Relaxation training is used when patients complain of difficulty relaxing, especially if these patients are physically tense or emotionally distressed. Various procedures to reduce somatic arousal can be used, including progressive muscle relaxation, autogenic training, and biofeedback. Imagery training, meditation, and thought stopping are attention-focusing techniques that center on cognitive arousal (see [Chapter 13](#)).

Psychoeducation

Teaching Strategies

Education regarding interventions is crucial for patients with sleep disorders. An explanation of the sleep cycle and the factors that influence sleep are important for these patients. For those with insomnia, teaching about avoiding foods and beverages that might interfere with sleep should be highlighted ([Box 34.9](#)).

Box 34.9

Sleep Disorders

When teaching patients with sleep disorders, be sure to include the following topics:

- Maintenance of a sleep log
- Foods to avoid before going to bed
- Importance of developing a bedtime ritual and good sleep habits
- Use of sleep medications as prescribed
- Avoidance of caffeine and rigorous exercise within the 6 hours before bedtime
- Avoidance of cigarette smoking 1 hour before bedtime and during nighttime awakenings
- Allowing for 8 hours of sleep per night
- Maintenance of a regular sleep schedule, specifically a routine rise time
- An occasional “bad night” happens to nearly everyone
- Avoidance of alcohol because it disrupts sleep and is a poor hypnotic
- Daytime sleepiness as a symptom of sleep disorders
- How to do relaxation exercises
- Bedroom rituals
- Appropriate family support

Wellness Strategies

There are sleep hygiene strategies that specifically promote sleep ([Box 34.6](#)), but there are many other activities associated with physical and psychological well-being that should also be considered. Eating a healthy diet, avoiding excessive weight gain, and identifying and managing psychological and physical stressors are examples of wellness strategies that promote sleep. Yoga is associated with improvement in sleep quality (Wang et al., 2020). Other strategies include relaxation, massage therapy, and meditation (National Center for Complementary and Integrative Health, 2020a).

Providing Family Education

Family and friends should be encouraged to support the new habits the patient is trying to establish. Patients, spouses, and friends must understand that activities engaged in just before sleep can greatly affect sleep patterns and sleep difficulties, such as socializing, alcohol consumption, use of caffeine, and

engaging in stimulating activities. Relaxing activities before bedtime are vital contributors to establishing a routine conducive to sleep. Family and friends can help create a positive environment with an emphasis on sleep as a priority.

Evaluation and Treatment Outcomes

The primary treatment outcome is establishing a normal sleep cycle. Changes in diet and behavior (e.g., initiation of an exercise program) should be evaluated for their impact on the individual's sleep. Environmental modifications, such as a change in the level of lighting in the bedroom, decreased stimulation (e.g., turning off cell phone or moving the television out of the bedroom), or modification in room temperature, can be monitored for any changes affecting the sleep cycle.

Integration with Primary Care

Sleep problems are usually treated in the primary care setting. Cardiovascular and metabolic disorders are associated with sleep disturbances. Sleep deprivation is associated with obesity and hypertension (Matenchuk et al., 2020; Thomas & Calhoun, 2016). If a sleep disorder is being treated by a mental health specialist, it is important that the mental health specialists communicate with the primary care provider.

OTHER DISORDERS

Hypersomnolence Disorder

The essential characteristic of hypersomnolence disorder is excessive sleepiness at least three times a week for at least 3 months. Sleepiness occurs on an almost daily basis and causes significant impairment in social and occupational functioning. They have an excessive quantity of sleep, deteriorated quality of wakefulness, and sleep inertia (a period of impaired performance occurring during the sleep–wake transition characterized by confusion, ataxia, or

combativeness) (Cook et al., 2019). This diagnosis is reserved for individuals who have no other causes of daytime sleepiness (e.g., narcolepsy, OSA syndrome).

Clinical Course

People with hypersomnolence typically sleep 8 to 12 hours per night. They fall asleep easily and sleep through the night, often having difficulty awakening in the morning. They often have difficulty meeting morning obligations. They exhibit poor concentration and memory. Excessive sleepiness may not be impacted by napping because they may awaken from a nap feeling unrefreshed. They may even describe dangerous situations, such as being sleepy while driving or operating heavy machinery.

Diagnosis

On the day after overnight polysomnography, a multiple sleep latency test (MSLT) may be used. The MSLT is a standardized procedure that measures sleep variables during a 20-minute period. The process is repeated every 2 hours, occurring approximately five times during the day (Arand & Bonnet, 2019). The faster a person falls asleep during testing, the greater the physiologic sleep tendency. The presence of sleep-onset REM (SOREM) during the MSLT and a report of cataplexy assist providers in determining a sleep diagnosis. Polysomnography shows short sleep latency, a normal-to-long sleep duration, and normal sleep architecture. Subjective symptoms of sleepiness are recognized as heavy eyelids, loss of initiative, reluctance to move, and yawning or slowed speech. Sleepiness is unique to the person and situation, varying from mild to severe.

Evidence-Based Nursing Care of Persons with Hypersomnolence Disorder

Nursing assessment for the patient with hypersomnolence focuses on excessive

sleepiness. The following are examples of assessment questions.

- Have you ever nodded off unintentionally?
- When did your sleepiness begin?
- Does anyone in your family experience the same sleepiness symptoms?
- Do you suddenly find yourself awakening feeling refreshed?

Interventions stress the importance of sleep hygiene and helping the patient establish normal sleep patterns. If medications are given, the most commonly prescribed stimulants for treating excessive daytime sleepiness are dextroamphetamine and amphetamine mixtures (Adderall), modafinil (Provigil), methylphenidate (Ritalin, Concerta), and pemoline (Cylert). These agents increase the patient's ability to stay awake and perform. Abuse of these medications should be assessed. In some cases, serotonin antagonists are used off-label.

Sleepy people often self-medicate with caffeine. A cup of brewed coffee contains about 100 to 150 mg of caffeine. A 12-oz can of Mountain Dew contains 54 mg of caffeine. Caffeine contents of popular "energy" drinks range from 80 to 300 mg. Peak plasma concentration is reached 30 to 60 minutes after consumption, and the duration of effect is 3 to 5 hours in adults. Caffeine improves psychomotor performance, particularly tasks involving endurance, vigilance, and attention. High doses, especially in people who are not habitual users, may exhibit side effects such as irritability and anxiety.

Narcolepsy

The overwhelming urge to sleep is the primary symptom of narcolepsy. This irresistible urge to sleep occurs at any time of the day, regardless of the amount of sleep. Falling asleep often occurs in inappropriate situations, such as while driving a car or reading a newspaper. These sleep episodes are usually short, lasting 5 to 20 minutes, but may last up to an hour if sleep is not interrupted. Individuals with narcolepsy may experience sleep attacks and report frequent dreaming. They usually feel alert after a sleep attack, only to fall asleep unintentionally again several hours later.

Clinical Course

Narcolepsy is a chronic disorder that usually begins in young adulthood between the ages of 15 and 35 years. Excessive sleepiness is the first symptom to appear. The severity of sleepiness may remain stable over the lifetime. Narcolepsy has no cure. Treatment is designed to control symptoms based on clinical presentation and severity. A secondary sleep disorder should be considered if the level of sleepiness changes.

Narcolepsy is distinguished by a group of symptoms, including daytime sleepiness, cataplexy, hypnagogic hallucinations, and sleep paralysis. The symptom of daytime sleepiness is found in all individuals with narcolepsy, but existence of the other three symptoms varies.

- Cataplexy is the bilateral loss of muscle tone, triggered by a strong emotion, such as anger or laughter. This muscle atonia can range from subtle (drooping eyelids) to dramatic (buckling knees). Respiratory muscles are not affected. Cataplexy usually lasts for seconds. Individuals are fully conscious, oriented, and alert during the episode. Prolonged episodes of cataplexy may lead to unintentional sleep episodes. The frequency and severity of events generally increase when the individual is sleep deprived.
- Hypnagogic hallucinations are intense dreamlike images that occur at sleep onset and usually involve the current environment. Hallucinations can be visual or auditory, such as hearing one's name called or a door slammed.
- Sleep paralysis, the inability to move or speak when falling asleep or waking up, is often described as terrifying and is accompanied by a sensation of struggling to move or speak. Although the diaphragm is not involved, patients may also complain of not being able to breathe or feeling suffocated. These episodes are typically brief in duration and usually terminate spontaneously or when the individual is touched.

Diagnosis

Excessive daytime sleepiness and the presence of cataplexy are diagnostic of narcolepsy. It is possible to have narcolepsy without cataplexy. The diagnosis should be confirmed by an in-lab polysomnogram demonstrating at least 6 hours of sleep, followed by the MSLT showing a sleep latency of less than or equal to 8 minutes and two or more SOREM periods. The diagnosis can also be confirmed by a cerebrospinal fluid hypocretin-1 level less than or equal to 110 mg/mL (Rosenberg et al., 2019).

Epidemiology and Etiology

The prevalence of narcolepsy is between 20 and 50 per 100,000 people in the United States (Dye et al., 2018). The etiology of most cases of narcolepsy is unknown, but it is thought that there are many triggers such as head trauma, viral illness, exposure to toxins, and development factors. In some patients, there is a deficiency of hypocretin, a hypothalamic peptide that may be linked to chromosome 6 in class II human leukocyte antigen. Hypocretin neurons are part of the neurologic system that wakes and maintains wakefulness (Rosenberg et al., 2019).

Evidence-based Nursing Care of Persons with Narcolepsy

Nursing assessment is similar to that for insomnia. In general, sleepiness is treated with CNS stimulants. Methylphenidate, dextroamphetamine, modafinil, and pemoline are the most frequently prescribed stimulants. Cataplexy may be treated with tricyclic antidepressants because these drugs suppress REM. Sodium oxybate (Xyrem), classified as a Schedule II drug, is indicated for excessive sleepiness and cataplexy. Because of its high abuse potential, patients who are prescribed this medication are closely monitored.

Patient education focuses on factors that can make symptoms worse, such as sleep deprivation. Patients need to develop strategies to manage symptoms. Naps can be integrated into their daily routines such as during work breaks or before engaging in activities that require sustaining alertness.

Breathing-Related Disorders

The *DSM-5* identifies three breathing disorders, including OSA–hypopnea, central sleep apnea, and sleep-related hypoventilation. This section will discuss OSA–hypopnea disorder (OSA syndrome) (APA, 2013). The term *obstructive sleep apnea syndrome* is more commonly used in nonpsychiatric areas and will be used in this section instead of the term *obstructive apnea–hypopnea disorder*. Central sleep apnea and sleep-related hypoventilation will not be discussed.

Obstructive Sleep Apnea Syndrome

OSA syndrome, the most commonly diagnosed breathing-related sleep disorder, OSA is characterized by snoring during sleep and episodes of sleep apnea (cessation of breathing) that fragments sleep and contribute to daytime sleepiness. The hallmark symptoms are snoring and daytime sleepiness. Often, snoring is so loud and disturbing that partners choose separate bedrooms for sleeping. On physical examination, an enlarged, elongated uvula is associated with increased severity of snoring and apneic events (Chang et al., 2018). Snoring affects 57% of men, 40% of women, and 27% of children (National Sleep Foundation, 2020).

Clinical Course

Apneic episodes, which last from 10 seconds up to several minutes, cause disrupted sleep and abrupt awakenings with feelings of choking or falling out of bed; some people even leap out of bed to restore breathing. The person may not later recall the awakening. These brief awakenings deprive essential sleep, resulting in excessive daytime sleepiness that may reach the same degree of pathologic sleepiness found in narcolepsy. Unlike narcolepsy, naps tend to be unrefreshing.

Esophageal reflux, or heartburn, is a common complaint. Genitourinary symptoms include nocturia (three to seven trips to the bathroom), nocturnal enuresis, and erectile dysfunction. Bradycardia, in association with tachycardia, is often seen with apneic events. Other cardiac arrhythmias are also seen,

including sinus arrest. The onset of symptoms and sleepiness may coincide with weight gain. Obesity is a major risk factor for apnea and predictor across populations (Sutherland et al., 2019).

Diagnosis

Polysomnography, usually performed at night during sleep, monitors many body functions, including brain wave activity, eye movements, muscle activity, heart rhythm, breathing function, and respiratory effort. Polysomnography may show poor sleep continuity, increased stage 1 and decreased slow-wave and REM sleep, and an increased amount of EEG alpha wave activity while the individual is asleep. Clinical evaluation includes oral and nasal airflow, respiratory effort, oxyhemoglobin saturation, and electromyogram of limb muscle activity. Typically, patients with OSA demonstrate numerous respiratory events per night, resulting in intermittent hypoxemia and changes in intrathoracic pressure during polysomnographic measurement (Sutherland et al., 2019).

Epidemiology and Risk Factors

The prevalence of OSA is worldwide and is said to impact up to one billion adults globally, between the ages of 30 and 69 years (Benjafield et al., 2018), affecting both men and women. OSA is most common in men aged 45 to 65 who are overweight. The female-to-male ratio is estimated to be 1:8, with women becoming more likely to develop this syndrome after menopause. Men are twice as likely to snore as women (APA, 2013).

Research supports ethnic and racial differences in sleep disturbances. African American individuals and Hispanic individuals have an increased frequency of snoring as compared with White individuals, but the increase may be related to poorer physical health (Petrov & Lichstein, 2016). Lost workplace productivity, motor vehicle accidents, workplace injuries, and increased use of health care services account for some of the societal consequences of untreated OSA (Wickwire et al., 2019). OSA is a risk factor for cardiac events and is commonly associated with metabolic syndrome disorders (Li et al., 2020). OSA is more prevalent in people with mental health disorders than in the general population.

Depression, anxiety, PTSD, and bipolar disorder are associated with OSA. The symptoms of depression, such as fatigue, irritability, depressed mood, and poor concentration, are similar to the symptoms of OSA. Evidence suggests that the successfully treated OSA may improve depressive symptoms (Edwards et al., 2020).

Etiology

An obstruction or collapse of the airway causes apnea, or cessation of breathing. In most cases, the site of obstruction is in the pharyngeal area. Vibrations of the soft, pliable tissues found in the pharyngeal airway cause the snoring sounds that occur during breathing.

Teamwork and Collaboration: Working Toward Recovery

There are nonsurgical and surgical options for the treatment of patients with OSA. Nonsurgical options vary based on the severity of the obstructive breathing. For obese patients with less severe OSA, weight loss may help. For others, whose apnea is mild, changing sleeping position from supine to lateral can help control the severity of OSA. There has also been some effort in devising an oral appliance to reduce snoring and the occurrence of apnea. Currently, the most effective nonsurgical treatment is continuous positive airway pressure. This treatment takes place during sleep and involves wearing a nose mask that is connected by a long tube to an air compressor. Airway patency is maintained with air pressure. Although this method of treatment is highly effective, compliance can be a problem. Individuals who have severe OSA symptoms and daytime sleepiness are more compliant with CPAP (continuous positive airway pressure) treatment and report an improved quality of life (Bue et al., 2019).

The most commonly performed surgical procedure to treat patients with OSA is uvulopalatopharyngoplasty. This procedure involves the removal of redundant soft palate tissue, uvula, and tonsillar pillars. The surgery usually eliminates snoring and is judged to be about 50% effective in reducing the amount of sleep

apnea. Severity of OSA, body mass index, and pharyngeal anatomic features are factors that impact surgical outcomes (He et al., 2019).

Circadian Rhythm Sleep Disorder

The chief feature of a circadian rhythm sleep disorder is the mismatch between the individual's internal sleep–wake circadian rhythm and the timing and duration of sleep (Burgess & Emens, 2018). People with these disorders complain of insomnia at particular times during the day and excessive sleepiness at others. This diagnosis is reserved for those individuals who present with marked sleep disturbance or significant social or occupational impairment.

Diagnosis and Clinical Course

- *Delayed sleep phase type*: Individuals with delayed sleep phase type, or “night owls,” tend to be unable to fall asleep before 2 AM to 6 am; hence, their whole sleep patterns shift, and they have difficulty rising in the morning.
- *Advanced sleep phase type*: Opposite of the night owls, these individuals are “larks” or earlier risers. They are unable to stay awake in the evening and consistently wake up early.
- *Irregular sleep–wake type*: People with this type have a temporarily disorganized sleep pattern that varies in a 24-hour period.
- *Non–24-hour sleep–wake type*: Individuals with this type have an abnormal synchronization between the 24-hour light–dark cycle and their endogenous circadian rhythm, which leads to periods of insomnia, excessive sleepiness, or both. This type is most common among blind or visually impaired individuals.
- *Shift work type*: The endogenous sleep–wake cycle is normal but is mismatched to the imposed hours of shift work. Rotating shift schedules are disruptive because any consistent adjustment is prevented. Compared with

day and evening shift workers, night and rotating shift workers have a shorter sleep duration and poorer quality of sleep. They may also be sleepier while performing their jobs. This disorder is further exacerbated by insufficient daytime sleep resulting from social and family demands and environmental disturbances (i.e., traffic noise, telephone). Because of the job requirements of the profession, nurses often experience this disorder. Furthermore, 20% of the U.S. workforce is engaged in shift work and thereby at risk for circadian rhythm disorders.

- *Jet lag type:* This type of sleep disturbance occurs after travel across time zones, particularly in coast-to-coast and international travel. The normal endogenous circadian sleep–wake cycle does not match the desired hours of sleep and wakefulness in a new time zone. Individuals traveling eastward are more prone to jet lag because it involves resetting one’s circadian clock to an earlier time—it is easier to delay the endogenous clock to a later time period than adjust it to an earlier one.

Epidemiology and Etiology

There are no data regarding the prevalence of circadian rhythm disorders in the general population. The prevalence of circadian rhythm disorders among patients diagnosed at sleep disorder centers accounts for 2% or less of the total patients diagnosed. However, this is a gross underestimate, given that jet lag, a circadian rhythm disorder, affects nearly everyone traveling over three time zones.

Circadian rhythm disorders are caused by the dissociation of the internal circadian pacemaker and conventional time. The cause might be intrinsic, such as genetic factors called “clock genes” or extrinsic, as in jet lag and shift work. Each result is overwhelming daytime sleepiness and overflowing wakefulness at night.

Teamwork and Collaboration: Working Toward

Recovery

The goals of treatment of circadian rhythm disorder are to strengthen timed clues (when to go to sleep), timed bright or blue light (stay awake during the day), and timed exogenous melatonin (initiate melatonin secretion at bedtime). Melatonin is often helpful in initiating sleep (Pavlova & Latreille, 2019).

Chronotherapy, timed interventions, manipulates the sleep schedule by progressively delaying bedtime until an acceptable bedtime is attained. Chronopharmacotherapy resets the biologic clock by using medications to induce sleep. Tasimelteon (Hetlioz) is a melatonin receptor agonist that is approved for the treatment of this disorder. Small amounts of hypnotics can also produce high-quality sleep in people who wish to reset their circadian schedules after long transmeridian flights. Conversely, for night shift workers, caffeine taken while working at night improves alertness and performance. However, caffeine should be used judiciously by night shift workers because they become quickly tolerant to the effects after a few nights (Burgess & Emens, 2018).

Luminotherapy (light therapy) is used to manipulate the circadian system. Timing, wavelength intensity and prior light exposure are key factors when considering light therapy (Pavlova & Latreille, 2019). Commercially prepared light boxes produce therapeutic light at 2500 to 10,000 lux. In contrast, indoor light is about 150 lux (Burgess & Emens, 2018).

Parasomnias

Parasomnias are sleep–wake disorders that occur in association with sleep, specific sleep stages, or sleep–wake transitions. The person experiences abnormal behavioral, experiential, or physiologic events. Parasomnias are divided into two primary categories: NREM-related and rapid eye movement (REM)-related NREM sleep arousal disorders, including sleepwalking and sleep terror types, which usually occur during the first third of the major sleep episode. Nightmare disorder is a REM disorder that generally occurs during the second half of the major sleep episode. RLS is considered a sleep disorder and is classified as a sleep-related movement disorder (Carter & Wrede, 2017).

Sleep Terrors and Sleepwalking

In sleep terrors (also called night terrors or pavor nocturnes), there are episodes of screaming, fear, and panic, causing clinical distress or impairing social, occupational, or other areas of functioning. Sleep terrors usually last 1 to 10 minutes, are frightening to the person and to anyone witnessing them. Often, individuals abruptly sit up in bed screaming; others have been known to jump out of bed and run across the room. Other symptoms include a rapid heart rate and breathing, dilated pupils, and flushed skin. Usually, the person having a sleep terror is inconsolable and difficult to awaken completely. Efforts to awaken the individual may prolong the episode. Once awake, most are unable to recall the dream or event that precipitated such a response. A few report a fragmentary image. Often, the individual does not fully awaken and cannot recall the episode the next morning (Ellington, 2018).

In sleepwalking or somnambulism, there are repeated episodes of complex motor behavior during sleep that may involve getting out of bed and walking around. While sleepwalking, people typically have a blank stare and are difficult to awaken. Often, they awaken to find themselves in a different place from where they went to sleep. If awakened during the episode, there is a brief period of confusion.

Clinical Course

Polysomnography shows that these disorders usually begin when slow-wave NREM sleep predominates during the first third of the night. They rarely occur during daytime naps.

Epidemiology and Etiology

The prevalence of sleep terrors is estimated at 6.5% in children and 2.2% in adults. Males and females are affected equally. The prevalence of sleepwalking is 30% in children and 4% in adults. Sleepwalking peaks between 8 and 12 years of age and is more common in males (Ellington, 2018). Fever, stress, and sleep

deprivation can increase the frequency of episodes. There appears to be some genetic predisposition for disorders of arousal, and they tend to run in families.

Teamwork and Collaboration: Working Toward Recovery

Learning about parasomnias and the need for safety precautions for patient and family should be the focus of patient education. Hypnosis supplemented by psychotherapy may be considered. Treatment might also include medications, such as benzodiazepines. These disorders usually resolve by adolescence.

Evidence-Based Nursing Practice for the Persons with Parasomnias

Although polysomnography may be used to diagnose or confirm a sleep disorder, the evaluation of a response to an NREM disorder involves a careful sleep history. Episodes of sleep terrors or sleepwalking are often unrealized by the patient but can be described in detail by the parent or partner. Support persons should be advised to avoid attempting to wake the person/child and ensure a safe environment surrounds the individual. Safety features may include a sleep space absent of stairs, as well as securing windows and doors with locks. Sleep diaries should focus on the person's bedtime activities, time of sleep onset and wake up, time to prepare for bed and fall asleep, use of medications, number of awakenings, subjective assessment of quality of sleep, and daytime naps. Sleep hygiene and a routine, to avoid insufficient sleep, should be promoted (Manni et al., 2018).

Nursing interventions range from referring to sleep specialists to patient education about the disorder and strategies in dealing with the disorder. In some instances, nurses care for patients in the inpatient setting who have arousal disorders. In these instances, nurses should develop care plans that address the individual patient's needs. In instances of sleepwalking, staff should be alert to the safety issues and protect the patient from injury (see [Box 34.10](#)).

Nightmare Disorder

The repeated occurrence of frightening dreams that occur during REM sleep and often awaken an individual is the essential characteristic of nightmare disorder. Typically, the individual can recall detailed dream content that involves physical danger (e.g., attack or pursuit) or perceived danger (e.g., embarrassment or failure). On awakening, the individual is fully alert and experiences a persisting sense of anxiety or fear. Many people have difficulty returning to sleep. Multiple same-night nightmares may be reported. Some people avoid sleep because of their fear of nightmares. Consequently, people may report that excessive sleepiness, poor concentration, and irritability disrupt their daytime activities. The occurrence of nightmares may be more serious than previously suspected. Nightmares are commonly experienced by military combat personnel who have PTSD (see [Chapter 29](#)).

Diagnosis and Clinical Course

Nightmares occur in REM sleep almost exclusively. They most often occur during the second half of the night when REM sleep dominates. Polysomnography demonstrates abrupt awakenings from REM sleep. In most cases, the REM sleep episode lasts for at least 10 minutes. Tachycardia and tachypnea may be evident.

Box 34.10

General Safety Precautions for Sleepwalkers and Their Families

- Ensure adequate sleep. The occurrence of sleepwalking dramatically increases after sleep loss.
- Anticipate sleepwalking. Family members should be aware of the likelihood of sleepwalking for the first 2–3 hours after the sleepwalker goes to bed.
- Keep a sleep log to assist in identifying how much sleep is needed to prevent a sleepwalking event.
- Consider use of a noise device on the door of the sleepwalker's room to alert others that the sleepwalker is up.
- Deadbolt locks should be installed on doors leading outside. Windows should be secured to limit their opening.

- When the sleepwalker is spending the night away from home, alert appropriate individuals to the possibility that sleepwalking may occur. Ensure adequate sleep on the preceding nights.

Etiology and Epidemiology

The cause and prevalence of nightmares are unknown. Intriguing evidence provokes a debate as to whether nightmares are a symptom or an adaptive reaction to pathophysiologic factors. Negative emotions, primarily fear, are the most common dream emotions. Brain imaging demonstrates increased metabolic activity during REM sleep in the most primitive regions of the brain, the paralimbic and limbic regions. Many classes of drugs trigger nightmares, including catecholaminergic agents, beta-blockers, some antidepressants, barbiturates, and alcohol. Additionally, withdrawal from barbiturates and alcohol causes REM rebound and more vivid dreaming.

Nightmares often begin in children between the ages of 3 and 6 years, and most children outgrow them. In adults, at least 50% of the population reports occasional nightmares. Women are more likely to report nightmares than men.

Teamwork and Collaboration: Working Toward Recovery

If the nightmares cause significant distress, a person will be treated by multiple providers. Traditionally, psychotherapy aimed at conflict resolution has been the treatment of choice. Today, CBT is recommended, specifically imagery rehearsal therapy, a technique in which patients change the endings of the nightmares while they are awake. After rehearsing new, nonthreatening images and changing the content of the nightmare while awake, a reduction in the frequency of nightmares and associated distress has been shown (Levriar et al., 2016). Pharmacologically, the best studied and most effective medication to treat nightmares with PTSD is prazosin (Minipress), a centrally active alpha-1 adrenergic antagonist indicated for hypertension (El-Solh, 2018). It does not have FDA approval for use with nightmares, but prazosin is recommended by the Standards of Practice Committee of the American Academy of Sleep

Medicine for PTSD-associated nightmares (Morgenthaler et al., 2018).

Evidenced-Based Nursing Care

While caring for patients with other disorders, the nurse often is the first health professional to identify nightmares as a problem in a patient. Sleep assessment is vital in every nursing assessment. If nightmares are causing distress, a referral for a sleep evaluation should be made. Sleep hygiene techniques and education about the treatment of nightmares should be included in patient teaching. During hospitalization, the nurse should document that the patient has nightmares, and the nurses on the night shift should monitor for them.

Restless Legs Syndrome

RLS is a sleep–wake disorder characterized by an urge to move the legs, which begins or worsens at rest or periods of inactivity, typically in the evening or at night. The urge to move legs is reduced or relieved by movement.

Diagnostic Criteria and Clinical Course

RLS is a sensorimotor, neurologic disorder described as the intense desire to move legs accompanied by uncomfortable sensations such as creeping, crawling, tingling, burning, or itching. The diagnosis is made on the basis of self-report. These symptoms can interfere with sleep and cause considerable clinical distress or functional impairment. RLS is usually diagnosed in the second and third decade of life and can get progressively worse later in life.

Epidemiology and Etiology

RLS affects approximately 2.5% of adults in the United States. The prevalence is about twice higher in women than in men and increases with age in North America and Europe, but not observed in Asian countries. Comorbid conditions

of insomnia, excessive sleepiness, and depressive and/or anxiety symptoms are consistently associated with RLS. RLS is the most common movement disorder occurring during pregnancy, usually developing in the third trimester and impacting 1 in 5 women (Esposito et al., 2019; Steinweg et al., 2020).

The etiology of RLS remains unclear, but genetic predisposition, dopaminergic dysfunction, and deficiencies in iron metabolism partially explain the underlying causes. RLS is linked to cardiovascular disease and metabolic syndrome (diabetes, obesity, hypertension, and dyslipidemia) (Yatsu et al., 2019). There is emerging evidence that suggests inflammation and/or immunologic disorders have a role in RLS. Recent studies show an increased prevalence of small intestinal bacterial overgrowth, HIV infection, systemic lupus erythematosus, and cases of hepatitis C (Trenkwalder et al., 2017).

Teamwork and Collaboration: Working Toward Recovery

The treatment of RLS involves a biopsychosocial approach using pharmacologic and nonpharmacologic treatment options. In cases of mild and intermittent RLS, behavioral therapy, sleep hygiene, and lifestyle interventions (avoiding caffeine, alcohol, and heavy meals) help reduce the likelihood of having an episode. If serum ferritin is <50 mcg/L, supplementation with ferrous sulfate is initiated (Khoury & Doghramji, 2015). For moderate-to-severe RLS, there is strong evidence to support the use of pramipexole, rotigotine, cabergoline, and gabapentin enacarbil. There is moderate evidence to support the use of ropinirole, pregabalin, and IV FCM. Augmentation, also diagnosed as refractory RLS, with use of dopaminergic drugs occurs in approximately 7% of clients and can occur after multiple years of use. Assessment for augmentation, sleepiness, and compulsive behaviors are factors of focus for the health care team. The evidence to support the use of levodopa is weak (Winkelman et al., 2016).

Evidence-based Nursing Practice for Persons with Restless Legs Syndrome

A thorough nursing assessment will provide direction for the nursing

interventions for a person with RLS. In many instances, there are underlying medical conditions such as diabetes or peripheral neuropathy, which contribute to the severity of RLS, particularly for the older adult. If the underlying medical condition is being treated adequately, the patient can be encouraged to engage in moderate regular physical activity 3 days a week or taking a hot bath before going to sleep. If medication is prescribed, the patient and family will benefit from medication education. If iron supplement is given, follow-up testing should be monitored to prevent overload. Sleep hygiene and encouragement to avoid exacerbating factors should be recommended (Steinweg et al., 2020).

SUMMARY OF KEY POINTS

- The normal sleep–wake cycle runs in a pattern called circadian rhythm. Most body systems follow a circadian rhythm and are often associated with the sleep–wake cycle. Hormones, such as melatonin and cortisol, help promote wakefulness during the day and sleepiness at night.
- Assessment is key. Information should focus on a comprehensive sleep history, including specific details of the sleep complaint, current sleep patterns, and sleep patterns before sleep difficulties, medical problems, current medications, current life events, and emotional and mental status.
- Nursing interventions for sleep disorders focus on nonpharmacologic approaches (e.g., exercise, nutrition, activity, thermoregulation) and pharmacologic interventions.
- Psychosocial nursing interventions for sleep disorders include educating patients about good sleep habits, instructing patients in relaxation exercises and sleep-promoting activities, providing patients with nutritional suggestions regarding foods and substances to avoid, and educating family members and friends regarding the importance of supporting the need for making high-quality sleep a priority.
- Insomnia disorder is characterized by difficulty falling asleep or difficulty maintaining sleep. Insomnia is often precipitated by feelings of stress or tension, with associations and behaviors persisting after the crisis or stressful situation has passed.
- OSA syndrome is a diagnosed breathing-related sleep disorder characterized by excessive snoring and episodes of apnea (i.e., cessation of breathing). These episodes disrupt sleep and may cause daytime sleepiness.
- In circadian rhythm sleep–wake disorders, a mismatch takes place between the individual’s internal sleep–wake circadian rhythm and the timing and duration of sleep.
- Parasomnias occur in association with sleep, specific sleep stages, or sleep–wake transitions and include sleepwalking, sleep terrors, nightmare disorders, and RLS. They are characterized by abnormal behavioral, experiential, or physiologic events. The etiology is unknown but appears to be of genetic predisposition. Unrestorative sleep, excessive sleepiness, poor concentration, and irritability are often the result.

CRITICAL THINKING CHALLENGE

1. Describe the sleep hygiene interventions that would be useful for the person with insomnia disorder.
2. Identify the primary problems related to the sleep–wake disorders.
3. A 25-year-old woman reports that she has not slept for 3 days. What are the primary assessment questions for her?
4. A 55-year-old truck driver presents reporting excessive daytime sleepiness. Develop a list of assessment questions that could be used to investigate his chief complaint.
5. Outline nursing interventions and educational highlights for the parents of a 12-year-old child diagnosed with sleepwalking disorder.

Movie Viewing Guides

Insomnia: (1997). This movie is a compelling thriller that occurs in a state of perpetual light. The setting is north of the Arctic Circle in the middle of summer, where it is daylight 24 hours a day. Jonas Engström (Stellan Skarsgård) and Erik Vik (Sverre Anker Ousdal) are cops from Oslo brought into a small town to help with a murder investigation. Things go wrong, and Engström finds himself trapped in a web of deceit. His guilty conscience and the never-ending light keep him awake at night, and the lack of sleep makes him increasingly desperate and error prone.

VIEWING POINTS: How did the lack of sleep have an impact on Engström’s ability to make sound decisions? If the setting of this movie were in an area that had normal nighttime darkness, would the outcome have been different? If you were conducting a sleep assessment, what priorities of care would be generated from the data?

Sexual Disorders

Nursing Care of Persons with Sexual Dysfunctions and Paraphilias

Mary Ann Boyd

KEYCONCEPTS

- sexual arousal
- sexual disorders
- sexuality
- sexual health

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of sexuality in mental disorders.
2. Analyze sexual response and theoretical models.
3. Analyze primary theories of female orgasmic and erectile disorders and their relationships to comorbidities.
4. Apply a person-centered, recovery-oriented nursing process for persons with sexual disorders.
5. Identify medications used to treat people with sexual disorders.

6. Discuss the importance of integration of primary care for persons with sexual disorders.
7. Describe other sexually related situations that impact mental health.

KEY TERMS

- Anorgasmia
- Biosexual identity
- Cisgender
- Dyspareunia
- Erectile dysfunction (ED)
- Excitement phase
- Gender identity
- Gender dysphoria
- Genderqueer identity
- Human sexual response cycle
- LGBTQ
- Non-binary identity
- Orgasmic disorder
- Orgasmic phase
- Paraphilias
- Plateau phase
- Premature ejaculation
- Resolution
- Sensate focus
- Sex role identity
- Sex therapist
- Sexual desire
- Sexual maturation
- Sexual orientation
- Vaginismus

Case Study

Alice is a 35-year-old woman diagnosed with multiple sclerosis 3 years ago. She experiences transitory visual blurring, weakness of the lower limbs, and mood swings. She also has problems with urinary leakage and occasional bowel incontinence.

INTRODUCTION

Sexuality is associated with sensuality, pleasure and pleasuring, intimacy, trust, communication, love and affection, attractiveness, affirmation of one's masculinity and femininity, and reverence for life. Sexuality influences how we view ourselves (self-concept) and consequently how we relate to others.

Sexuality is influenced by a person's emotional and physiologic status, beliefs and values, and morals and laws of society. Barriers to sexual fulfillment can arise from medical problems (e.g., neurologic, musculoskeletal, cardiovascular, respiratory, renal, hepatic, and cognitive impairments); from pain, weakness, and fatigue; and from sequelae of surgical procedures and drugs. More often, sexual problems are a result of the interplay of multiple causes that can include intrapsychic, interpersonal, and sociocultural factors. This chapter focuses on sexuality and sexual functioning and discusses nursing care for persons experiencing sexual dysfunction.

KEYCONCEPT Sexuality is a life force that encompasses all that is male or female and how these characteristics relate to all that is human.

SEXUAL DEVELOPMENT

All of us are sexual beings, whether we are or are not sexually active. Sex is what we are, not what we do—the sum total of all of our biologic and experiential influences. **Sexual maturation** encompasses four areas: **biosexual identity**, **gender identity**, **sex role identity**, and **sexual orientation**. Although bisexual identity refers to the anatomic and physiologic states of being male or female, gender identity refers to an individual's identification with maleness/masculinity, femaleness/femininity, neither or both, and it does not

always correspond with sex or biology. The innermost concept of self as male or female, neither nor both can be different than physical state.

Sex role identity (or gender role) is the outward expression of gender, including behaviors, feelings, and attitudes. Gender identity is a component of gender that describes a person's psychological sense of their gender. Gender is a set of social, cultural, psychological, and/or emotional traits or norms, often influenced by societal expectations, that classify an individual along a spectrum of man, woman, neither nor both. Cisgender is a term used to describe a gender identity that aligns with the same sex that was assigned at birth. Non-binary gender (e.g., genderqueer, gender-nonconforming, gender neutral, agender, gender-fluid) may or may not correspond to a person's sex assigned at birth, presumed gender based on sex assignments, or primary or secondary sex characteristics (Amherst College Resource Center, 2020). Individuals may identify as lesbian, gay, bisexual, transgender, and questioning or queer (LGBTQ) or as having two or more genders and move between genders, or having no gender (Amherst College Resource Center, 2020).

Other gender identities are also recognized. Intersexual is a term used in which a person's sexual or reproductive anatomy does not fit the definition of male or female. Asexual is an identity term used for a person with little or no sexual attraction. Pansexual or pan refers to a person who is sexually attracted to people of all and/or many gender identities (Amherst College Resource Center, 2020). An in-depth discussion of gender identity is beyond the scope of this chapter. LGBTQ will be used in this chapter to describe multiple gender identities.

Sexual orientation is part of individual identity that refers to the physical and emotional attraction to another person. Sexual orientation is determined early in development because of the influence of genetic factors and the interactions between sex hormones and the developing brain. There is no evidence that interventions can change sexual orientation (Grabowska, 2017; Roselli, 2018; SAMHSA, 2015).

Genes and Determination of Sex

As a result of the sex-determining genes on the Y chromosome, testosterone is present in male fetuses and, by weeks 6 to 12, is responsible for the formation of the penis, prostate, and scrotum. The formation of ovaries in female fetuses depends on the absence of this male hormone. After the male sex organs are

formed, testosterone levels temporarily rise, causing a permanent sexual organization of the brain that is different than that of females. Testosterone is also elevated during the first 3 months after birth, causing the brain's structures and circuits to be fixed for the rest of a male's life.

These structural differences are thought to be the basis of sex differences that are reflected in behavior from birth. For example, female newborns are more likely to watch human faces; male infants look more at mobiles. During puberty, rising hormones stimulate these structures and circuits that were set up many years earlier to further respond in feminine or masculine directions. Since the sexual differentiation of the genitals takes place earlier (during the first 2 months of pregnancy) than the sexual differentiation of the brain (second half of pregnancy), these two processes may be influenced differently. In such cases, individuals with male sexual organs may experience their identity as female (Eid & Biason-Lauber, 2016; Ristori, et al., 2020).

Sexual Behaviors in Children and Adolescents

In infants, sexual behaviors are rare with the exception of hand-to-genital contact. As children become more aware of their body parts and the physical sensations deriving from their genitals, they become more interested in gender differences. For 2- to 5-year-old children, sexual behaviors are varied and more common than in older children, who are more aware of the social norms of concealing sexual behaviors. For example, young children observe and comment on body differences, demonstrate interest in bathroom habits and urination, and handle their genitals for pleasure and comfort. Their curiosity leads them to want to look at and touch adult bodies and breasts. Mutual genital exploration or urination among children may be seen at this time along with questions about where babies come from.

Age-appropriate solitary sexual behaviors (i.e., touching one's own genitals) are also common. At this early age, these behaviors do not have the sexualized meaning they do in adults. However, if young children are exposed to sexually explicit material (internet, movies, observation of parental sexual activities) or if their parents overreact to age-appropriate behaviors, these activities can take on additional, more adult like, meanings. If preoccupation with the sexual behaviors interferes with the child's ability to grow and function, then the behaviors are problematic. For example, an 8-year-old boy sneaking to the bathroom several times a day to touch his genitals needs help in addressing this behavior.

Sexual behaviors are common and occur in 42% to 73% of children by the time they reach 13 years of age. Generally, the frequency of overt sexual behaviors decrease with age. These behaviors may not be as obvious because as children mature, they become increasingly more covert in their sexual behavior. For example, whereas 6- to 9-year-old boys and girls often touch their genitals at home, stand too close to others, and try to look at persons when they are nude, 10- to 12-year-old children, who are actually more interested in and know more about sex, limit their behavior to looking at nudity in magazines, television, and the internet (Lussier et al., 2018; Miragoli et al., 2017).

Sexual contact with others occurs at a relatively early age in the United States. In 2015 to 2017, 42% of never-married female teenagers aged 15 to 19 and 38% of never-married male teenagers had had sexual intercourse (Martinez & Abma, 2020). A variety of circumstances lead to this sexual activity. Sex may be engaged in because of peer pressure or because friends or social groups condone sex. The need to be convinced of being in love, wanting to feel loved, and fear of rejection all precipitate risk-taking behavior. Depending on the family environment, stresses, and observation of adult sexual activities, children may exhibit more adult sexual behaviors, which may be considered normal for the environment in which they live. For children and adolescents, sexual behavior (usually involving other people) is considered abnormal when it occurs at a greater frequency or at a much earlier age than would be developmentally or culturally expected.

Sexual Behaviors in Adulthood

Sexual activities occur throughout young adulthood and continue through middle and late adulthood. Although the frequency and types of sexual encounters may change, the quality need not change. During the fourth to fifth decades of life, physical changes become more obvious, and so various chronic illnesses, such as hypertension or arthritis, may also develop. As a result of decreased endocrine production, gradual changes to body tissues occur over a 15- to 20-year span. Most physical symptoms arise from vasomotor instability, which can include morning fatigue, vague pains, hot flashes, dizziness, chills, sweating, nervousness, crying spells, decreased sexual potency, and palpitations.

In women, estrogen deficiency during menopause affects the sexual system by causing a gradual thinning of the vaginal mucosa, decreasing the elasticity of muscles and orgasmic force, and increasing breast involution (sagging of breast

tissue). Vaginal lubrication decreases, which may cause dyspareunia (i.e., pain during intercourse), often requiring the use of a water-soluble lubricant or saliva. Although many women experience little or no change in sexual function, both decreased and increased sexual activity and interest are possible. In some women, more time is required to lubricate the vulvovaginal areas and to strengthen clitoral response. Orgasmic capacity and breast response remain fairly constant in appropriately stimulated women.

In men, decreasing testosterone production is responsible for sexual changes. The amount and viability of sperm decrease, erections become less firm, and more direct sexual stimulation is needed. The testicles begin to decrease in elasticity and size, ejaculation time increases, and the force of ejaculation decreases. Spermatogenesis decreases, although viable sperm, capable of impregnation, continue to be produced. Seminal fluid is less voluminous and viscous, and ejaculatory force is decreased. Older men, however, are capable of sustaining erection much longer with decreased ejaculatory demand, potentially benefiting older partners, who may require increased time to reach orgasm. Sexual activity is often perceived as more satisfactory than previously experienced.

Sexual continuity depends to a great extent on good physical health, activity, and regular opportunities for sexual expression and sexual activity in all forms, including masturbation and same-gender behavior. An important influence on sexuality is the attitudes of others, especially attitudes that define specific behaviors as acceptable or unacceptable. This is especially true in later life (Miragoli, et al., 2017; Syme & Cohn, 2016). In healthy adults, sexual function, although modified by the aging process, should remain satisfying despite a differently timed sequence. Frequent sexual activity, whether by coitus, masturbation, or other practices, usually preserves sexual potency.

SEXUAL RESPONSES

Understanding normal sexual responses helps when discussing this very personal, but important, aspect of being human with patients. The following section provides an overview of major concepts and theories related to sexual responses.

Sexual Desire and Arousal

Sexual desire is the ability, interest, or willingness to receive or a motivational state to seek sexual stimulation. In healthy adults, the sex drive is integrated through the central nervous system (CNS) with the autonomic nervous system governing extragenital changes (increased respiration and heart rate). The parasympathetic nervous system largely controls arousal; the sympathetic nervous system largely controls orgasmic discharge. Sexual stimulation brings about a total-body response with dramatic changes seen in the genitals and breasts. Sex hormones, particularly androgen, influence desire in individuals, but less is known about hormonal influence in women. That the higher centers of the brain apparently mediate the lower reflex response centers supports the relationship between cognitive and affective states and sexual function.

During sexual arousal, individuals experience an increased heart rate, blood pressure, respiration, and myotonia.

KEYCONCEPT Sexual arousal is state of mounting sexual tension characterized by vasoconstriction and myotonia.

In men, visual stimulation (i.e., seeing a naked person), fantasies, memories, or physical stimulation of the genitals or other regions (e.g., nipples) causes the parasympathetic system to involuntarily release chemicals that dilate penile arteries. A rapid inflow of arterial blood to the cavernous spaces of corpora cavernosa, facilitated by high levels of intrapenile nitric oxide, causes stiffening and elongation of the penis. With continued stimulation, an emission of semen and an ejaculation occurs. Subcortical structures (hypothalamus, brainstem, spinal cord) and cortical area regulate sexual response. Dopaminergic and serotonergic systems play an important role along with other neurotransmitter systems such as the adrenergic and cholinergic systems (Calabrò, et al., 2019). Testosterone is involved throughout the male sexual response (Rastrelli et al., 2018).

Fantasies, visual stimuli, and physical stimulation are also important for sexual arousal in women, but physical stimulation seems more important for women and visual stimuli for men. The parasympathetic nervous system increases blood flow to the female genitalia, lubricating the vagina and enlarging the breast and clitoris. Estrogens and progestins are involved in female sexual functioning, but androgens are needed by people to maintain arousal.

Theoretical Models of Sexual Response

In 1966, Masters and Johnson described the classic **human sexual response cycle** as consisting of four phases: excitement, plateau, orgasm, and **resolution**. In the excitement phase, erotic feelings lead to a penile erection in men and vaginal lubrication in women. Heart rate and respirations also increase. The plateau phase is represented by sexual pleasure and increased muscle tension, heart rate, and blood flow to the genitals. For men, the orgasmic phase is ejaculation of semen, and for women, it consists of rhythmic contractions of the vaginal muscles. For most men, immediately after orgasm and before resolution, a refractory period occurs when no response is possible. Resolution is the gradual return of the organs and body systems to the nonaroused state. Muscle tension and vasocongestion subside. Breathing and heart rate gradually return to normal rates. Usually, the person feels a sense of relaxation, relief of tension, and satisfaction (Masters & Johnson, 1966, 1970).

After publication of Masters and Johnson's works, Kaplan (1979) proposed a three-phase model of sexual response—desire, excitement, and orgasm—and identified low-desire states as a frequent cause of sexual dysfunction.

This linear approach is criticized as being primarily a biologic model and does not account for nonbiologic experiences such as pleasure, satisfaction, and the context of the relationship. To account for emotional and psychological aspects of sexual response, a circular model focusing on women's sexual responses was developed by Basson (2001). This model proposes that nonsexual interpersonal factors, such as a desire for physical connection and intimacy needs, also motivate women to engage in sexual relations, not only sexual release. Arousal and desire appear to be interchangeable and inseparable from one another, with one reinforcing the other. Subjective feelings of interest may follow the sensation of arousal, and sexual satisfaction may be experienced without orgasm.

These two models—linear and circular—have been debated for years. Both models are supported empirically as being relevant to sexual responses in women. Women report that sexual experiences are at times consistent with the linear and circular models at other times (Ferenidou, et al., 2016; Meston, & Stanton, 2019). There is emerging evidence that the circular model is a better fit for men than the linear model (Connaughton et al., 2016).

Dual-Control Model

Another conceptualization, the dual-control model, focuses on individual variability and proposes that sexual responses involve an interaction between sexual excitement and sexual inhibition (Bancroft et al., 2009). This model assumes that (1) neurobiologic inhibition of sexual response is adaptive and occurs in situations when sexual activity would be a disadvantage, dangerous, or distracting; (2) individuals vary in their propensity for sexual excitation and inhibition; and (3) the context and cultural meaning attributed to the interaction of the individuals are important stimuli for both excitatory and inhibitory processes. Emerging research is showing that the dual-control model is an important framework in understanding how mood influences both subjective and genital sexual in individuals (Hodgson et al., 2016; Turner et al., 2019; Velten et al., 2019).

SEXUAL HEALTH AND WELLNESS

Sexual health is an important aspect of wellness. Sexual health is viewed holistically and positively and is relevant throughout the individual's lifespan. Influenced by gender norms, expectations, and power dynamics, sexual health is understood within specific social, economic, and political contexts (WHO, 2017). Major health threats related to sexuality are human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), hepatitis, and sexually transmitted diseases.

KEYCONCEPT According to the working definition of the World Health Organization (WHO), **sexual health** is “a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence. For sexual health to be attained and maintained, the sexual rights of all persons must be respected, protected and fulfilled” (WHO, 2021).

The mental health of the LGBTQ community is at risk due to discrimination in environments where they live, learn, and work (Vargas et al., 2020). Sexual orientation discrimination is most prevalent in early young adulthood, but it occurs in all ages. Higher risks for alcohol, tobacco, and drug use disorders are

associated with discrimination at the older ages (Evans-Polce, et al., 2019). One of the goals of *Healthy People 2030* is to improve the health, safety, and well-being of LGBTQ individuals (Healthy People 2030, 2021). Nurses are in a unique position to provide gender-affirming care in order to improve the safety and well-being of the LGBTQ communities.

SEXUAL DYSFUNCTIONS AND PROBLEMATIC BEHAVIORS OVERVIEW

Sexual dysfunctions are a group of disorders that are characterized by clinically significant disturbances in the person's ability to respond sexually or to experience sexual pleasure (American Psychiatric Association [APA], 2013). Unhealthy lifestyle and obesity contribute to the development of sexual dysfunctions, due to their negative impact on cardiovascular and metabolic functions. Tobacco smoking, alcohol-use and substance-use disorders, and chronic stress lead to the development of sexual dysfunction (Mollaioli et al., 2020).

The *DSM-5* identifies the following as sexual disorders: delayed ejaculation (DE), erectile disorder, female **orgasmic disorder**, female sexual interest/arousal disorder, genito-pelvic pain/penetration disorder, male hypoactive sexual desire disorder, and **premature ejaculation (PE)**. These dysfunctions can be lifelong or acquired and are categorized as mild, moderate, or severe. An occasional episode is not considered dysfunctional (APA, 2013). In this chapter, female orgasmic disorder is highlighted because it is among the most commonly occurring sexual disorders in women, and **anorgasmia** (the inability to achieve an orgasm) is a frequent medication side effect. Male PE and erectile disorder are emphasized. **Paraphilias** and gender dysphoria are included in the discussion.

KEYCONCEPT Sexual disorders are clinical disturbances caused by the inability to respond sexually or to experience sexual pleasure.

FEMALE ORGASMIC DISORDER

A female orgasm is the least understood of all sexual responses; no universal definition exists (Bancroft & Graham, 2011). Women's descriptions of the orgasmic experience vary from altered consciousness to focused sensation. Many women require clitoral stimulation to reach orgasm and only a small group of women report that they always experience orgasm during intercourse. According to the *DSM-5*, an orgasmic disorder is the inability to reach orgasm by any means, either alone or with a partner and/or markedly reduced intensity of orgasmic sensations for at least 6 months. The inability to experience an orgasm must cause clinically significant distress to be considered a disorder (Wheeler & Guntupalli, 2020).

Diagnostic Criteria

Female orgasmic disorder is characterized by the inability of a woman to experience orgasm or the intensity of the orgasm is markedly reduced at least 75% of the time. If other explanations for the anorgasmia exist, such as substance use, medications, or interpersonal issues, the diagnosis is not used.

Epidemiology and Risk Factors

Debate about the issue of female orgasms is considerable. Estimated prevalence of women's inability to reach orgasm ranges from 9% (in the United States) to 41.2% in Southeast Asia (Bancroft & Graham, 2011).

Poor physical health, mental health, and relationship issues, especially partner difficulties, are the primary risk factors. Age, arousal difficulty, and lubrication difficulty are related to difficulty reaching orgasm (Rowland et al., 2018).

Etiology

In general, any local genital or pelvic pathology, trauma, or surgery that causes pain on intercourse can produce impaired response to sexual stimulation. Spinal cord damage, endocrine disorders, systemic diseases, chronic pain, and general debility can interfere with sexual responses. CNS depressants (e.g., alcohol, barbiturates, narcotics), psychiatric disorders, infections, inflammatory disorders, and pregnancy have all been associated with female orgasmic disorder. Additionally, many medications such as antidepressants,

antihypertensives, and substances (e.g., alcohol) can also affect the sexual response (Thomas et al., 2018).

Consider Alice.

Alice admits that her sexual activity is far less frequent than before her illness. She feels she is no longer attractive or able to fulfill her functions as a wife.

How would you discuss her feelings? What information would you give her to help her look at her situation realistically?

Sexual responses can be inhibited by many different emotional and cognitions, including sexual anxiety and guilt, anger or hostility toward one's partner, indifference toward one's partner, depression, or excessive and intrusive thoughts. Misinformation or lack of information contributes to the inhibition. Cultural expectations also play an important role in the sexual experience. Religious prohibitions and cultural taboos often contribute to a woman's view of her sexuality. If a woman believes that sexual relationships are sinful or "a woman's duty," she is not as likely to explore her own sexual potential.

RECOVERY-ORIENTED CARE FOR PERSONS WITH FEMALE ORGASMIC DISORDER

Teamwork and Collaboration: Working Toward Recovery

The treatment of the person with an orgasmic disorder is best left to clinicians who specialize in this area, but other health care providers can first treat underlying health, mental health, and relationship issues. If the orgasmic problem is not related to any of these areas, she should be referred to a qualified **sex therapist**, who blends education and counseling with psychotherapy and specific sexual exercises. For example, **sensate focus** is a method for partners to learn what each finds arousing and to learn to communicate those preferences. It begins with nongenital contact and gradually includes genital touch and sexual intercourse.

Safety Issues

Low sexual functioning is linked to suicide ideation in female service members and veterans. The low sexual functioning is associated with probable depression and posttraumatic stress disorder. It is important to include a suicide screening when caring for persons with sexual dysfunction (Blais et al., 2018).

EVIDENCE-BASED NURSING CARE FOR A PERSON WITH FEMALE ORGASMIC DISORDER

The psychiatric–mental health nurse has a responsibility to conduct an assessment to determine the presence of any sexual issues or problems. The scope of practice dictates the level of assessment and interventions. The nurse will most likely be seeing the patient for a different problem (e.g., psychiatric problem, acute or chronic physical health problem) and will discover a sexual problem during a health assessment. Patients are sometimes reluctant to discuss sexual problems, especially those who are socially stigmatized (same-sex couples, developmentally disabled people, and old people).

Attention should be paid to special populations' high risk for sexual problems, such as those with mental illnesses or chronic health problems. For older adults, poor physical health and lack of a partner are common barriers to sexual continuity. Other barriers include a lack of privacy or institutionalization. Lack

of knowledge about the impacts of aging or health conditions on sexuality, the normality of continued sexual desire and interest, and the alternatives for sexual gratification may also inhibit sexual activity.

Remember Alice?

Alice believed that she could not have sexual relations with her husband because of her physical problems. Her nurse practitioner provided education and hope.

What information would you reinforce through discussion? What would you say to reinforce her self-esteem and hope for sexual relations?

If sexual dysfunction exists, one of the most important questions is does the individual want to change sexual functioning? Many women may not see a need to pursue therapy even if a sexual problem exists. See [Box 35.1](#).

BOX 35.1 • THERAPEUTIC DIALOGUE: **ASSESSING INTEREST IN SEXUAL ACTIVITY**

INEFFECTIVE APPROACH

Nurse: Alice, are you currently sexually active?

Alice: Once in a while.

Nurse: How would you describe your sexual activity?

Alice: How would you feel if you were in my condition?

Nurse: Well, you could still have sexual relations.

Alice: Sure thing. (Getting irritated)

Nurse: Is there a problem?

Alice: Look, I just don't want to talk about it.

EFFECTIVE APPROACH

Nurse: Alice are you currently sexually active?

Alice: Once in a while.

Nurse: Once in a while?

Alice: Yeah, I really don't feel like it anymore.

Nurse: Oh (Silence)

Alice: My illness is messing up things in the bedroom.

Nurse: How so?

Alice: Well, I just feel so ugly—I have to urinate, my legs are weak.

Nurse: Are you feeling that you want to have sex?

Alice: Sometimes I think about it, but then I remember my illness. My poor husband. He should find someone else.

Nurse: Have you talked with him about your feelings?

Alice: Well, no. He is so patient.

Nurse: There are many women who have similar feelings but are able to begin to enjoy sex again. Is that something that you would like to consider?

Alice: Well, maybe.

Nurse: We can talk more about this. There are resources that can help you and your husband.

Alice: OK, sounds good.

CRITICAL THINKING CHALLENGE

- Compare the course of the first dialogue with the second one. What did the second nurse do differently to elicit information about Alice's feelings and concerns?
- What is problematic about the first dialogue?

Mental Health Nursing Assessment

Current sexual functioning, age, physical health, and the presence of any medical or psychiatric and substance use problems as well as factors that contribute to sexual functioning (e.g., rest, nutrition, personal hygiene) are considered in the sexual assessment ([Box 35.2](#)). A careful medication history is important because so many medications have a negative effect on sexual performance (see [Chapter 12](#)).

Physical Health

Adults with chronic medical illnesses and disabilities who have problems with sensation, movement, body structure, fertility, or energy should be asked about the impact of the medical problems on their sexual function. Diabetes mellitus, heart disease, hormonal imbalances, menopause, and chronic illness such as kidney disease or liver failure are associated with sexual dysfunction in women (Scavello et al., 2019). Sexual activity often changes after a cardiac event because of fear about causing another attack (Mornar et al., 2018). Obesity and pregnancy can both compromise sexual responses (Sarwer et al., 2018).

The woman's sexual knowledge should also be determined. Does she understand the sexual responses, effects of medications, hormonal changes that occur during the woman's life cycle (e.g., adolescence, menstruation, pregnancy, menopause, aging), and the importance of adequate rest and nutrition?

Box 35.2

Medical Conditions and Substances Affecting Sexual Function

- Cardiovascular conditions and vascular conditions

- Endocrine conditions, particularly diabetes mellitus, which cause gradual impotence in half of men and orgasmic dysfunction in one third of women
- Cancer or cancer treatments, such as radiation
- Surgery, particularly hysterectomy, mastectomy, prostatectomy, and bowel surgery
- Arthritis and neuromuscular disorders
- Spinal cord injury
- Head injury
- Cerebrovascular accident (stroke)
- Organic brain syndrome (senile dementia, Alzheimer disease)
- Cerebral palsy
- Asthma, emphysema, and chronic obstructive pulmonary disease
- Chronic renal failure
- Obesity
- Localized genital conditions, such as Sjögren syndrome, balanitis, vulvar ulcers, and psoriasis
- Prescription medications (e.g., antihypertensive drugs, anticholinergic drugs, some antidepressants)
- Chronic use of most recreational drugs
- Chronic alcohol abuse

Self-Concept

The assessment also includes the woman's self-concept and body image and her relationship with her partner. A poor self-concept can prevent a woman from engaging in sexual relationships. Mood states, such as chronic depression and grief, also seriously affect the woman's ability to have an orgasm.

Stress and Coping

The amount of stress and the ability to relax and focus on her sexuality are important assessment data. An unsatisfactory partner relationship may be at the core of the sexual problem.

Social Network and Support Systems

Cultural and family values play an important role in understanding a patient's response to orgasmic dysfunction and should be considered. Lifestyle disruptions, a birth of a child, a move to another city, or a change in financial or social status may coincide with sexual dysfunction. See Nursing Care Plan 35.1.

NURSING CARE PLAN 35.1

The Person with Multiple Sclerosis and Sexual Dysfunction

Alice, a 35-year-old woman, happily married for 11 years and the mother of two children, was diagnosed with multiple sclerosis 3 years ago. She is being seen for a periodic checkup by the nurse practitioner. Some of Alice's present symptoms include transitory visual blurring, weakness of the lower extremities, and mood swings. She also has had problems with urinary leakage and occasional bowel incontinence. She admits, with some obvious discomfort, that she is experiencing sexual difficulty and that her sexual activity is far less frequent than before her illness. Although Alice claims her husband has remained attentive and affectionate, she feels she is no longer attractive or able to fulfill her functions as a wife. She says she wouldn't blame her husband if he found someone else.

Setting: Outpatient Clinic

Baseline Assessment: The physical examination has demonstrated decreased sensation and reflexes in the lower extremities, decreased hand grasp, slight delayed blink response and nystagmus, clear speech pattern, nondistended bladder, normal bowel sounds, BP 124/76, P 76, and R 24. The patient wears an absorbent pad for urinary incontinence with a slight odor of urine. She is weepy and wrings her hands, and her eyes are downcast when discussing marital relationship. Alice's husband accompanied her to the appointment, holding her hand in the waiting room. He offered to be present during the examination or answer questions if desired. Alice has had difficulty experiencing orgasm for 2 years. She has difficulty communicating her needs.

Associated Diagnosis

Medications

Rule out:	female	Interferon- β (Betaseron) 22 mcg three times per
orgasmic	disorder	week Oxybutynin (Ditropan) 5 mg three times a
Multiple sclerosis		day

Priority of Nursing Care; Low Self-esteem and Poor Body Image

Important Characteristics

Associated Considerations

Feels unattractive,	can't fulfill	States she often feels tired and weak.
---------------------	---------------	--

matrimonial roles, would understand husband finding another woman. “How would you feel if you had an ‘accident’ right before you were supposed to make love?” States husband has remained attentive and considerate but believes it’s because he feels pity. States she has moods, “... really feeling sorry for myself. I suppose ... I’m depressed ... frustrated ... MS affects you that way.”

Outcomes

Initial

Alice and her husband will identify three barriers and three enhancers to effective communication regarding their sexual needs and problems.

Discharge

Alice will adapt to limitations and regain a positive body image. Alice and her husband will experience comfortable and satisfactory sexual expression.

Interventions

Interventions

Rationale

Ongoing Assessment

Lack of Knowledge

Educate Alice and family; provide written materials; encourage questions.	Patients and families need factual information on the trajectory, treatment, and impact of multiple sclerosis.	Alice and her husband correctly explain the emotional aspects and pathophysiology of multiple sclerosis.
---	--	--

Communication

Demonstrate empathy for Alice's difficulty in communicating sexual needs. Talking about sex makes some people embarrassed. Alice and her husband correctly identify factors that promote or impede their communication.

Explain common reasons for experiencing difficulty when discussing sexual issues. Individuals may not know how to phrase what they mean. They may be afraid of insulting their partner or have a religious or cultural taboo. The couple increases comfort in discussing sexual needs.

Emphasize the importance of being able to tell each other what is personally satisfying. Clear communication is more successful than "telepathy." Alice is able to identify her need for more time and foreplay.

Help Alice establish effective communication patterns by using role play or teaching assertive communication skills (e.g., beginning statements with "I really like it when you ..."). Becoming assertive often requires changing male/aggressive and female/passive learned behavior patterns. Use of a fictional situation that can be role-played and analyzed is an instructive nonthreatening model for learning new behaviors. Alice and her husband report more open communication, which allows more sharing of true feelings and fears.

Encourage the establishment of a consistent, mutually agreeable, relaxed time to talk. Communication is easier when it is planned and viewed as a value. Alice and her husband report that communication is improved by allotting a half hour for "together time" each evening.

Encourage the use of support or self-help groups.	Communication can be enhanced through sharing thoughts, feelings, and experiences with others.	Has contacted Multiple Sclerosis Society.
---	--	---

Describe sexual concerns commonly identified by partners.	Partner may feel guilty about sexual desire when mate is ill; fear of harming, increasing discomfort, or overburdening mate; difficulty when mate assumes caretaking and lover role, often helped by use of a home health aide.	The couple is beginning to address their issues; express difficulty in adapting to the current changes of the disease; express fear of complete loss of function in all aspects of function, not just sexuality.
---	---	--

Body Image Disturbance

Related to illness and change in function	Common sequela of chronic illness.	Alice is able to express her thoughts and feelings about the effects of the disease.
---	------------------------------------	--

Help Alice confront reality but identify positive aspects of her personality.	Allows Alice to focus on health function and inner being.	Sees herself as a good mother and wife.
---	---	---

Encourage Alice to maintain good hygiene, dress attractively, use grooming aids such as perfume, and treat herself to manicures.	Optimizing appearance is a mood enhancer.	Alice states she is having a friend take her to hairdresser every other week; bought a new outfit through a catalogue.
--	---	--

Fatigue and Weakness

Identify optimal time	Decreases stress; increases	Reports using time when
-----------------------	-----------------------------	-------------------------

for sexual relaxation. interaction.	children are with grandparents for intimacy.
--	--

Do not eat or drink before activity.	Decreases expenditure of energy and potential for incontinence.	Able to cite correct rationale for food and fluid limitations.
--------------------------------------	---	--

Teach use of side lying or rear entry position during intercourse.	Decreases energy expenditure of Alice.	Reports ability to use these positions.
--	--	---

Use pillows to support weakened limbs.	Assists positioning when there is muscle weakness.	Reports increased satisfaction in sexual activity when pillows are used for positioning.
--	--	--

Inform Alice of side effects of sexual response medications being taken.	Some drugs cause impaired response and fatigue.	Not applicable at this time.
--	---	------------------------------

Impaired Mobility

Teach active or passive range-of-motion exercises.	Helps to prevent contractures.	Has been evaluated by physical therapist; reports range of motion exercises done twice daily.
--	--------------------------------	---

Consider use of a waterbed.	Assists with movement.
-----------------------------	------------------------

Teach possibility and treatment of contractures or adductor spasms.	Antispasmodics may be needed and are effective when taken 10 to 15 min before sexual activity.	Not applicable at this time.
---	--	------------------------------

Bladder Incontinence

CLINICAL JUDGMENT

Low self-esteem and depression are nursing care priorities for a woman with a sexual disorder. The nurse should determine the significance of this disorder to the person. For some women, this problem may not be a major concern; for others, it may represent loss of femininity.

MENTAL HEALTH NURSING INTERVENTIONS

Establishing Mental Health and Wellness Goals

Sexual problems impact all aspects of health and wellness. The nurse should help a person examine current sexual needs. The nurse can help the person identify ways to enhance sexual health. If there is a sexual problem, the nurse and patient can collaborate on establishing realistic goals. For example, encouraging patient to discuss sexual needs with partner is a beginning step.

Physical Care and Wellness Challenges

Wellness activities are especially challenging because of the importance of sexual health to a person's well-being. Co-occurring illnesses may interfere with sexual functioning. Feeling unattractive or stigmatized can compromise the willingness to discuss sexual needs. Wellness strategies can support sexual health (see [Box 35.3](#)).

Box 35.3

Wellness Challenges

- Feeling positive about sexuality and sexual health
 - Strategies: Discuss the importance of sexual health to wellness
- Seeking pleasant environments that support sexual activities
 - Strategies: Discuss realistic environmental changes that are conducive to sexual activity.
- Recognizing the need for physical activity, healthy foods, and sleep

- Strategies: Encourage regular physical activity, discuss healthy diets, encourage establishing healthy sleep hygiene routines
- Developing a sense of connection, belong, and a support system
- Strategies: Seek positive relationships and reduce number of unpleasant interactions.

Psychosocial Interventions

Nursing interventions include providing counseling, sex education, problem-solving opportunities, or referrals. Several health care practices are also known to promote sexual health such as getting adequate rest, maintaining optimal nutrition, and exercising regularly. Explaining the dynamics of sexual responses is another important nursing action. Individuals who report difficulties with sexual response often benefit from factual information and helpful suggestions and do not need sex therapy. However, when long-standing or highly complex problems emerge in the assessment, it is better to refer the individual or couple to a formally trained, certified, sex therapist. Nurses should be aware that certain processes, techniques, and adaptive devices can improve sexual functioning.

Psychoeducation

Unless the nurse has had additional preparation in sexual counseling, simply providing factual information and helping patients identify issues related to sexual problems and develop problem-solving skills are the primary psychosocial interventions. Patients often benefit from learning how to communicate their sexual needs better in such areas as type of stimulation desired, positioning, and the amount of time required for maximum sexual pleasure. Resource materials and referral sources can be recommended. [Box 35.4](#) outlines topics for patient education.

Box 35.4

Female Orgasmic Disorder

When caring for the patient with female orgasmic disorder, be sure to include the following topics in your

teaching plan for the patient and partner:

- Possible etiologic factors
- Anxiety reduction techniques
- Communication skills
- Impact of medication on orgasm

Support groups

Women with orgasmic dysfunction can also benefit from a support group that includes women with similar problems. Group modalities are useful in helping patients decrease their embarrassment and uneasiness about sexual topics and increase their knowledge. Partner support is critical and should be encouraged throughout treatment.

Evaluation and Treatment Outcomes

Outcomes related to improved sexual functioning are developed with the patient and may vary from acquiring knowledge to increasing communication with her partner and to deciding about a referral for specialized treatment.

Integration with Primary Care

Sexual disorders are treated by specialists, but often the patient's initial concern is shared with a nurse. It is important that mental and health problems are treated from a holistic perspective. Mental health and primary health clinicians should be monitoring the sexual health of the patient and provide appropriate, evidence-based interventions.

EJACULATORY DYSFUNCTIONS

Ejaculatory dysfunction is one of the most common male sexual disorders and

ranges from PE, inability to control ejaculation before or shortly after penetration to DE, delay or absence of ejaculation. These dysfunctions cause negative personal consequences, clinical distress, frustration, and the avoidance of sexual intimacy (Stephenson et al., 2018). The dysfunction needs to be present for 6 months to be diagnosed as a sexual dysfunction and is not diagnosed in a man whose difficulty is caused by drug or alcohol abuse. In those cases, a substance abuse diagnosis is made, with the sexual disorder generally resolving when the substance abuse is treated (APA, 2013).

Epidemiology

Based on patient self-report, PE is viewed as the most common male sexual dysfunction, with prevalence rates of up to 30% of men with an ED. It is estimated that about 27% of men seeking treatment report PE as a problem. Most men with PE, however, do not seek treatment (Rastrelli, et al., 2019).

Etiology

The etiology of PE is unknown with few data to support suggested biologic or psychological theories such as anxiety, penile hypersensitivity, and serotonin receptor dysfunction. Age does not seem to be an etiologic factor or a risk (El-Hamd et al., 2019).

RECOVERY-ORIENTED CARE FOR PERSONS WITH EJACULATORY DYSFUNCTIONS

Teamwork and Collaboration: Working toward Recovery

The treatment of PE involves medication and behavioral strategies. Men with PE are usually treated by specialists. Nurses are instrumental in teaching patients about the disorder and potential treatments and facilitating decision-making about seeking treatment.

BOX 35.5

Premature Ejaculation

When caring for the patient with PE, be sure to include the following topics in your teaching plan for the patient and partner:

- Possible etiologic factors
- Pharmacologic agents, if indicated, including drug, dosage, action, frequency, and possible side effects
- Measures to decrease anxiety performance
- Communication skills
- Sexual counseling
- Sensate focus
- Sex therapy

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH EJACULATORY DYSFUNCTIONS

The problem of PE may become apparent during a health history that includes specific sexual data. Patients need assurance that many men have similar problems and that treatment is possible ([Box 35.5](#)). Patients can be referred to specialists for behavioral strategies. Younger men may find that masturbation before anticipation of sexual intercourse may help.

Integration with Primary Care

Treatment of PE should be coordinated within the context of primary care. Since medications and medical illness can impact sexual functioning, it is important that one provider coordinates care. There is emerging evidence that alternative treatments, such as acupuncture, may be helpful (Dai et al., 2019).

ERECTILE DYSFUNCTION

Erectile dysfunction (ED) refers to the inability of a man to achieve or maintain an erection sufficient for satisfactory completion of the sexual activity.

Diagnostic Criteria

Although most men experience an occasional lack of erection, intervention is required when there is consistent (more than 6 months) erectile inefficiency during masturbation, intercourse, or on awakening (APA, 2013).

Epidemiology

Estimates of ED vary 5% to 20% of men. ED may occur at any age, although incidence increases with aging. Men with diabetes mellitus, cardiovascular disease, or chronic renal failure also have a higher incidence of ED. For those undergoing treatment for prostate cancer, there is a high probability of ED (Vernooij, et al, 2020). ED increases with age with and comorbidities such as diabetes, cardiovascular disease, depression, anxiety, obesity, metabolic syndrome, smoking, and substance use. Single men are more likely to experience ED than those with stable partners (Colson, et al., 2018). Although less common in younger men, ED still affects 5% to 10% of men below the age of 40. Findings from these studies show that ED impacts significantly on mood state, interpersonal functioning, and overall quality of life (Nguyen et al., 2017).

Etiology

Biologic Theories

Common biologic causes of ED include genital trauma, vascular insufficiency, renal disease, hormonal deficiencies, Parkinson disease, diabetes mellitus, multiple sclerosis, surgical procedures, use of antihypertensive and antidepressant drugs, and heavy cigarette smoking. Long-term alcohol or

cocaine consumption can affect the erectile response. It is also more common with the aging process (Mollaioli, et al., 2020).

Many men with mental disorders attribute their ED to their psychiatric medication. Consequently, these individuals stop taking their medications. Within a few weeks to months, they have a psychiatric relapse.

Psychological Theories

ED may also have a psychogenic basis. Numerous psychosocial etiologies have been identified. Fear of failure, relationship stress, poor body image, fear of rejection, partner hostility, guilt, cultural taboos, religious proscriptions, lack of knowledge, and negative attitudes are some of the identified related factors (Balon, 2017; Chen, et al., 2018).

RECOVERY-ORIENTED CARE FOR PERSONS WITH ERECTILE DYSFUNCTION

Teamwork and Collaboration: Working toward Recovery

The treatment of men with ED is usually managed in primary care setting except for those with mental disorders, who may seek treatment within the mental health system. Since the introduction of the phosphodiesterase 5 (PDE5) inhibitors, pharmacologic agents such as sildenafil citrate, tadalafil, and vardenafil, many men choose the convenience of medication. For persons with psychiatric disorders, monitoring medications and their potential interaction is important. However, behavioral interventions have also been shown to be useful.

EVIDENCE-BASED NURSING CARE FOR THE PERSON WITH ERECTILE DYSFUNCTION

Mental Health Nursing Assessment

Some men are not comfortable discussing sexuality and sexual problems. The assessment should be conducted in an atmosphere of trust and understanding. In many cultures, male self-esteem is related to the ability to perform sexually. When a man has problems maintaining an erection, it is embarrassing and demeaning to him. Sensitivity to the patient's feelings should be reflected throughout the assessment.

Many medical problems are reported that compromise male sexual activity and responses. Obesity, smoking, diabetes mellitus, hypertension, hyperlipidemia, cardiovascular disease, and obstructive sleep disorder are a few (Akdemir, et al., 2019). In addition, low testosterone, chronic kidney disease, and some neurologic disorders also associated with male sexual dysfunction (Costa, et al., 2018; Huang, et al., 2019; Zamorano-Leon, et al., 2018.).

Assessment should include a discussion about the impact of sexual dysfunction on the quality of the relationship with the partner. If a mental disorder, such as depression or posttraumatic stress disorder, is present, comparing the timing of the dysfunction with the onset of symptoms and prescribed medication can determine whether the ED is related to the disorder and medication.

CLINICAL JUDGMENT

ED affects men differently, and the priorities of care will depend on its meaning to the patient. Low self-esteem and self-identity are two priorities that should be considered. ED may indicate an undiagnosed medical disorder such as diabetes or a medication side effect. There may be wellness priorities such as diet and exercise modifications that emerge.

MENTAL HEALTH NURSING INTERVENTIONS

Wellness Strategies

Promotion of positive health practices that focus on adequate nutrition, rest, and exercise is important in promoting erectile functioning. Weight loss may improve overall health and enhance the strength of the erection. Regular exercise

is also related to sexual health. Helping the patient develop a better lifestyle is important in promoting sexual functioning. Reducing alcohol consumption can also improve sexual performance.

Medication Interventions

PDE5 inhibitors are the treatment of choice. With sexual stimulation, nitric oxide is released into the nerve terminations and endothelial cell, stimulating the production of cyclic guanosine monophosphate (cGMP), a substance that enables the smooth muscle cells of the corpora cavernosa to relax. The PDE enzymes are involved in the breakdown of cGMP. The PDE inhibitors inactivate PDE5, thereby enabling the buildup of cGMP, sustaining relaxation of the corpora cavernosa.

Approved PDE5 inhibitors include sildenafil citrate (Viagra), vardenafil HCl (Levitra), tadalafil (Cialis), and avanafil (Stendra). These medications enhance the effect of nitric oxide, which is released in the corpora cavernosa during sexual stimulation. These medications are rapidly absorbed, with maximum observed plasma concentrations reached within 30 to 120 minutes of oral dosing in the fasted state. Cialis acts for up to 36 hours. Although these medications are approved for the treatment of ED in men, they have not been shown to be efficacious in sexual arousal disorders in women.

Before the introduction of PDE5 inhibitors, intracavernosal pharmacotherapy was the treatment of choice for ED. A vascular smooth muscle relaxant such as papaverine hydrochloride, phentolamine mesylate, or prostaglandin is directly injected into the corpora cavernosa by the patient or partner. This increases arterial flow of blood into the corpora cavernosa and decreases venous outflow. Neurogenic, rather than vascular, ED appears to respond better. Complications can include excessive bleeding, scarring and priapism, and potential hepatic involvement. Counseling, strict monitoring, and specific teaching are required (Balon, 2019a).

Another treatment is the use of alprostadil (prostaglandin) in microsuppository form inserted into the urethra using a special applicator. The system called MUSE (Medicated Urethral System for Erections) causes a rapid absorption of the medication through the urethral mucosa into the corpus spongiosum. It is particularly useful for men who are unable to inject themselves (Balon, 2019a).

Other Interventions

When erection is determined to be permanently impaired, several options may be considered to facilitate intercourse. An external penile prosthesis can be placed over the flaccid penis, although some find this esthetically displeasing. A pumping device that creates a vacuum can be used for blood entrapment followed by placement of a rubber band at the base of the penis. Surgical techniques for improving vascular sufficiency are also showing promising results.

Psychoeducation

Education is important for the patient with ED. Teaching the patient about positive health practices and treatment options (i.e., mechanical devices, medications, surgical procedures) is usually needed ([Box 35.6](#)). The patient's concern about his partner's satisfaction needs to be explored. Many times, men believe that partner satisfaction is related only to penile penetration and their ability to sustain an erection. Encouraging the patient to talk with his partner about her (or his) sexual needs and other aspects of their sexual experience (physical closeness, kissing, hugging, mutual exploration of their bodies) helps him broaden his understanding of the sexual experience.

BOX 35.6

Male ED

When caring for the patient with male erectile disorder, be sure to include the following topics in your teaching plan for the patient and partner:

- Possible etiologic factors
- Psychopharmacologic agents (e.g., intracavernosal therapy, yohimbine), including drug, action, frequency, administration technique, and possible side effects
- Alternative methods of sexual expression
- Prosthesis use
- Sexual education and counseling

- Communication skills
- Sex therapy

Evaluation and Treatment Outcomes

The primary outcome for ED is improved sexual functioning. Acceptance of change of physical status is an outcome that is difficult to obtain. Improvement in sexual satisfaction may include increasing the ability for erectile functioning. If ED is permanent, exploration of other avenues of sexual expression may indicate a successful outcome. In this disorder, partner satisfaction is usually of prime concern. Improved communication with the man's partner may also be a positive outcome.

FEMALE SEXUAL INTEREST/AROUSAL DISORDER

A female sexual interest/arousal disorder may occur at any age and may cause relationship difficulties and personal stress along with avoidance of sexual activity and impaired communication. Other etiologic factors, such as anxiety, guilt, and history of sexual abuse, and changes in androgen levels during the menstrual cycle, have been shown to affect arousal. Aging also affects sexual arousal because vasocongestion develops more slowly in older women, so vaginal lubrication decreases after menopause; lower estrogen levels at this life stage may affect sexual arousal.

Intervention focuses on treating factors that contribute to the lack of arousal. Flibanserin, a medication designed and studied for premenopausal women with sexual desire disorder, is approved by the US Food and Drug Administration (FDA) generalized hypoactive sexual desire disorder. The primary side effects of the daily pill are dizziness, sleepiness, and fatigue (Sprout Pharmaceuticals, 2021). Cognitive behavioral therapy is recommended for psychosocial issues. For hormonal changes, a referral to a women's health provider is useful (Balon, 2019a).

MALE HYPOACTIVE SEXUAL DESIRE DISORDER

Male hypoactive sexual desire disorder is a recurrent deficiency or absence of sexual fantasies and desire for sexual activity. Individuals with this disorder are not interested in sex, do not or cannot get “turned on,” and require no sexual gratification. Active avoidance of potential sexual relationships may exist. The prevalence is unknown, but it is believed to affect only a small proportion of men. Often, the disorder develops in adulthood after a period of adequate sexual interest and is associated with psychological distress, stressful life events (e.g., childbirth), or relationship difficulties (Balon, 2019a; Parish & Hahn, 2016).

Therapy for psychological issues related to hypoactive sexual desire aims at helping the patient understand the problem and develop strategies to enhance sexual arousal. Treatment approaches may include individual and couples therapy, sex-therapy techniques, clinical hypnosis, cognitive behavioral therapy, guided fantasy exercises, and sexual assertiveness training. If the problem is related to medication, changing to another classification of medication, giving drug holidays, or lowering the dose may help.

GENITO-PELVIC PAIN/PENETRATION DISORDER

Genito-pelvic pain/penetration disorder is characterized by persistent or recurrent difficulties with vaginal penetration during intercourse, marked vulvovaginal or pelvic pain during vaginal intercourse or penetration attempts, or significant fear or anxiety about the vulvovaginal or pelvic pain in anticipation of, during, or as a result of vaginal penetration (APA, 2013).

Dyspareunia is a term used to describe the genital pain associated with sexual intercourse that may be caused by **vaginismus**, which is spastic involuntary constriction of the perineal and outer vaginal muscles fostered by imagined, anticipated, or real attempts at vaginal penetration. This disorder may be related to interpersonal or emotional factors such as sexual dissatisfaction or poor technique leading to inadequate relaxation and lubrication. Biologic etiologies include intact or biperforate hymen, postmenopausal atrophic changes, trauma,

malignancy, intestinal disease, or other pelvic disorders (Balon, 2019a).

PARAPHILIAS

Paraphilias are described as “intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners characterized by recurrent, intense sexual urges, fantasies, or behaviors involving unusual objects, activities, or situations” (APA, 2013, p. 685). These interests cause significant distress to the individual or impair social or occupational functioning. The paraphilias include voyeurism, exhibitionism, frotteurism, sexual masochism, sexual sadism, pedophilia, and fetishism, disorders (APA, 2013).

Paraphilias are rarely diagnosed; the situation is complicated across cultures because acceptability of sexual practices varies across cultures. Although very few studies exist, some assert that comorbid mood disorders are often associated with paraphilia disorders (Balon, 2019b). These disorders often come to the attention of mental health professionals within the context of illegal sexual activity or sexually violent predators. Treatment of paraphilias is rarely sought by the individual; rather, it is a result of the psychosocial or criminal ramifications.

Certain behaviors and fantasies associated with paraphilias are said to begin in childhood and become more elaborate and better defined during adolescence and early adulthood. The disorders are often found to be chronic and lifelong, with the fantasies and behavior finally diminishing with aging. [Table 35.1](#) includes the different categories of paraphilias along with their descriptions.

TABLE 35-1: PARAPHILIAS

Paraphilia Description

Exhibitionism	The behavior involves exposing one’s genitals to strangers, with occasional masturbation. There may be an awareness of the desire to shock the individual or the fantasy that the individual will become sexually aroused on observation of the exposure.
Fetishism	An object such as women’s undergarments or foot apparel is used for sexual arousal. The individual usually masturbates while holding, rubbing, or smelling the item, or it is worn by a partner during sexual activity. Fetishism usually begins in adolescence and continues throughout life.
Frotteurism	Sexually arousing urges, fantasies, and behaviors occur when touching or rubbing one’s

	genitals against the breasts, genitals, or thighs of a nonconsenting person. This paraphilia usually begins in early adolescence or young adulthood and diminishes with age.
Pedophilia	Sexual activity occurs with a child usually 13 yrs of age or younger by an individual at least 16 yrs of age or 5 yrs older than the child. Pedophilic acts include fondling, oral sex, and anal or vaginal intercourse with the penis, fingers, or objects, with varying amounts of force.
Sexual masochism	This behavior involves the act of being humiliated, beaten, bound, or made to suffer. Self-induced masochistic acts include use of electric shock, pin sticking, restraints, and mutilation; partner-induced acts may include bondage, whipping, being urinated or defecated on; and being forced to crawl, bark, or wear diapers. One dangerous form of sexual masochism that may be practiced alone or with a partner is “hypoxophilia.” Oxygen deprivation by means of a noose, plastic bag, chest compression, or drug effect is used during sexual activity to heighten orgasmic sensation. Deaths have occurred as a result of these techniques.
Sexual sadism	Sexual excitement occurs when causing physical or psychological suffering to another individual. Commonly, the individual with sadistic behavior interacts with a masochistic partner. Sadistic behavior includes various forms of physical punishment, use of restraints, rape, burning, stabbing, strangulation, torture, and murder. This is usually a chronic paraphilia that begins as early sexual fantasies and increases in severity over time.
Voyeurism	This behavior involves “peeping,” for the purpose of sexual excitement, at unsuspecting people who are nude, undressing, or engaged in sexual activity. ¹
Other paraphilias	Sexual fantasies, urges, and activities involving animals (zoophilia), corpses (necrophilia), feces (coprophilia), urine (urophilia), body parts (partialism), and obscene telephone calls (telephone scatologia).

GENDER DYSPHORIA

Gender dysphoria is not classified as a sexual dysfunction. *Gender dysphoria* is the term used to describe a person’s discomfort or distress regarding the gender that is assigned by society. These symptoms occur because of the way society labels and responds to gender-diverse people. If society were more open to a spectrum of gender expression, these symptoms might not be present (Yarbrough, 2019).

Wellness Challenges

One of the biggest issues facing the gender-diverse community is lack of access to competent gender-affirming care. Gender-diverse individuals face discrimination and health care disparities within the context of a western history of pathologizing a whole group of people.

RECOVERY-ORIENTED CARE FOR PERSONS WITH GENDER DYSPHORIA

Teamwork and Collaboration: Working toward Recovery

For non-binary individuals with gender dysphoria, moving toward gender affirmation requires support and care from gender-affirming clinicians. Some individuals may decide to align their physical state to their true gender identity. Hormones may be used to feminize (estrogen) or masculinize (testosterone) the body. For those that want to feminize their bodies, a testosterone blocker is usually given along with estrogen. The changes that occur takes months to years. Others may decide on surgical procedures that are increasing in possibility as third-party payers are starting to cover the cost. There is much to learn about gender and its expression (Yarbrough, 2019).

SUMMARY OF KEY POINTS

- Female orgasmic disorder is a common disorder affecting women; ED and PE are the most common disorders affecting men.
- Nursing interventions for people experiencing sexual dysfunction include (but are not limited to) counseling, education, and referral to sex therapists.
- Various medical conditions, psychological states, and medications negatively affect the sexual response cycle. Education about medication side effects and sexual experiences is important in maintaining health.
- Paraphilias are rarely diagnosed, but the prevalence may be higher than usually presented.
- Gender dysphoria occurs when the individual is distressed with assigned sex or gender role.

CRITICAL THINKING CHALLENGES

1. A 36-year-old woman was recently diagnosed with depression and treated with a selective serotonin reuptake inhibitor (an antidepressant). Her depression is improving, but she has not been interested in sexual relations

with her husband. Her lack of sexual interest is beginning to cause problems in her marriage. What could account for the changes in sexual interest?

- 1. A 52-year-old married man who is being successfully treated with lithium carbonate for his bipolar disorder was recently diagnosed with diabetes mellitus. He was told that his diabetes mellitus could be controlled by weight loss and diet. His major worry is that the disease and lithium are causing his impotence. He casually mentions that he is considering stopping the lithium. What issues should the nurse explore with the patient? What actions could the patient begin that would improve his sexual health?
- 2. During a nursing assessment, a young woman reveals that she identifies as a lesbian and that she is currently living with her partner. She has not yet told her parents about her sexual identification and is experiencing some anxiety about sharing this part of her life with her family. Her partner is supportive and encourages the young woman to take her time in telling her family members. Is this patient experiencing symptoms of a gender dysphoria? Explain.

Movie Viewing Guides

Kinsey: (2004). This critically acclaimed, American biographical drama describes the life of Alfred Charles Kinsey, a pioneer in the area of sexology. Professor Kinsey is being interviewed about his sexual history. During the interview, he has flashbacks to his childhood and young adulthood. His father, a minister, denounces modern inventions as leading to sexual sin and is shown as humiliating his young son. Kinsey, a biologist at Indiana University, marries a student in his class. He comes to terms with his own sexual needs and realizes that sexuality is more varied than originally thought. He publishes books on sexual habits and debunks many 1950s-era myths.

VIEWING POINTS: How did Dr. Kinsey's work contribute to normalizing same-sex relationships and premarital sex? Identify the sexual myths that Dr. Kinsey was able to challenge.

movie: Moonlight (2016) This movie depicts three periods—young adolescence, mid-teen, and young adult—in the life of Chiron, a child who was born to a single mother, Paula, who was addicted to crack. Chiron is a shy withdrawn child with a small for his age. He is bullied and experiences discrimination because of his race, poverty, and identity. Chiron has a sexual encounter with a classmate Kevin, who is a part of Chiron’s story throughout the three time periods.

VIEWING POINTS: How did the discrimination that Chiron experience during his childhood impact his development? Speculate on the role of Chiron’s sexual encounters in his gender identify.

Unit VII: Care of Children and Adolescents

36

Mental Health Assessment of Children and Adolescents

Rebecca Luebbert

KEYCONCEPTS

- assortative mating
- comprehensive assessment

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Define the assessment process for children and adolescents.
2. Discuss techniques of data collection used with children and adolescents.
3. Delineate important areas of assessment for children and adolescents.

KEY TERMS

- Attachment
 - Attachment disorganization
 - Developmental delays
 - Egocentrism
 - Maturation
 - Temperament
-

INTRODUCTION

The mental health assessment of children and adolescents is a specialized process that considers their unique problems and responses within the context of their development. Any nurse who cares for a child should be comfortable with conducting a mental health nursing assessment because the emotional and psychological aspects are central to understanding health needs and behaviors.

The assessment of children and adolescents generally follows the same format as for adults (see [Chapter 11](#)), but there are significant differences. Children think in more concrete terms; thus, the nurse needs to ask more specific and fewer open-ended questions than would typically be asked of adults. The nurse should use simple phrasing because children have a narrower vocabulary than do adults. Examples include saying “sad” instead of “depressed” or “nervous” instead of “anxious.” The nurse needs to corroborate information that children offer with more sources (e.g., parents, teachers) than they would for adults. The nurse may want to use artistic and play media (e.g., puppets, family drawings) to engage children and evaluate their perceptions, inner worlds, fine motor skills, and intellectual functions. Children have a less specific sense of time and a less developed memory than do adults. When children are asked about a sequence of events or specific times when events occurred, they may not be able to provide accurate information.

A comprehensive evaluation includes a history, mental status examination, additional testing (e.g., cognitive or neuropsychological), if necessary, records of the child’s school performance and medical–physical history, and information from other agencies that may be providing services (e.g., Department of Child and Family services [DCF], juvenile court). The nurse may use various

assessment tools, including the Child Attention Profile (CAP) and the Devereux Childhood Assessment (DECA), the Behavior Assessment System for Children (BASC), the Child Behavior Checklist (CBCL), or the Children's Depression Inventory (CDI).

NCLEXNOTE Whenever assessing children or adolescents, developmental level will frame the assessment and implementation of the management plan.

TECHNIQUES FOR DATA COLLECTION: THE CLINICAL INTERVIEW

The clinical interview is the primary assessment tool used in child and adolescent psychiatry. A unique set of skills is necessary for interviewing children and adolescents. How the nurse obtains mental health information depends on the developmental level of each child, specifically considering the child's language, cognitive, social, and emotional skills. For example, the nurse should simplify questions for young children or children with developmental delays so they can understand and respond appropriately.

The assessment interview may be the initial contact between the child and parent or guardian and the nurse. The first step is to establish a therapeutic alliance with both the child and parent, and the second is to assess the interactions between the child and parent.

Establishment of a Therapeutic Alliance

The nurse can establish rapport by greeting the child or adolescent in a friendly, polite, open manner and putting them at ease. Speaking clearly and at a normal volume and using friendly, reassuring tones are essential measures. The nurse can establish a treatment alliance by recognizing the child's individuality and showing respect and concern for them. The nurse should demonstrate sensitivity, objectivity, and confidentiality. The child will be more forthcoming if they feel that the nurse is listening carefully and is interested in what they have to say.

Child and Parent Observation

Because the child's primary environment is with the parent or guardian, child–parent interactions provide important data about the child–parent attachment and parenting practices. The nurse's observations focus on both the child alone and the child within the family. The nurse can actually make some of these observations while the family is in the waiting area, including:

- How the child and parent talk to each other, including how frequently each initiates conversation
- How the parent disciplines the child
- How attached the parent and child appear
- How the child and parent separate
- If the parent and child play together
- How the child gets the parent's attention and how responsive the parent is to the child's attention-seeking initiatives
- How the parent and child show affection to each other

Separate Child and Parent Interviews

To get an accurate picture of the child, the nurse should interview the child and parent individually because each can provide unique meaningful information. Research has shown that when parent and child are interviewed separately in a structured interview about the child's psychopathology, they rarely agree on the presence of diagnostic criteria, particularly regarding depression and anxiety (Baumgartner et al., 2020; Orchard et al., 2019; Popp et al., 2017). Generally, there is greater child–parent agreement on external symptoms and behaviors than on non-observable symptoms, such as mood, feelings, and emotions (Hemmingsson et al., 2017).

Discussion with the Child

After talking with the parent and child together, the nurse should ask to speak

with the child alone for a while. Young children may fear separating from their parents. The nurse can reassure children by showing them where the waiting area is and telling them that if they get scared, the nurse will accompany them to check on their parents. Introducing a toy or game or allowing the child to hold a transitional object may help. Remember that observing how the child separates from the parent is part of the data needed to complete the assessment.

Adolescents may act indifferent or even hostile when the nurse asks to speak with them alone. Teens tend to be skeptical that adults can really understand their experience, suspicious that they will be blamed for their problems, and fearful that their thoughts and feelings are abnormal. The nurse should convey their genuine interest in wanting to hear the adolescent's perspective. The nurse should be patient with adolescents and say something like, "I can see you're pretty angry about being here. What are you particularly angry about? Perhaps there is some way I can help you." Another useful and reassuring question is, "During the last few minutes, you've been quiet. I'm wondering what you are feeling." Or the nurse may ask, "It can be uncomfortable to tell personal information to someone you don't know. Do you feel this way?" (Frick, Barry, & Kamphaus, 2020).

To begin the initial assessment of a child, the nurse introduces themselves and explains briefly what they will be doing. For children younger than 11 years of age, the nurse should explain that they help worried or upset children by talking, playing, and giving advice to them and their parents. The nurse should then ask about the child's understanding of why they are there. This question often helps to identify children's misperceptions (e.g., believing the nurse is going to give them an injection, thinking they have done something bad) that could create barriers to working with them. When conducting the child interview, the nurse needs to get several releases of information from the child's guardian to obtain the corroborating reports, such as the child's physical assessment from the pediatrician or pediatric nurse practitioner; the school's report about the child's academic and behavioral performance, including the child's report card, behavior at school, peer interactions, and adult interactions; and records of diagnosis and treatment from any previous psychiatric provider.

The nurse must adapt communication to the child's age level ([Box 36.1](#)). The challenge is to avoid using overly complex vocabulary or talking down to children. Young children often express themselves more easily in the context of play than through adult like conversation. For example, a child may reenact a conversation that he had with a sibling or parent using puppets. Children respond

well to third-person conversation prompts, such as “Some kids don’t like being compared with their brothers and sisters,” or “I know a kid who was so sad when he lost his dog that he thought he would never be happy again.”

BOX 36.1

Strategies for Interviewing Children

- Use a simple vocabulary and short sentences tailored to the child’s developmental and cognitive levels.
- Be sure that the child understands the questions and that you do not lead the child to give a particular response. Phrase your questions so the child does not receive any hint that one response is more acceptable than another.
- Select the questions for your interview on an individual basis using judgment and discretion and considering the child’s age and developmental level.
- Be sure that the manner and tone of your voice do not reveal any personal biases.
- Speak slowly and quietly and try to allow the interview to unfold, using the child’s verbalizations and behavior as guides.
- Use simple terms (e.g., “sad” for “depressed”) in exploring affective reactions and ask the child to give examples of how they behave or how other people behave when emotionally aroused.
- Assume an accepting and neutral attitude toward the child’s communications.
- Learn about children’s current interests by looking at Saturday morning television programs, talking with parents, visiting toy stores, looking at children’s books, and visiting day care centers and schools to observe children in their natural habitats.

Early in the interview, the goal is to explain the nurse’s purpose, elicit any concerns the child may have about what is happening, and establish rapport with the child by engaging in unthreatening discussion. Many adults rarely ask children about things that truly interest them but expect children to respond readily to adult conversation. The nurse can establish a high degree of credibility simply by taking note of and asking about things that are obviously important to children (e.g., a sport the child participates in, a rock group displayed on a shirt, a toy a child has brought with her). However, children have an uncanny natural “radar” for phony adult behavior. Attempts to establish rapport work only when the nurse is genuinely interested in the child’s life.

Discussion with the Parents

After meeting alone with the child, the nurse should spend some time alone with the parents and ask for a detailed description of their view of the problem. When alone, parents may feel comfortable discussing their children in depth and sharing frustrations with their behavior. Parents need this opportunity to speak freely without being constrained by concern for the child's feelings. In some cases, it would be detrimental for the child to hear the full force of the parents' complaints and feelings, such as helplessness, anger, or disappointment. Parents need the nurse to allow them to express their feelings without passing judgment. This is the nurse's opportunity to enlist the help of parents as partners in the child's evaluation and treatment. This time is also good for filling in any gaps in the history and clarifying the data obtained from the interview with the child.

Parents need the chance to describe the presenting problem in their own words. The nurse can encourage them by asking general questions, such as, "What brings you here today?" or "How have things been in your family?" The nurse should then reflect their understanding of the problem, showing empathy and respect for both the parent and child. Asking any other family members about their view of the problem is always a good idea to clarify discrepant points of view, obtain additional data, and communicate awareness that different family members experience the same problem in different ways.

Development of Rapport

To reduce anxiety about the evaluation, the nurse must develop rapport with the family members. Establishing rapport can be facilitated by maintaining appropriate eye contact; speaking slowly, clearly, and calmly with friendliness and acceptance; using a warm and expressive tone; reacting to communications from interviewees objectively; showing interest in what the interviewees are saying; and making the interview a joint undertaking (see [Chapter 10](#)). Suggestions for building rapport with children and adolescents are also addressed in each of the developmental sections that follow. The information in [Box 36.2](#) can serve as a guide to asking specific questions during a comprehensive assessment.

Semi-structured Interview with School-Aged Children

Precede the following questions with a preliminary greeting, such as the following: “Hi, I am (your name and title). You must be (child’s name). Come in.”

FOR ALL SCHOOL-AGED CHILDREN

1. Has anyone told you about why you are here today?
2. (If yes) Who?
3. (If yes) What did they tell you?
4. Tell me why *you* think you are here. (If child mentions a problem, explore it in detail.)
5. How old are you?
6. When is your birthday?
7. Your address is ...?
8. And your telephone number is ...?

School

9. Let’s talk about school. What grade are you in?
10. What is your teacher’s name?
11. What grades are you getting?
12. What subjects do you like the best?
13. And what subjects do you like least?
14. What subjects give you the most trouble?
15. And what subjects give you the least trouble?
16. What activities are you in at school?
17. How do you get along with your classmates?
18. How do you get along with your teachers?
19. Tell me how you spend a usual day at school.

Home

20. Now let’s talk about your home. Who lives with you at home?
21. Tell me a little about each of them.
22. What does your father do for work?
23. What does your mother do for work?
24. Tell me what your home is like.
25. Tell me about your room at home.
26. What chores do you do at home?

27. How do you get along with your father?
28. What does he do that you like?
29. What does he do that you don't like?
30. How do you get along with your mother?
31. What does she do that you like?
32. What does she do that you don't like?
33. (When relevant) How do you get along with your brothers and sisters?
34. What do they do that you like?
35. What do they do that you don't like?
36. Who handles the discipline at home?
37. Tell me about how they handle it.

Interests

38. Now let's talk about you. What hobbies and interests do you have?
39. What do you do in the afternoons after school?
40. Tell me what you usually do on Saturdays and Sundays.

Friends

41. Tell me about your friends.
42. What do you like to do with your friends?

Moods and Feelings

43. Everybody feels happy at times. What things make you feel happiest?
44. What are you most likely to get sad about?
45. What do you do when you are sad?
46. Everybody gets angry at times. What things make you angriest?
47. What do you do when you are angry?

Fears and Worries

48. All children get scared sometimes about some things. What things make you feel scared?
49. What do you do when you are scared?
50. Tell me what you worry about.
51. Any other things?

Self-Concerns

52. What do you like best about yourself?
53. Anything else?
54. What do you like least about yourself?
55. Anything else?

56. Tell me about the best thing that ever happened to you.
57. Tell me about the worst thing that ever happened to you.

Somatic Concerns

58. Do you ever get headaches?
59. (If yes) Tell me about them. (How often? What do you usually do?)
60. Do you get stomach aches?
61. (If yes) Tell me about them. (How often? What do you usually do?)
62. Do you get any other kinds of body pains?
63. (If yes) Tell me about them.

Thought Disorder

64. Do you ever hear things that seem funny or usual?
65. (If yes) Tell me about them. (How often? How do you feel about them? What do you usually do?)
66. Do you ever see things that seem funny or unreal?
67. (If yes) Tell me about them. (How often? How do you feel about them? What do you usually do?)

Memories and Fantasy

68. What is the first thing you can remember from the time you were a very little baby?
69. Tell me about your dreams.
70. Which dreams come back again?
71. Who are your favorite television characters?
72. Tell me about them.
73. What animals do you like best?
74. Tell me about these animals.
75. What animals do you like least?
76. Tell me about these animals.
77. What is your happiest memory?
78. What is your saddest memory?
79. If you could change places with anyone in the whole world, who would it be?
80. Tell me about that.
81. If you could go anywhere you wanted to right now, where would you go?
82. Tell me about that.
83. If you could have three wishes, what would they be?
84. What things do you think you might need to take with you if you were to go to the moon and stay there for 6 months?

Aspirations

85. What do you plan on doing when you become an adult?
86. Do you think you will have any problem doing that?
87. If you could do anything you wanted when you become an adult, what would it be?

Concluding Questions

88. Do you have anything else that you would like to tell me about yourself?
89. Do you have any questions that you would like to ask me?

FOR ADOLESCENTS

These questions can be inserted after number 67.

Sexual Relations

1. Do you have any special girlfriend (boyfriend)?
2. (If yes) Tell me about her (him).
3. What kind of sexual concerns do you have?
4. (If present) Tell me about them.

Drug and Alcohol Use

5. Do your parents drink alcohol?
6. (If yes) Tell me about their drinking. (How much, how frequently, and where?)
7. Do your friends drink alcohol?
8. (If yes) Tell me about their drinking.
9. Do you drink alcohol?
10. (If yes) Tell me about your drinking.
11. Do your parents use drugs?
12. (If yes) Tell me about the drugs they use. (How much, how frequently, and for what reasons?)
13. Do your friends use drugs?
14. (If yes) Tell me about the drugs they use.
15. Do you use drugs?
16. (If yes) Tell me about the drugs you use.

KEYCONCEPT A **comprehensive assessment** includes a very detailed, focused interview that elicits all aspects of the responses and health promotion information that provides direction for care.

Preschool-Aged Children

When interviewing preschool-aged children, the nurse should understand that they may have difficulty putting their feelings into words and that their thinking is very concrete. For example, a preschool-aged child might assume that a tall container holds more water than a wide container even if both containers hold the same amount of fluid.

The nurse can achieve rapport with preschool-aged children by joining their world of play. Play is an activity by which children transform an experience from real life into a symbolic, nonliteral representation (Sezici, Ocakci, & Kadioglu, 2017). As a natural form of expression, play encourages verbalizations, promotes manual strength, teaches rules and problem solving, and helps children master control over their environment (Al-Yateem & Rossiter, 2016; Boyle-Toledo, 2019). With children younger than 5 years of age, the nurse may conduct the assessment in a playroom. Useful materials are paper, pencils, crayons, paints, paint brushes, easels, clay, blocks, balls, dolls, doll houses, puppets, animals, dress-up clothes, and a water supply. The nurse must inform preschool-aged children about any rules for the play. For example, the nurse must tell the child that the nurse must ensure safety, so there will be no hitting in the playroom.

When observing the child in a free play setting, the nurse should pay attention to initiation of play, energy level, manipulative actions, tempo, body movements, tone, integration, creativity, products, age appropriateness, and attitudes toward adults. In addition, themes of play, expression of emotions, and temperament are important to observe. The nurse must allow children to direct and initiate these themes. When evaluating a young child's peer relationships through play therapy in a playgroup or school setting, observe play settings and themes, initiation of play, response to peer initiations of play, integration of affect and action during play, resolution of conflicts, responses to suggestions of others during play, and the ability to engage in role taking and role reversals.

The nurse's roles are to be a good listener; use appropriate vocabulary; tolerate a child's anxious, angry, or sad behavior; and use reflective comments about the child's play. Through play, the nurse can assess the child's sensorimotor skills, cognitive style, adaptability, language functioning, emotional and behavioral responsiveness, social level, moral development, coping styles, problem-solving techniques, and approaches to perceiving and interpreting the surrounding world. Lidz (2003) developed a tool that clinicians can use to assess preschoolers' play (Box 36.3). Analyzing children's perceptions of fairy tales can provide clinicians with clues to culture, problems, solutions, and elements of mental functioning (Raufman & Weinberg, 2016).

BOX 36.3

LIDZ Assessment Tool

Child's Name: _____ Birth Date: _____ Age: _____

Assessor: _____ Date of Assessment: _____

Describe typical play style/sequence.

Describe range of levels of play from lowest to highest level with age estimates and within contexts of independent/facilitated, familiar/unfamiliar, single/multiple toys.

Describe language and evidence of self-talk and internalized speech.

Describe interpersonal interactions with assessor and facilitator (if not assessor).

Describe content of any play themes.

What held the child's attention the longest? (For how long?) And what were the child's toy/play preferences?

Describe the child's affective state during play.

Implications of aforementioned for intervention.

Republished with permission of John Wiley & Sons from Lidz, C. S. (2003). *Early childhood assessment* (p. 92). Hoboken, NJ: John Wiley & Sons, Inc.; permission conveyed through Copyright Clearance Center, Inc.

Drawings may be used in conjunction with other assessment strategies, and are especially useful when assessing children who are less able to articulate their thoughts and emotions verbally. Through drawings, children can depict basic emotions such as happiness, sadness, fear, and anger. Social emotions, such as pride, shame, and jealousy, can also be conveyed through drawings (Fig. 36.1). Clinicians including child drawings in their assessments should note verbal, paraverbal, and nonverbal observations during the drawing activity. Assessment of human figure drawings generally include facial expressions, posture, and context included in the drawing (Kotroni, Bonoti, & Mavropoulou, 2019; Stauffer, 2019).

FIGURE 36.1 Me and my mom going for ice cream. Drawing and writing by a 5-year-old girl.

School-Aged Children

Unlike preschool-aged children, school-aged (5–11 years) children can use more constructs, provide longer descriptions and make better inferences of others, and acquire more complete conceptions of various social roles. Children in middle school are more capable of verbal exchange and can tolerate limited periods of

direct questioning (Box 36.4). The nurse can establish rapport with school-aged children by using competitive board games, such as checkers and playing cards. A therapeutic game helpful in assessing the child's perceptions, cognition, and emotions and in establishing rapport between a clinician and child is the thinking–feeling–doing game. In this game, the clinician and child take turns drawing cards that pose hypothetical situations and ask what a person might think, feel, or do in such scenarios. For example, one card might say, “A boy has something on his mind that he is afraid to tell his father. What is he scared to talk about?” Another might read, “A girl heard her parents fighting. What were they fighting about? What was the girl thinking while she listened to her parents?”

Adolescents

Adolescents have an increased command of language concepts and have developed the capacity for abstract and formal operations thinking. Their social world is also more complex. Some early adolescents tend to assume that their subjective experiences are real and congruent with objective reality, which can lead to egocentrism. Egocentrism includes the concepts of the imaginary audience (others are watching them) and the personal fable (they are special and unique and omnipotent) (Rycek et al., 1999). Egocentrism is a preoccupation with one's own appearance, behavior, thoughts, and feelings. For example, a preteen may think that he caused his parents to divorce because he fought with his father the day before the parents announced their decision to separate. Egocentrism is increased when emotions associated with uncertainty increase (Todd et al., 2016). Because teenagers have a heightened sense of self-consciousness, they may be preoccupied during the interview with applying makeup or other self-grooming tasks.

BOX 36.4

Psychiatric-Mental Health Nursing Assessment of Children and Adolescents

1. Identifying information

Name

Sex

Date of birth

Age

Birth order
Grade
Ethnic background
Religious preference
List of others living in household

2. Major reason for seeking help

Description of presenting problems or symptoms
When did the problems (symptoms) start?
Describe both the child's and the parent's perspective.

3. Psychiatric history

Previous mental health contacts (inpatient and outpatient)
Other mental health problems or psychiatric diagnosis (besides those described currently)
Previous medications and compliance
Family history of depression, substance abuse, psychosis, etc., and treatment

4. Current and past health status

Medical problems
Current medications
Surgery and hospitalizations
Allergies
Diet and eating habits
Sleeping habits
Height and weight
Hearing and vision
Menstrual history
Immunizations
If sexually active, birth control method used
Date of last physical examination
Pediatrician or nurse practitioner's name and telephone number

5. Medications

Prescription (dosage, side effects)
Over-the-counter drugs

6. Neurologic history

Right handed, left handed, or ambidextrous
Headaches, dizziness, fainting
Seizures
Unusual movement (tics, tremors)
Hyperactivity
Episodes of weakness or paralysis
Slurred speech, pronunciation problems
Fine motor skills (eating with utensils, using crayon or pencil, fastening buttons and zippers, tying

shoes)

Gross motor skills and coordination (walking, running, hopping)

7. Responses to mental health problems

What makes problems (symptoms) worse or better?

Feelings about those experiences (what helped and did not help)

What interventions have been tried so far?

Major loss or changes in past year

Fears, including punishment

8. Mental status examination

See [Box 36.5](#).

9. Developmental assessment

Mother's pregnancy, delivery

Child's Apgar score

Physical maturation

Psychosocial

Language

Developmental milestones: walking, talking, toileting

10. Attachment, temperament or significant behavior patterns

Attachment

Concentration, distractibility

Eating and sleeping patterns

Ability to adjust to new situations and changes in routine

Usual mood and fluctuations

Excitability

Ability to wait, tendency to interrupt

Responses to discipline

Lying, stealing, fighting, cruelty to animals, fire setting

11. Self-concept

Beliefs about self

Body image

Self-esteem

Personal identity

12. Risk assessment

History of suicidal thoughts, previous attempts

Suicide ideation, plan, lethality of plan, accessibility of plan

History of violent, aggressive behavior

Homicidal ideation

13. Family relationships

Relationship with parents

- Deaths or losses
- Family conflicts (nature and content)
- Disciplinary methods
- Quality of sibling relationship
- Sleeping arrangements
- Who does the child relate to or trust in the family?
- Relationships with extended family

14. School and peer adjustment

- Learning difficulties
- Behavior problems at school
- School attendance
- Relationship with teachers
- Special classes
- Best friend
- Relationships with peers
- Dating
- Drug and alcohol use
- Participation in sports, clubs, other activities
- After-school routine

15. Community resources

- Professionals or agencies working with child or family
- Day care resources

16. Functional status Global Assessment of Functioning Scale (GAF)

17. Stresses and coping behaviors Psychosocial stresses

- Coping behaviors (strengths)

18. Summary of significant data

During early adolescence, cognitive changes include increased self-consciousness, fear of being shamed, and demands for privacy and secrecy. An adolescent's willingness to talk to a nurse will depend partly on their perception of the degree of rapport between them. The nurse's ability to communicate, respect, cooperation, honesty, and genuineness is important. Rejection by the adolescent, even outright hostility, during the first few interactions is common, especially if the teen is having behavior problems at home, at school, or in the community. The nurse should be patient and avoid jumping to conclusions. Hostility or defiance may be a test of how much the teen can trust the nurse, a defense against anxiety, or a transference phenomenon (see [Chapter 7](#)).

Adolescents are likely to be defensive in front of their parents and concerned

with confidentiality. At the start of the interview, the nurse should clearly convey to the adolescent what information will and will not be shared with parents. Adolescents generally prefer a straightforward, candid approach to the interview because they often distrust those in authority. Mentioning to adolescents that they do not have to discuss anything that they are not ready to reveal is also a good idea, so they will feel in control while they gradually build trust.

Mental Health Nursing Assessment of Children and Adolescents

As discussed, the comprehensive assessment of the child or adolescent includes interviews with the child and parents, child alone, and parents alone. After completing these components, the nurse should bring the child and parents back together to summarize their view of their concerns and to ask for feedback regarding whether these perceptions agree with theirs. The nurse must give the family a chance to share additional information and ask questions. Then the nurse should thank them for their willingness to talk and give them some idea of the next steps. Use of an assessment tool is helpful in organizing data for mental health planning and intervention.

When interviewing both a child and parents, directly asking the child as many questions as possible is generally the best way to get accurate, firsthand information and to reinforce interest in the child's viewpoint. Asking the child questions about the history of the current problem, previous psychiatric experiences (both good and bad), family psychiatric history, medical problems, developmental history (to get an idea of what the child has been told), school adjustment, peer relationships, and family functioning is particularly important. If necessary, the nurse can ask some or all of these same questions of the parents to verify the accuracy of the data, attain supplemental information, or both. Keep in mind that developmental research shows moderate to low correlation between parent and child reports of family behavior.

Children's Rating Scales for Psychiatric Disorders

A number of children's rating scales can assist in the assessment of various

psychiatric disorders. The BASC, developed by Reynolds and Kamphouse (1998), is a tool used to measure behaviors and emotions in children aged 2 to 18 years. The scales include a teacher rating scale, a parent rating scale, and a 180-item self-report of personality. The scale evaluates several dimensions, including attitude to school, attitude toward teachers, sensation seeking, atypicality, locus of control, somatization, social stress, anxiety, depression, sense of inadequacy, relations with parents, interpersonal relations, self-esteem, and self-reliance. The CBCL, developed by Achenbach and Edelbrock (1983), is a 113-item self-report tool used to identify forms of psychopathology and competencies that occur in children aged 4 to 16 years. This instrument provides scores on internalizing and externalizing behaviors.

Several scales are useful for diagnosing specific problems in children and adolescents. The CDI, developed by John March (1997), is a 27-item self-rated symptom orientation scale for children aged 7 to 17 years that is useful for diagnosing physical symptoms, harm avoidance, social anxiety, and separation and panic disorder. The pediatric anxiety rating scale (PARS) developed by the Rupp Anxiety Study Group, is a clinician-administered, 50-item semi-structured interview used to assess severity of anxiety in children aged 6 to 17 years (Riddle et al., 2001). The Swanson, Nolan, and Pelham Scale, fourth revision (SNAP_IV), is a 90-item teacher and parent rating scale containing items from the Conners questionnaire for measuring inattention and overactivity (Swanson, 1983); it is useful for diagnosing ADHD (inattentive and impulsive types) and oppositional defiant disorder. The Children's Yale-Brown Obsessive Compulsive Scale, developed by Goodman et al. (1989), is a 19-item scale that can help diagnose childhood obsessive-compulsive disorder in children 6 to 17 years of age.

Safety Issues

The nurse must ask the child about any suicidal or violent thoughts. The best way to assess these areas is to ask straightforward questions, such as, "Have you ever thought about hurting yourself? Have you ever thought about hurting someone else? Have you ever acted on these thoughts? Have you thought about how you would do it? What did you think would happen if you hurt yourself? Have you ever done anything to hurt yourself before?" Contrary to popular belief, even young children attempt suicide, and they are capable of violent acts

toward other children, adults, and animals. When a child shares the intent to commit a suicidal or violent act, the nurse must remind them that they will have to discuss this concern with the parent to keep the child and others safe.

Physical Health and Functioning

Nurses should include a thorough history of psychiatric and medical problems in any comprehensive assessment. A physical assessment is necessary to rule out any medical problems that could be mistaken for psychiatric symptoms (e.g., weight loss resulting from diabetes, not depression; substance-induced psychosis).

Genetic Vulnerability

The line between nature and nurture is not always clear. Characteristics that appear to be inborn may influence parents and teachers to respond differently toward different children, thus creating problems in the family environment. A phenomenon called **assortative mating** may contribute to the genetic transmission of psychiatric disorders.

Research increasingly shows that major psychiatric disorders (e.g., depression, anxiety disorder, schizophrenia, bipolar disorder, substance abuse) run in families. Thus, having a parent or sibling with a psychiatric disorder usually indicates an increased risk for the same or another closely related disorder in a child or adolescent. In addition, many childhood psychiatric disorders, such as autism, intellectual disability, developmental learning disorders, some language disorders (e.g., dyslexia), attention-deficit hyperactivity disorder (ADHD), and Tourette syndrome, appear to be genetically transmitted (Polimanti & Gelernter, 2017; Tsetsos et al., 2016).

KEYCONCEPT **Assortative mating** is the tendency of individuals to select mates who are similar in genetically linked traits such as intelligence and personality style.

Neurologic Examination

A full neurologic evaluation is beyond the scope of practice for a baccalaureate-level or master's-level nurse without specific neuropsychiatric training.

However, a screening of neurologic soft signs can help establish a database that will clarify the need for further neurologic consultation. The nurse should ask the brief neurologic screening questions suggested in [Box 36.4](#) directly of the child and should also note any soft signs of neurologic dysfunction, such as slurred speech, unusual movements (e.g., tics, tremors), hyperactivity, and coordination problems. The nurse can ask young children to hop on one foot, skip, or walk from toe to heel to assess their gross motor coordination and to draw with a crayon or pencil or play pickup sticks or jacks to assess their fine motor coordination.

Medication

Pharmacologic assessment should include prescription and over-the-counter medications. Nurses should ask about any allergies to food, medications, or environmental triggers. Compliance with the prescribed regimen should be assessed. Specifically, the nurse should assess whether the medication is producing the desired effect, the presence of adverse effects, and logistical barriers associated with obtaining or administering the medication (Brinkman, Simon, & Epstein, 2017). Individuals taking medications requiring dosing during school hours may find administration to be disruptive to their day, thus individualized treatment options should be considered (Aston, Wilson, & Terry, 2019).

Substance Use

Substance abuse disorders across the life span account for more deaths, illness, and disabilities than any other preventable health condition. Screening for potential use and abuse of substances is becoming a priority in mental health assessment of adolescents. House (2002) developed an interview protocol that can be useful in identifying substance abuse problems in youth ([Box 36.6](#)). It is important to determine the use of substances, including prescription drugs and polysubstance use. The child and family should be referred to community resources. The *Adolescent Screening, Brief Intervention and Referral for Treatment for Alcohol and other Drug Use (SBIRT) Toolkit for Providers* is a

useful resource (Levy & Shrier, 2015).

Psychological Assessment

Children can usually identify and discuss what improves or worsens their problems. The assessment may be the first time that someone has asked the child to explain their view of the problem. It is also a perfect opportunity to discuss any life changes or losses (e.g., death of grandparents or pets, parental divorce) and fears, especially of punishment.

Mental Status Examination

As discussed in [Chapter 11](#), the mental status examination is an organized systematic approach to assessment of an individual's current psychiatric condition. It is essential in formulating a diagnosis. It can provide initial data that alert the clinician to obtain further cognitive, neurologic, or psychological testing. The mental status examination of children combines observation and direct questioning ([Box 36.5](#)). The nurse should note any areas where the child or adolescent is symptomatic or has difficulty with the task. A mental status examination should be obtained on subsequent visits so improvements or changes in the patient's functioning can be noted.

BOX 36.5

Mental Status Examination

APPEARANCE

Provide a head-to-toe assessment: Describe head shape and size (Down syndrome, fragile X syndrome, Turner syndrome, fetal alcohol syndrome), eyes (clarity, gaze, glasses, eye contact), height, weight, cleanliness, facial expressions, mannerisms, ears, hearing, skin (bruising could indicate physical abuse), gait, posture, nutritional status (possible eating disorder).

Evaluate dress: Is it appropriate for the weather? Does the child wear shirts with logos or groups? Does the child appear older or younger looking? Inquire about symptoms of physical illness.

MOTOR ACTIVITY

Use the following descriptors to assess motor activity: calm, psychomotor retardation, akathisia, agitated, hyperalertness, tics, muscle spasms, nail biting, hyperactivity, anxiety, restlessness, or compulsions.

SELF-CONCEPT

Ask about play, favorite stories, and three wishes. Ask the child to draw a self-portrait, describe best-liked and least-liked qualities. Ask what they imagine doing for an occupation when grown up. Also evaluate planning ability and sense of a future.

BEHAVIOR

Observe for temper tantrums, attention span, separation from family member, self-care activities, dressing, toileting, feeding, oppositionality, compliance, and so on.

SOCIAL INTERACTION

How does the child relate to the examiner? Is the child wary, submissive, attentive, friendly, manipulative, approval seeking, conforming, hostile, or guarded? Assess the child's relationships with the child's parent or guardian, siblings, and friends.

GENERAL INTELLIGENCE

Assess the child's general vocabulary, fund of knowledge, alertness, orientation, concentration, memory, calculations, organization, abstract reasoning creativity, spontaneity, and frustration tolerance. Ask about school, including regular or special education, grades, and grade retention.

FUND OF KNOWLEDGE

Ask child the following: How many legs does a dog have? How many pennies in a nickel? Have child identify body parts, draw a person, name colors, count as high as possible, and inquire about letter identification (younger children).

Inquire about the time. How many states are in the United States? Who was George Washington? How many days are in a week? What are the seasons of the year? (middle schoolers) What does the stomach do? Who is Charles Darwin? (teenagers)

ORIENTATION

Ask questions such as the following: How old are you?

Who is the current president of the United States?

Do you know who was the president before our current president?

What are two major news events in the past month? (older children)

What are the year, seasons, date, day, and month?
Where are we? (country, state, city, clinic)

RECENT MEMORY

Ask the child to repeat a memory phrase; remember three to five objects that you say or show and then recall them in a few minutes. Ask the following: What school do you currently attend? What did you have for breakfast or lunch today?

REMOTE MEMORY

Ask questions such as the following: What did you do last weekend? What was your last birthday like? What is your address and telephone number? Who is your first best friend? How old were you when you learned to ride a bike? What was the name of your kindergarten teacher?

ABSTRACT REASONING AND ANALOGIES

Ask what is meant by a stitch in time saves nine; a rolling stone gathers no moss; a bird in the hand is worth two birds in a tree; too many cooks spoil the broth.

Which object does not belong in this group: fish, tree, rock? Why?

Assess the similarity about objects such as peaches and lemons, oceans and lakes, a pencil and typewriter, a bicycle and a bus.

To evaluate comparative ability complete this sentence: An engine is to an airplane as an oar is to a _____.

ARITHMETIC CALCULATIONS

Provide simple addition and subtraction questions based on the child's age. Ask older children multiplication and division problems. Count backward 20 to 1 for younger children. Ask how many quarters are in \$3.50 or if you buy something that cost \$2.50 and you have \$5, how much change you will receive.

WRITING AND SPELLING ABILITY

Ask a first or second grader to spell *cat*, *hat*, *bad*, *old*, *dog*. Ask a third or fourth grader to spell words such as *clock*, *face*, *house*, or *flower*. Ask older children to write a sentence such as: "The grass is greener on the mountains."

READING

Have the child read a paragraph from an age-appropriate book? Reading begins in first grade. Children should demonstrate basic reading skills by the end of second grade.

GROSS MOTOR SKILLS

Assess level of activity, type of activity, and any unusual gestures or mannerisms and compulsions.

Have the patient walk, jump, hop on one foot, and walk heel to toe, throw a ball, balance and climb stairs.

By age 3 years, a child should walk up stairs with alternating feet, pedal a tricycle, jump in one place, and broad jump.

By age 4 years, a child can balance on one foot for 5 seconds, and catch a bounced ball two of three times.

By age 5 years, a child can do heel-to-toe walking.

By age 6 years, a child should jump, tumble, skip, hop, walk a straight line, skip rope with practice, and ride a bicycle.

By age 7 years, a child should skip and play hopscotch, and run and climb with coordination.

By age 9 years, a child should have highly developed eye-hand coordination.

FINE MOTOR SKILLS

Have the child draw a picture or self-portrait as well as pickup sticks.

Have the child copy a design that you have drawn. Ask the child to draw a circle (age 3 years), an X (age 3 to 4 years), a square (age 5 years), a triangle (age 6 years), a diamond (age 7 years), and connecting diamonds (age 8 years).

At age 3 years, a child should unbutton front buttons, copy a vertical line, copy a circle, and build an eight-block tower.

By age 4 years, a child should copy a cross and button large buttons.

By age 5 years, a child should dress themselves with minimal assistance, color within lines, and draw a three-part human.

By age 6 years, a child should be able to draw a six-part human.

By age 7 years, a child should print well and begin to write script.

By age 8 years, a child should demonstrate mature handwriting skills.

ATTENTION SPAN

Ask the patient to follow a series of short commands. Observe motor activity, attention, concentration, impulsivity, hyperactivity, outbursts, and organization.

Observe the child's ability to stay on task and focus during the course of the interview. Tasks include counting backward by seven, spelling the word "world" backward, and saying the letters of the alphabet backward.

INSIGHT AND JUDGMENT

Ask the child to provide a solution to a hypothetical situation such as what would you do if you found a stamped envelope lying on the ground? What would you do if a policeman stopped you for driving your bike through a red light? What would you do if you saw two children fighting on the school ground? Assess the child's ideas about the current problem and the solutions tried so far. Assess if child can make use of assistance. Evaluate how impaired child is in activities of daily living, including attending school, attending recreational activities, making friends, self-care activities, and so on.

COMPREHENSION

Read a few pages or paragraphs from a short book or newspaper article and ask the child to relate what happened in the story.

MOOD AND FEELINGS

Affect is the child's emotional tone. Evaluate the child's range of emotions, intensity, and appropriateness.

Assess for any mood swings, crying, anxiety, depression, anger, hostility, hyperalertness, lability, or pressured speech. Assess mood by asking how many times a week do you feel sad and how often do you cry? What makes you sad, angry, anxious, and so on? Risk assessment questions include the following: Have you ever felt like hurting yourself or someone else? Do you have a plan to hurt yourself? Have you ever done anything to hurt yourself in the past?

THOUGHT PROCESS AND CONTENT

Were there any recurrent themes?

Observe the child's patterns of thinking for appropriateness of sequence, logic, coherence, and relevance to the topics discussed. Does the child talk about age-appropriate topics; is there any thought blocking, or disturbance in the stream of thinking, repetition of words, circumstantial or tangential thinking, perseverations, preoccupations, obsessive thoughts, actions, or compulsive behaviors, any grandiose reasoning, ideas of reference, or paranoia (feelings of being watched or followed, controlled, manipulated, and ritual or checking routines)?

Evaluate the child's perceptions for hallucinations (false perceptions or false impressions or experiences) and delusions (false beliefs that contradict social reality, such as hears voices, sees images or shadowy figures, smells offensive odors, tastes offensive flavors, feels worms crawling on skin). Assess hallucinations in all five senses: auditory, visual, tactile, gustatory, and

olfactory. Assess for command hallucinations, which tell the patient to do something.

SPEECH AND LANGUAGE

Note any speech impediments and incongruence between verbal and nonverbal communication. Show a pencil and a watch and ask the patient to name them. Have the patient repeat “no ifs, ands, or buts.”

Assess communication skills, including expressive language, vocabulary, and the ability to understand what you are saying (receptive language). Check voice quality, articulation, pronunciation, fluency, rhythm, rate, and ease of expression and volume.

Assess comprehension by giving the child a task. Assess coherence for flight of ideas, loose associations, word salad (meaningless, disconnected word choices), neologisms, clang associations (words that rhyme in a nonsensical way), echolalia (repetition of another person’s words), thought blocking, perseveration, irrelevance, and vagueness. Check for aphasia by listening for an omission or addition of letters, syllables, and made-up words or misuse or transposition of words.

BOX 36.6

Practice Note: An Interview Protocol for Reviewing Chemical Use in Youths

As with other topics, questions about substance use are interactive—the answers given determine to some extent the subsequent questions. However, certain topics and areas should be addressed irrespective of the previous responses. In the following sample questions, those marked with an asterisk should always be asked.

- Now I’d like to ask you about your experience with cigarettes, alcohol, and other drugs.
- When was the last time you smoked tobacco?
- Have you ever smoked? Tell me about that.
- How old were you when you first smoked a cigarette?
- How many cigarettes do you smoke a day now?
- How long have you smoked this much?
- Where do you usually do your smoking?
- Where do you usually get your cigarettes from?

- What kind of problems has smoking caused for you?
- How do your parents feel about your smoking?
- Have you gotten into trouble at school for smoking?
- Have you lost any friends or had problems with friends over smoking?
- What other tobacco products have you used?
- When was the last time you drank any alcohol?
- How much alcohol did you drink? What kinds of alcohol were you drinking? What happened afterward?
- Who was with you the last time you were drinking? What happened?
- How about the time before that? Tell me about that.
- What is the most alcohol you have ever drunk? What happened?
- How do you get alcohol?
- What kinds of problems have drinking caused for you?
- How do your parents feel about your drinking?
- Have you ever gotten into problems at school because of drinking?
- Have you ever gotten into legal problems because of drinking?
- Have you had problems with your friends because of drinking?
- What is the worst thing that has happened while you were drinking?
- How old were you the first time you drank alcohol? When did most of your friends start drinking? How does your drinking compare with other kids in your classes at school or other kids your age?
- How has your drinking changed over the past year?
- When was the last time you used any marijuana?
- How old were you when you first tried marijuana?
- How often have you used marijuana in the past month?
- What's usually going on when you use marijuana?
- What other drugs have you used?
- When was the first time you used _____?
- When was the last time you used _____?
- How many times have you used _____?
- Where did you get the _____? How did you know that's what it was?
- How did _____ affect you?
- What has been the biggest effect you have gotten using _____?
- What has been the worst thing about using _____?
- Have you ever 'huffed' or inhaled something to get high? Tell me about that.
- Have you ever used another person's prescription medications? Tell me about that.
- How many people do you regularly do things with—hang out, party with, talk to?

- How many of your friends smoke tobacco occasionally?
- How many of your friends smoke tobacco regularly?
- How many of your friends drink alcohol occasionally?
- How many of your friends drink alcohol regularly?
- How many of your friends smoke marijuana occasionally?
- How many of your friends smoke marijuana regularly?
- What other drugs do your friends use?
- How has drug use affected your friends?

The first session with children and adolescents: conducting a comprehensive mental health evaluation by House, Alvin E. Reproduced with permission of Guilford via Copyright Clearance Center.

The nurse should note the child's general appearance, including the level of attractiveness. Although it perhaps should not be so, social-psychological research shows that the appearance and attractiveness of both children and adults strongly influence their social relationships (Jacobson, Trivers, & Palestis, 2020). The nurse also should note the following:

- Do they seem to have difficulty focusing on the interview, sitting still, refraining from impulsive behavior, and listening without interrupting? (possible signs of ADHD)
- Does the child seem underactive, lethargic, distant, or hopeless? (possible signs of depression)
- Are there problems with speech patterns, such as rate (overly fast or slow), clarity, and volume, or any speech dysfluencies (e.g., stuttering, halting)?
- Are there possible mood disorders (e.g., depression, mania), language disorders, or psychotic processes?

When assessing thought processes, keep in mind that whereas young children are in the concrete operations stage, middle schoolers can begin to use logic and understand conversations. Adolescents should be able to demonstrate abstract thinking and think hypothetically, although they may appear to be self-conscious and introspective. Assessment of preteens and adolescents should address substance use and sexual activity because responses may provide useful information about high-risk behavior or substance abuse. In addition, the nurse should inquire about any obsessions or compulsions (e.g., worries about germs,

severe handwashing).

Temperament and Behavior

Temperament is a person's characteristic intensity, activity level, threshold of responsiveness, rhythmicity, adaptability, energy expenditure, and mood. According to research findings, temperamental differences can be observed early in life, suggesting that they are at least partly biologically determined, and patterns of temperament can be correlated with emotional and behavioral problems (Van Heel et al., 2020). When looking at the cerebral activity in 9-month-old infants, consistent with early development of externalizing behaviors, electroencephalographic activity increased in response to fear rather than love and comfort (Santesso, Schmidt, & Trainor, 2007).

The classic *New York Longitudinal Study* (Thomas, Chess, & Birch, 1968) identified three main patterns of temperament seen in infancy that often extend into childhood and later life:

- *Easy temperament* characterized by a positive mood, regular patterns of eating and sleeping, positive approach to new situations, and low emotional intensity
- *Difficult temperament* characterized by irregular sleep and eating patterns, negative response to new stimuli, slow adaptation, negative mood, and high emotional intensity
- *Slow-to-warm-up temperament* characterized by a negative, mildly emotional response to new situations that is expressed with intensity and initially slow adaptation but evolves into a positive response

On the positive side, an easy temperament can serve as a protective factor against the development of psychopathology. Children with easy temperaments can adapt to change without intense emotional reactions. Difficult temperament places children at high risk for adjustment problems, such as with adjustment to school or bonding with parents.

Temperament has a major influence on the chances that a child may experience psychological problems; however, temperament is not unchangeable,

and environmental influences can change or modify a child's emotional style (Miller et al., 2020). Children who respond positively to the environment continue in this pattern. Children who have other temperaments may develop positive temperaments at a later time.

The concept of temperament provides an excellent example of the interaction between biologic–genetic and environmental factors in producing child psychopathology. Although a child may be born with a particular temperament, longitudinal studies show that the temperament can be influenced by other factors such as parental control (Elizur, Somech, & Vinokur, 2017). However, difficult children, in particular, may evoke negative reactions in parents and teachers, thereby creating environments that exacerbate their biologically based behavior problems, initiating a vicious cycle. Difficult temperament that persists beyond 3 years of age is correlated with the development of child psychopathology (Kushner, 2015). The nurse can help parents accept biologically based differences in their children and learn to adapt their behavior to each child's needs.

Developmental Assessment

Children respond to life's stresses in different ways and in accord with their developmental level. Knowing the difference between normal child development and psychopathology is crucial in helping parents view their children's behavior realistically and respond appropriately. The key areas for assessment include maturation, psychosocial development, and language.

Maturation

Healthy development of the brain and nervous system during childhood and adolescence provides the foundation for successful functioning throughout life. Such development, called maturation, unfolds through sequential and orderly growth processes. These processes are biologically and genetically based but depend on constant interactions with a stimulating and nurturing environment. If trauma or neglect impairs the process of normal biologic maturation, developmental delays and disorders that may not be fully reversible can result. For example, babies born with fetal alcohol syndrome experience permanent brain damage, often resulting in intellectual disability, learning disabilities,

behavior disorders, and delays in language (Patel et al., 2020). A pregnant woman's use of crack cocaine deprives the fetus of nutrients and oxygen, leading to developmental delays, speech and language problems, deformities, and behavior disorders (e.g., impulsivity, withdrawal, hyperactivity). The nurse can assess for developmental delays by asking questions from specific sections of the mental status examination:

- *Intellectual functioning:* Evaluate the child's creativity, spontaneity, ability to count money and tell time, academic performance, memory, attention, frustration tolerance, and organization.
- *Gross motor functioning:* Ask the child to hop on one foot, throw a ball, walk up and down the hall, and run.
- *Fine motor functioning:* Ask the child to draw a picture or pick up sticks.
- *Cognition:* The nurse can evaluate the child's general level of cognition by assessing the child's vocabulary, level of comprehension, drawing ability, and responsiveness to questions. Testing, such as the Wechsler Intelligence Scale for Children (WISC-III), provides measures of intelligence quotient (IQ). A psychologist usually performs such tests. The nurse can request cognitive testing if they have concerns about a child's developmental delays or learning disabilities.
- *Thinking and perception:* Evaluate level of consciousness; orientation to date, time, and person; thought content; thought process; and judgment.
- *Social interactions and play:* Assess the child's organization, creativity, drawing capacity, and ability to follow rules. Children experiencing developmental delays may remain engaged solely in parallel play instead of moving to reciprocal play. They may consistently play with toys designed for younger children, draw crude body pictures, or display receptive or expressive language problems.

Psychosocial Development

Assessment of psychosocial development is very important for children with

mental health problems. Various theoretical models are available from which to choose; the most commonly used model is Erikson stages of development. When considering this model, the nurse should examine the child's gender and cultural background for appropriateness. The nurse also may use the Gilligan model (see [Chapter 7](#)).

Language

At birth, infants can emit sounds of all languages. Maturation of language skills begins with babbling, or the utterance of simple, spontaneous sounds. By the end of the first year, children can make one-word statements, usually naming objects or people in the environment. By age 2 years, they should speak in short, telegraphic sentences consisting of a verb and noun (e.g., "want cookie"). Between ages 2 and 4 years, vocabulary and sentence structure develop rapidly. In fact, a preschooler's ability to produce language often surpasses motor development, sometimes causing temporary stuttering when the child's mind literally works faster than their mouth.

Language development depends on the complex interaction of physical maturation of the nerves, development of head and neck musculature, hearing abilities, cognitive abilities, exposure to language, educational stimulation, and emotional well-being. Social needs create a natural inclination toward communication, but children need reinforcement to develop correct pronunciation, vocabulary, and grammar.

Before a diagnosis of a communication disorder (i.e., impairment in language expression, comprehension, or both) can be made, the child must be tested to rule out hearing, visual, or other neurologic problems. Brain damage, especially to the left hemisphere (dominant for language in most individuals), can seriously impair the development of communication abilities in children. Any child who has experienced brain damage from anoxia at birth, congenital trauma, head injury, infection, tumor, or drug exposure should be closely monitored for signs of a communication disorder. Before the age of 5 years, the brain has amazing plasticity, and sometimes other intact areas of the brain can take over functions of damaged areas, especially with immediate speech therapy. Genetically based disorders such as autism cause language delays that are sometimes permanent and severe.

The nurse must recognize normal variations in child development and assess lags in the development of vocabulary and sentence structure during the critical

preschool years. Delays in this area can seriously affect other areas, such as cognitive, educational, and social development. Many children who receive psychiatric treatment have speech and language disorders that are sometimes undetected, either leading to or compounding their emotional problems (Koomar & Michaelson, 2020).

Self-Concept

For young children, eliciting their view of themselves and the world is helpful. One technique is asking them what they would wish for if they had three wishes. Answers can be revealing. Whereas an inability to wish for anything beyond a nice meal or place to live may reflect hopelessness, wishes to conquer the world or put one's teacher in jail may indicate feelings of grandiosity. Another technique is to tell a story and ask the child to make up an ending for it. For example, a baby bird fell out of a nest—what happened to it? The nurse may design stories to elicit particular fears or concerns that may be relevant for the individual child.

Drawings also provide an excellent window into the child's internal world (Fig. 36.2). Asking the child to draw a picture of a person can provide data about the child's self-concept, sexual identity, body image, and developmental level. By age 3 years, children should be able to draw some facial features and limbs, but their drawings may have an "X-ray" quality, in which clothing is transparent and the body can be seen underneath. Older children should produce more sophisticated drawings unless they are resistant to the task. After the child has finished the drawing, the nurse can ask what the person in the drawing is thinking and feeling, using this device to assess the child's mental processes. For example, one adolescent with school phobia drew a person fully dressed, in great detail, but with no feet. When asked about the drawing, he said that the boy could not go anywhere because his mother was afraid to let him leave home.

FIGURE 36.2 Self portrait of a girl, age 5 years.

Other ways to assess children's self-concepts include asking them what they want to do when they grow up, what their best subjects are in school, what things they are really good at, and how well-liked they are at school. Before concluding the individual interview with a child, the nurse should always ask if the child has any other information to share and whether they have any questions.

Stress and Coping Behaviors

Physical, behavioral, and personality predispositions; family; and community environment may affect a child's ability to cope with stressful life events. Stressful experiences for children include the death of a loved person or pet, parental divorce, violence, physical illness (especially chronic illness), mental illness, social isolation, racial discrimination, neglect, and physical and sexual abuse.

The number of stressful events that a child experiences (including trauma), the supports that the child has in place, and the child's developmental stage may also influence their ability to cope with stressors. Children who appear to have experienced early life stress may manifest posttraumatic stress symptoms (Lee & Oswald, 2018). It is important to consider a stressful situation within the context of each child's support system and developmental stage.

Attachment

Attachment is the emotional bond between an infant and their parental figure. Studies of attachment show that the quality of the emotional bond between the infant and parental figures provides the groundwork for future relationships. The need to touch and be close to a parental figure appears biologically driven and has been demonstrated in classic studies of monkeys who bonded with a terry-cloth surrogate mother (Harlow, Harlow, & Suomi, 1971). A secure attachment is based on the caretaker's consistent, appropriate response to the infant's attachment behaviors (e.g., crying, clinging, calling, following, protesting). Children who have developed a secure attachment protest when their parents

leave them (beginning at about age 6 to 8 months), seek comfort from their parents in unfamiliar situations, and playfully explore the environment in the parent's presence. Mother–child separation for 1 week or longer within the first 2 years of life has been shown to be related to higher levels of child negativity (at age 3 years) and aggression (at ages 3 to 5 years) (Martin et al., 2011).

Secure attachments in early childhood produce cooperative, harmonious parent–child relationships in which the child is responsive to the parents' socialization efforts and likely to adopt the parents' viewpoints, values, and goals. Securely attached young children also socialize competently, are popular with well-acquainted peers during the preschool years, and have warm relationships with important adults in their lives. Securely attached children see themselves and others constructively and have relatively sophisticated emotional and moral understanding (Behrendt et al., 2019).

Although the importance of the parent's responsiveness is unquestionable in determining the development of a secure attachment, the process works both ways. Some babies seem to encourage attachment naturally with their parents by responding positively to holding, cuddling, and comforting behaviors. Others, such as those with developmental delays or autistic disorders, may respond less readily and even reject parental attempts at bonding.

Attachment Theories

Bowlby's early studies (1969) of maternal deprivation formed the initial framework for attachment theory based on the notion that the infant tends to bond to one primary parental figure, usually the mother. Although this pattern is common, recent studies show that children make multiple attachments to parents and other caregivers, but high-quality, intense bonds remain essential for healthy development. Contemporary nursing theories, such as Barnard parent–child interaction model, have stressed the importance of the interaction between the child's spontaneous behavior and biologic rhythms and the mother's ability to respond to cues that signal distress (Barnard & Brazelton, 1990). Whereas a positive attachment is likely to result in a happy child with a sense of self-worth, insecure attachment is associated with depressive symptoms (Spruit et al., 2020). Although most attachment research has been done with mothers, the father's role in child development has become better understood through research done during the past two decades. Fathers' emotional support tends to enhance the quality of mother–child relationships and facilitates positive adjustment by

children. When fathers are unsupportive and marital conflict is high, children suffer (Silva & Calheiros, 2018).

Fathers play an important role in children's play, which affects the quality of the child's attachment. Playful interactions involving emotional arousal provide an especially good opportunity to learn how to get along with peers by reinforcing turn taking, affect regulation, and acceptable ways of competing. Fathers are important as role models who assist in their sons' identity formation and serve as models of gender-appropriate behavior, particularly around aggressive behavior. Evidence supports the importance of including the father in the mental health assessment of his child (Verschueren, 2020).

Disrupted Attachments

Disrupted attachments may result from deficits in infant attachment behaviors, lack of responsiveness by caregivers to the child's cues, or both and may lead to reactive attachment disorder, feeding disorder, failure to thrive, or anxiety disorder. A reactive attachment disorder is a state in which a child younger than 5 years of age fails to initiate or respond appropriately to social interaction and the caregiver subsequently disregards the child's physical and emotional needs. Attachment disorder behaviors are related to attention and behavior problems (Bizzi & Pace, 2020).

Attachment disorganization is a consequence of extreme insecurity that results from feared or actual separation from the attached figure. Disorganized infants appear to be unable to maintain the strategic adjustments in attachment behavior represented by organized avoidant or ambivalent attachment strategies, with the result that both behavioral and physiologic dysregulation occurs. Preschoolers with disorganized attachment manifest behaviors of fear, contradictory behavior, or disorientation or disassociation in the caregivers' presence. Attachment disorganization appears moderately stable over time and has been associated with distinct, apparently genetically based, physiologic profiles (Golds, de Kruiff, & MacBeth, 2020).

Social Network

Family Relationship

Children depend on adults to create a safe, nurturing, and appropriate environment to support their development. The nurse should assess the quality of the home, including living space, sleeping arrangements, safety, cleanliness, and child care arrangements, either through a home visit or by discussing these issues with the family. When gathering a family history, a genogram and timeline are useful tools to map family members' birth order and medical and psychiatric histories; family roles, norms, boundaries, strengths, and family subgroups; birth dates, deaths, and relationships; stage in the family cycle; and critical events. To understand fully the family's values, goals, and beliefs, the nurse must consider the family's ethnic, cultural, and economic background throughout the assessment. A comprehensive family assessment should be considered (see [Chapter 15](#)).

School and Peer Adjustment

The child's adjustment to school is also significant. Often, children are referred for a mental health assessment as a result of changes in behavior at school. Falling grades, loss of interest in normal activities, decreased concentration, or withdrawal from or aggression toward peers may indicate that the child is experiencing emotional problems. It is very important that the nurse obtain signed permission from the parents to talk to the child's teacher for their observations of the child. The nurse may want to observe the child in school, if feasible, to see how the child functions there. The parent can request a treatment planning conference in which the teacher, parent, and nurse discuss the child's school performance and plan ways to promote the child's emotional, cognitive, and social functioning in school. Suggestions may range from having the child tested for learning disabilities to designing behavior plans that include rewards for improved functioning, such as computer time at the end of the day.

Peers are an important aspect of child and adolescent social development. Assessment of peer relationships and activities with friends provides a rich source of information about the adolescent. Assessment of victimization by peers in the form of bullying is important because it can have a negative impact on social development and self-esteem.

Children and Adolescents Who Identify as LGBTQ

Children and adolescents who identify as Lesbian, gay, bisexual, transgender, questioning/queer (LGBTQ) are highly stigmatized and often face discrimination and victimization because they do not adhere to conventional gender expectations. Transgender children and youth are especially affected by lack of understanding and social support. The health and mental health care needs of these children and adolescents are unique, and they often have difficulty accessing health care services (Romanelli & Lindsey, 2020).

Mental health problems are the leading causes of morbidity and mortality in this population. LGBTQ youth have a higher risk for depression, suicide, and substance use than other adolescents. They are also at increased risk for violence, including being targeted with bullying, teasing, harassment, and physical assault (Centers for Disease Control and Prevention [CDC], 2021). Social prejudice, family rejection, and self-nonacceptance are major risk factors. Protective factors include self-esteem, social support at home, positive relationships with peers, and positive school climates. It is important that the nurse inquire about anti-LGBTQ experiences that could lead to increased mental health problems. For children and adolescents to thrive, it is essential that they feel socially, emotionally, and physically safe and supported. Nurses can contribute to creating safe spaces by helping to create policies that support LGBTQ youth, participating in LGBTQ-related trainings, incorporating inclusive language in their communication, normalizing the use of pronouns, and providing an environment (physical or digital) where the individual can freely seek care without stigma (Advocates for Youth, 2021).

Functional Status

Functional status is evaluated in children and adolescents using the Global Assessment of Functioning (GAF) scale, which tallies behaviors related to school, peers, activity level, mood, speech, family relationships, behavioral problems, self-care skills, and self-concept. The GAF scale ranges from 0 to 100; the lower the score, the higher the level of impairment, indicated by psychiatric symptoms and level of general functioning. For example, a score of 30 may indicate that the child is severely homicidal or suicidal and has made

previous attempts, that hallucinations or delusions influence the child's behavior, or that the child has serious impairment in communication or judgment. Moderate impairment scores usually fall in the range of 51 to 69. Indications of moderate impairment include difficulty in one area, such as school phobia, that hinders school attendance or performance, while the child is functioning well within other areas, such as with family and peers. Children in this category are not homicidal or suicidal and usually respond well to outpatient interventions. A score of 70 to 100 usually indicates that the child is functioning well in relation to school, peers, family, and community. The GAF is always measured at the initial assessment so treatment can be evaluated for symptom improvement.

Social Systems

Youth in healthy communities have been shown to be more likely to attend religious services, to believe their schools were places of caring and encouragement, to be involved in structured activities, and to remain committed to their own learning. Assessing the child's economic status, access to medical care, adequate home environment, exposure to environmental toxins (e.g., lead), neighborhood safety, and exposure to violence is important because these community factors place the child at risk (Pearce et al., 2019).

Children and adolescents function better if they are linked to community supports, such as churches, recreational programs, park district programming, and after-school programming. The Big Brother/Big Sister program fosters mentoring relationships for children. A parent or child may call the local Big Brother/Big Sister organization to request a mentor for the child. The mentor may perform a wide range of services, from taking a child to community events, helping with homework, or talking about how the child can achieve their dreams and goals. Some towns offer community-based juvenile justice programs to rehabilitate children who have had altercations with the legal system. Juvenile justice programs provide support, such as individual and family counseling and prosocial recreational activities; teach children how to make positive choices about spending free time; and closely monitor their behaviors.

Religious and Spiritual Assessment

Spiritual assessment is an integral part of a mental health assessment. There is a growing body of research suggesting that religious and spiritual practices may promote both physical and mental health (Gwin et al., 2020). The Joint Commission requires that each psychiatric evaluation include spiritual assessment questions.

Questioning about a patient's spiritual life should include interviewing strategies that are unbiased and facilitate understanding of the client's spiritual values. Questions can include but are not limited to the child's and family's specific faith background, level of activity with that group, support received from spiritual practices, religious rituals of importance, and religious influences on lifestyle and health choices. During a child interview, appropriate questions include, "Where is God?" or asking if the child could talk to God.

Childhood Sexual Abuse

There are several special considerations in interviewing an abused child. First, the nurse must establish a safe and supportive environment in which to conduct the evaluation. Second, the nurse needs to understand the forensic implications of assessment so that the interview format will be acceptable for disclosure in a court hearing. The American Academy of Pediatrics offers practice guidelines for evaluating children who may have been abused (Adams et al., 2016). If the child reports abuse, the nurse has a legal responsibility to report the abuse to child protection agencies. The nurse must use the same language and vocabulary that the child uses to describe the abuse or anatomical terms and ask nonleading questions. Nursing professionals who regularly interview children who have been abused may have special training in the use of anatomically correct dolls to obtain information about the abuse.

SUMMARY OF KEY POINTS

- Mental health assessment of children and adolescents includes evaluating the child's biologic, psychological, and social factors, primarily through interviewing and observation.
- Assessment of children and adolescents differs from assessment of adults in that the nurse must consider the child's developmental level, specifically addressing the child's language, cognitive, social, and

emotional skills. Establishing a treatment alliance and building rapport are essential to obtaining a good mental health history.

- The mental status examination includes observations and questions about the child's appearance, motor activity, self-concept, behavior, social interaction, general intelligence, fund of knowledge, attention span, insight and judgment, comprehension, mood and feelings, thought process and content, speech and language, orientation, memory, reasoning, writing and spelling, reading, and motor skills. Assessment of the child and caregiver together provides important information regarding child–parent attachment and parenting practices.
- The three main types of temperament include the easy temperament, difficult temperament, and slow-to-warm-up temperament. Temperament can be evaluated by assessing the child's sleep and eating habits, mood, emotional intensity, and responses to new stimuli.
- A child's self-concept can be evaluated using tools such as play, stories, asking three wishes, and asking the child to draw a picture of themselves.
- If a child reveals suicidal ideation in the interview, the nurse must determine whether the child has a plan; let the parent know the child is suicidal; and make a plan to keep the child safe, such as inpatient hospitalization.
- If a child reports to the nurse neglect or physical or sexual abuse, the nurse must by law report the child's disclosure to the state's DCF.

CRITICAL THINKING CHALLENGES

1. An adolescent is hostile and refuses to talk in an interview. How would you respond?
2. What are some strategies for building rapport with children?
3. A child reports that he is suicidal. What would be your next question? What measures would you take next?
4. What are some techniques and media for obtaining information about a child's inner world, such as self-concept, sexual identity, body image, and developmental level?
5. Explain why it may be detrimental to interview a child in front of their parent. Why may it be detrimental to interview a parent in front of their child?
6. Why is obtaining the mental health histories of parents relevant to the child's mental health assessment?

7. What assessment questions would be important for a transgender child?
8. What are useful tools in obtaining a family history from the child and parent?
9. What types of questions would you ask to inquire about a child's spiritual life?

Mental Health Disorders of Childhood and Adolescence

Rebecca Luebbert

KEYCONCEPTS

- Attention
- Neurodevelopmental delay
- Hyperactivity
- Impulsiveness
- Tics

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe mental disorders usually diagnosed in childhood or adolescence.
2. Discuss prevailing theories relevant to the mental health disorders in childhood and adolescence.
3. Discuss the nursing care of children with neurodevelopmental disorders.
4. Analyze the nursing assessment, diagnosis, intervention, and evaluation processes in caring for a child or adolescent with attention-deficit hyperactivity disorder.

6. Describe the nursing care of children and adolescents with disruptive behavior disorders.
7. Discuss the epidemiology, etiology, medications, and nursing care of children with tic disorders.
8. Discuss the nursing care of children and adolescents with separation anxiety and obsessive–compulsive disorders (OCDs).
9. Compare the nursing care of children and adolescents with mood disorders and schizophrenia with that for adults with similar disorders.
10. Discuss the significance of behavioral intervention strategies for children who have elimination disorders.

KEY TERMS

- Adaptive behavior
- Attention-deficit hyperactivity disorder (ADHD)
- Autism spectrum disorder (ASD)
- Communication disorders
- Conduct disorder
- Disruptive behavior disorders
- Dyslexia
- Encopresis
- Enuresis
- Intellectual disability
- Learning disorder
- Motor tics
- Oppositional defiant disorder
- Phonic tics
- Phonologic processing
- Separation anxiety disorder
- Tourette Syndrome

INTRODUCTION

Psychiatric problems are less easily recognized in children than in adults. Normal growth and development behaviors of one age group may be a symptom of a disorder in another age group. For example, an imaginary friend is age appropriate for a 4-year-old child but not for an adolescent. Despite the difficulty in diagnosis, an estimated one in six youth in the United States experiences a mental disorder in a given year (National Alliance on Mental Illness [NAMI], 2021). Among the most commonly diagnosed disorders in children and adolescents are **attention-deficit hyperactivity disorder (ADHD)** (in 9.4%, approximately 6.1 million), behavior problems (in 7.4%, approximately 4.5 million), anxiety (7.1%, approximately 4.4 million), and depression (3.2%, approximately 1.9 million) (CDC, 2020b). Unfortunately, despite this prevalence, significant gaps in treatment exist, particularly for children in low-income families (Ghandour et al., 2019).

This chapter presents an overview of selected childhood disorders and discusses nursing care for children and their families with these problems. Because it is beyond the scope of this text to present all child psychiatric disorders, this chapter discusses selected ones, including neurodevelopmental disorders (**intellectual disability**, **autism spectrum disorder (ASD)**, ADHD, and tic disorders), **separation anxiety disorder**, obsessive–compulsive disorder (OCD), mood disorders, childhood schizophrenia, and elimination disorders (**enuresis** and **encopresis**). Oppositional defiant and conduct disorders are discussed in [Chapter 30](#).

NCLEXNOTE All psychiatric disorders of childhood and adolescence should be viewed within the context of growth and development models. Safety and self-esteem are priority considerations.

The **neurodevelopmental disorders** occur early in a child's development, often before grade school. These disorders include developmental deficits that range from very specific limitations of learning to global impairments of social skills. They impact personal, social, academic, or occupational functioning. Under the primary influences of genes and environment, neurodevelopment of attention, cognition, language, affect, and social and moral behavior proceeds along several pathways. Developmental pathways and developmental delays are closely interwoven. For example, a language delay can interfere with a child's social development and contribute to behavior problems (Matte-Landry et al., 2020). This section discusses neurodevelopmental disorders of childhood that

include several conditions that are etiologically unrelated; however, their common feature is a significant delay in one or more lines of development.

KEYCONCEPT Neurodevelopmental delay means that the child's development in attention, cognition, language, affect, and social or moral behavior is outside the norm and is manifested by delayed socialization, communication, peculiar mannerisms, and idiosyncratic interests.

INTELLECTUAL DISABILITY

Intellectual disability is defined as a disability characterized by significant limitations in both intellectual function and in **adaptive behavior** that covers many everyday social and practical skills (American Association on Intellectual and Developmental Disabilities [AAIDD], 2021). The disability begins before the age of 18 years.

Diagnostic Criteria and Clinical Course

The diagnosis of intellectual disability involves an assessment of intellectual function such as reasoning, problem-solving, and adaptive function in personal independence and social responsibility (American Psychiatric Association [APA], 2013). A diagnosis is made through clinical assessment of behavioral features; historical accounts from parents and teachers; and performance on standardized tests such as the Stanford–Binet or the Wechsler Intelligence Scales for Children. The usual threshold for intellectual disability is an intelligence quotient (IQ) of 70 or less (i.e., two standard deviations below the population mean).

Adaptive behavior is composed of three skill types: *conceptual skills* (e.g., language and literacy, money, time, number concepts, and self-direction); *social skills* (e.g., interpersonal skills, social responsibility, self-esteem, gullibility, social problem-solving, and the ability to follow rules and obey laws and to avoid being victimized); and *practical skills* (e.g., activities of daily living [ADLs], occupational skills, health care, travel and transportation, schedules and routines, safety, use of money, use of telephone) (AAIDD, 2021). Impaired adaptive functioning is primarily a clinical judgment based on the child's capacity to manage age-appropriate ADLs. However, standardized assessment

instruments are available to assist with determination of the child's capabilities (Shields et al., 2020; Verdugo et al., 2020).

An intellectual disability is not necessarily lifelong. Some children may be diagnosed at school age as having an intellectual disability, but with guidance and education, they may no longer meet the criteria as adults.

Epidemiology and Etiology

Data from the 2017 Global Burden of Disease Study estimated the prevalence of intellectual disabilities to be about 3% in the United States and worldwide. A considerable variability worldwide exists, with low- and middle-income countries reporting significantly higher rates of disability than high-income countries (Olusanya et al., 2020). Children and adolescents with intellectual disabilities are at higher risk for other mental disorders than in those without an intellectual disability (Buckley et al., 2020; Mazza et al., 2020). The rate of co-occurring psychiatric disorders is estimated between 38% and 49%, with the most commonly reported disorders including ADHD (39%), anxiety disorders (7% to 34%), conduct disorders (3% to 21%), and depressive disorder (3% to 5%) (Buckley et al., 2020).

Intellectual disabilities result from a variety of causes with the most common etiology related to genetic syndromes. Chromosomal changes or defects (e.g., Down syndrome) and exposure to toxins during prenatal development (e.g., fetal alcohol syndrome), heredity, pregnancy and perinatal complications, medication conditions, and environmental influences are all associated with intellectual disabilities. The cause is unknown in many of the cases (Walkley et al., 2019).

Nursing Care of Children with Intellectual Disability

Assessment of a child with an intellectual disability focuses on current adaptive skills, intellectual status, and social functioning. A developmental history is a useful way to gather information about past and current capacities (Box 37.1). The nurse compares these data with normal growth and development. Developmentally delayed children who have not had a psychological evaluation should be considered for referral. These children also require evaluation for

other comorbid psychiatric disorders, which may be a challenge because of the child's cognitive limitations. Discussions about feelings and behavior may be too complex for these children. If children or adolescents with intellectual disabilities have a comorbid mental disorder or serious behavioral problems, a carefully constructed interdisciplinary behavioral plan will guide care and treatment.

The nurse also assesses the child's support systems (family, school, rehabilitative, and psychiatric) to ensure that the child's special needs have been identified and are being addressed. For example, occupational therapy may be recommended to improve motor coordination, but the family may not have transportation to these services available, so availability to alternative services should be explored.

BOX 37.1

History and Hallmarks of Childhood and Adolescent Disorders

- Maternal age and health status during pregnancy
- Exposure to medication, alcohol, or other substances during pregnancy
- Course of pregnancy, labor, and delivery
- Infant's health at birth
- Eating, sleeping, and growth in first year
- Health status in first year
- Interest in others in first 2 years
- Motor development
- Mastery of bowel and bladder control
- Speech and language development
- Activity level
- Response to separation (e.g., school entry)
- Regulation of mood and anxiety
- Medical history in early childhood
- Social development

- Interests

The child and family's response to intellectual disability and other comorbid conditions will determine the nursing interventions. Interventions most often include promoting coping skills (i.e., interventions directed at building strengths, adapting to change, and maintaining or achieving a higher level of functioning), patient education, and parent education.

The overall goals of treatment and nursing care are an optimal level of functioning for the family and eventual independent functioning within a normal social environment for the child. For many children with intellectual disability, achieving independence in adulthood will be delayed but not impossible.

Continuum of Care

Children and families may require varying levels of interventions at different times throughout the life cycle. When a child is young, the family requires special educational support and, for some, residential services. The need for psychiatric intervention varies according to the severity of disability, family functioning, and the coexistence of other disorders. Feelings of grief and loss in family members (especially parents) related to having a child with a disability may be relieved through family therapy. More specific parent training may be needed to deal with emerging maladaptive behaviors. See [Nursing Care Plan 37.1](#).

AUTISM SPECTRUM DISORDER

ASD is characterized by persistent impairment in social communication and social interaction with others (APA, 2013). Children with ASD may or may not have an intellectual disability, but they commonly show an uneven pattern of intellectual strengths and weaknesses. This condition may be a lifelong pattern of being rigid in manner, intolerant of change, and prone to behavioral outbursts in response to environmental demands or changes in routine. Two conditions, autism disorder and Asperger syndrome, were previously diagnosed as separate disorders. However, because they have many overlapping symptoms and are difficult to differentiate from each other, the *DSM-5* no longer considers autism

and Asperger syndrome as separate disorders, but considers both as an ASD differentiated by language or intellectual impairment (APA, 2013).

ASD with restricted repetitive patterns of behavior such as stereotypic or repetitive motor movement, use of objects, inflexible adherence to routine or ritualized patterns, and fascination with lights or movement has been a subject of considerable interest and research effort since its original description more than 70 years ago. Leo Kanner (1943) described the profound isolation of these children and their extreme desire for sameness. These children appear aloof and indifferent to others and often seem to prefer inanimate objects.

NURSING CARE PLAN 37.1

The Patient with Attention-Deficit Hyperactivity Disorder

Jamie, age 6 years, comes to the primary health care clinic with his mother Lillian because of motor restlessness, distractibility, and disruptive behavior in the classroom. According to Lillian, Jamie had a reasonably good year in kindergarten, but early in the first grade, the teacher began to report disruptive behavior. On reflection, Lillian recalls that kindergarten was a half-day program with more activity. By contrast, Jamie is expected to sit in his seat and pay attention for longer periods in first grade.

Jamie's medical history is unremarkable. Lillian's pregnancy with Jamie was her first and was unplanned. Although there were

no complications during the pregnancy, the period was marked by significant marital discord, culminating in divorce before Jamie's first birthday. Jamie was born by cesarean section after a long, unproductive labor. He was healthy at birth and grew normally, with no developmental delays. Despite genuine interest in other children, his intrusive style and inability to wait his turn resulted in frequent conflicts with them. The family history is positive for substance abuse in his father. In addition, Lillian reports that her ex-husband was disruptive in school, had trouble concentrating, and was highly impulsive. These problems have continued into adulthood.

During the two evaluation sessions, Jamie is active but cooperative. His speech is fluent and normal in tone and tempo but somewhat loud. His discourse is coherent, but at times, he makes rather abrupt changes in conversation without warning his listeners. Psychological testing done at the school revealed average to above-average intelligence. Parent and teacher questionnaires concurred that Jamie was overactive, impulsive, inattentive, and quarrelsome but not defiant.

Setting: Psychiatric Home Care Agency

Baseline Assessment: Jamie is a 6-year-old boy with prominent hyperactivity and disruptive behavior. He lives with Lillian, his single mother. These problems interfere with his interpersonal relationships and academic progress. Lillian is discouraged and feels unable to manage Jamie's behavior.

Associated Psychiatric Diagnosis	Medications
Attention-deficit hyperactivity disorder (ADHD)	Methylphenidate 7.5 mg at breakfast and lunch (i.e., at 8 am and 12 noon) and then adding 5 mg at 7 pm.

Priority of Care: Difficulty in Social Relationships

Important Characteristics

Cannot establish and maintain developmentally appropriate social relationships
Has interpersonal difficulties at school
Is not well accepted by peers
Is easily distracted
Interrupts others
Cannot wait his turn in games
Speaks out of turn in the classroom

Associated Considerations

Impulsive behavior
Overactive
Inattentive
Risk-taking behavior (tried to climb out the window to get away from his mother)
Failure to recognize effects of his behavior on others

Outcomes

Initial	Discharge
Decrease hyperactivity and disruptive behavior.	Improve capacity to identify alternative responses in conflicts with peers.
Improve attention and decrease distractibility.	Improve capacity to interpret behavior of age mates.
Decrease frequency of acting without forethought.	

Interventions

Intervention	Rationale	Ongoing Assessment
Educate mother and teach about ADHD and use of stimulant medication.	Better understanding helps to ensure adherence; also parents and teachers often miscast children with ADHD as “troublemakers.”	Determine the extent to which parent or teacher “blames” Jamie for his problems.
Monitor adherence to medication schedule.	Uneven compliance may contribute to failed trial of medication.	Administer parent and teacher questionnaires; inquire about behavior across entire day.
Ensure that medication is both effective and well tolerated.	Stimulants can affect appetite and sleep.	Administer parent and teacher questionnaires; check height and weight; ask about sleep and appetite.

Evaluation

Outcomes	Revised Outcomes	Interventions
Jamie shows decreased hyperactivity and less disruption in the classroom.	Improve ability to identify disruptive classroom behavior.	Initiate point system to reward appropriate behavior.
Jamie shows improved attention and decreased distractibility.	Improve school performance.	Move to front of classroom as an aid to attention.
Mother and teacher attest to Jamie's decreased impulsive behavior.	Increase Jamie's capacity to recognize the effects of his behavior on others.	Encourage participation in structured activities.
Jamie identifies alternative responses such as walking away until it is his turn.	Increase frequency of acting on these alternative approaches.	Inquire about social skills group at school, if available.
Jamie improves interpretation of motives and behaviors of others.	Improve acceptance by peers.	Encourage participation in community activities.

Priority of Care: Difficulty Parenting

Important Characteristics	Associated Considerations
Verbalizes discouragement and inability to handle situation with Jamie	Chronicity of ADHD More than average childrearing problems

Outcomes

Initial	Discharge
Verbalize frustration at trying to raise a child with ADHD alone.	Identify coping patterns that decrease the sense of frustration and increase parental competence.
Identify positive methods of interacting and disciplining Jamie that will support the parent-child relationship as well as meet Jamie's development needs.	Initiate a collaborative relationship with the school teacher.
	Identify sources of support in the community and begin to access these resources.

Interventions

Intervention	Rationale	Ongoing Assessment
Assess mother's discouragement and feelings about parenting, identifying specific problem areas.	Helping the mother verbalize her feelings and identifying problem areas help in formulating problem-solving strategies.	Assess the severity of the problems with which she is living.
Refer mother to Community Mental Health Center for free parenting class.	Parent training based on clear directives and rewards can be effective for decreasing impulsive and disruptive behavior.	Monitor mother's level of confidence and perceived change in Jamie's behavior.
Refer mother to self-help organization.	Parent groups such as Children and Adults with Attention-deficit Disorder (CHADD) can be sources of support and information.	Determine whether contact was made and whether it was helpful.
Make contact with school to enhance collaboration with mother.	Assess effectiveness of medication and other interventions; need feedback from teachers.	Determine whether mother has been able to contact teacher.

Evaluation

Outcomes	Revised Outcomes	Interventions
After four sessions, Lillian expresses her frustrations, but she has begun to identify different ways of relating to Jamie and his developmental needs.	None	None
Through attending the parenting class and joining a support group, Lillian begins to change her coping patterns, decrease her frustrations, and increase her parental competence.	Complete parenting class; attend at least two support group meetings each month.	If necessary, refer for additional parent counseling.
Lillian initiates a collaborative relationship with Jamie's teacher.	Lillian and teacher mutually develop and implement behavior plans for home and school.	Have mother observe in the classroom; have mother visit highly structured classroom.

Impairment in communication is severe and affects both verbal and nonverbal communication. Children with ASD may manifest delayed and deviant language development, as evidenced by echolalia (repetition of words or phrases spoken by others) and a tendency to be extremely literal in interpretation of language. Pronoun reversals and abnormal intonation are also common. Other common features of ASD are stereotypic behavior, self-stimulating, nonfunctional repetitive behaviors, such as repetitive rocking, hand flapping, and an extraordinary insistence on sameness. These children may also engage in self-injurious behavior, such as hitting, head banging, or biting. In some children, their unusual interests may evolve into fascination with specific objects, such as fans or air conditioners, or a particular topic, such as U.S. Civil War generals.

A child with ASD may have age-appropriate language and intelligence but also have severe and sustained impairment in social interaction and restricted, repetitive patterns of behavior, interests, and activities. This type of ASD was previously known as Asperger syndrome and appears to be a milder form of ASD. These children have social deficits marked by inappropriate initiation of social interactions, an inability to respond to normal social cues, and a tendency to be literal in their interpretation of language (APA, 2013). They may also display stereotypic behaviors, such as rocking and hand flapping, and have highly restricted areas of interest, such as train schedules, fans, air conditioners, or dogs. Signs of developmental delay may not be apparent until preschool or school age, when social deficits become evident ([Box 37.2](#)).

Epidemiology and Etiology

Recent studies by the CDC find that approximately 1 in 54 children has been identified with ASD. It is 4.3 times as prevalent among boys as among girls, and is found in all racial, ethnic, and socioeconomic groups (Maenner et al., 2020). Intellectual disability and seizures often occur in ASD (Strasser et al., 2018). Published claims that the prevalence of autism is increasing are confounded by improved methods of diagnosis (Myers et al., 2019).

While research has not identified an exclusive cause for ASD, evidence has identified many likely contributing factors, including environmental, biologic, and genetic factors. There is strong evidence supporting the majority of risk for ASD is from genetic factors. In a multinational cohort study of over 2 million

individuals, of whom 22,000 were diagnosed with ASD, the heritability rate was estimated to be approximately 80% (Bai et al., 2020). Other risk factors identified by the CDC as possible contributors to ASD include having a sibling with ASD, children born to older parents, individuals with certain genetic or chromosomal conditions, such as fragile X syndrome or tuberous sclerosis, and the use of prescription drugs valproic acid and thalidomide taken during pregnancy. Studies have shown that there is no link between receiving vaccines and developing ASD (CDC, 2020d) (Figure 37.1).

BOX 37.2 CLINICAL VIGNETTE

Frank (Autism Spectrum Disorder Asperger Syndrome)

A pediatrician refers Frank, age 5 years, 6 months, for an evaluation because of Frank's unusual preoccupation with ceiling fans and lawn sprinklers. According to his mother, Frank became interested in ceiling fans at age 3 years when he began drawing them, tearing pictures of them out of magazines, and engaging others in discussions about them. In the months before the evaluation, Frank also became fascinated by lawn sprinklers. These preoccupations so dominated Frank's interactions with others that he was practically incapable of discussing any other topics. He remained on the periphery of his kindergarten class and had few friends. Although he tried to make friends, his approaches were inept and he had trouble reading others.

Frank was the product of a full-term uncomplicated pregnancy, labor, and delivery to his then 25-year-old mother. It was her first pregnancy, and both parents eagerly anticipated Frank's birth. As an infant, Frank was healthy but seemed to cry a lot and was difficult to comfort, causing his mother to feel inadequate and depleted. His motor development was also delayed, and at age 3 years, nonfamily members had difficulty understanding his speech. His articulation, however, was within normal limits at the time of consultation. Frank received regular pediatric care and had no history of serious illness or injury. There was no family history of intellectual disability or psychiatric illness; results of genetic testing for chromosomal abnormality were negative.

In addition to his unusual preoccupations and social deficits, Frank resisted any change in his routine, was easily frustrated, and was prone to temper tantrums. His parents sharply disagreed about the nature of and appropriate response to his problems.

What Do You Think?

- What effect do you think Frank's preoccupation may have on his family and their relationships?
- What kind of teaching program would you develop if you were the nurse assigned to this family?

Teamwork and Collaboration: Working toward Recovery

ASDs require long-term care at various levels of intensity. The total costs per year for children living with ASD in the United States is estimated to be between \$11 billion and \$61 billion due to a culmination of direct and indirect costs. Youth with ASD have an average of \$4,000 to \$6,000 additional medical expenditures as compared to youth without ASD, and children needing intensive behavioral interventions incur an additional \$40,000 to \$60,000 cost per year (CDC, 2020d). Treatment consists of designing academic, interpersonal, and social experiences that support the child's development. Children with autism, even those who are severely affected, may be able to live at home and attend special schools that use behavioral techniques. Other outpatient services may include family counseling, home care, and medication. As the child moves toward adulthood, living at home may become more difficult given the appropriate need for greater independence. The level of structure required depends primarily on IQ and adaptive functioning.

FIGURE 37-1: Patients with autism (*right*) may have decreased metabolic rates in the cingulate gyrus and other associated areas; however, wide heterogeneity in brain metabolic patterns is seen in patients with autism. (Courtesy of Monte S. Buchsbaum, MD, *The Mount Sinai Medical Center and School of Medicine*, New York.)

Planning interventions for children with an ASD consider the child, family, and community supports, such as schools, rehabilitation centers, or group homes. First and foremost, the clinicians involved in the child's treatment should collaborate with the family toward the same general goals. As the number of clinicians and educators involved increases, the chance of fragmentation in treatment planning also increases. The nurse can serve as a case coordinator.

Residential care may be necessary in some cases. After making the decision to place a child into a residential facility, family members may experience guilt, loss, and a sense of failure concerning their inability to care for the child at home.

Evidence-Based Nursing Care for Children with ASD

Mental Health Nursing Assessment

Physical Health Assessment

Physical health assessment should include a review of physical health and neurologic status, giving particular attention to coordination, childhood illnesses, injuries, and hospitalizations. The nurse should assess sleep, appetite, and activity patterns because they may be disturbed in affected children. Lack of adequate sleep can increase irritability. Comorbid seizure disorders are common in those with autism; depression is often seen concurrently even when no intellectual or language impairment is evident. Thus, the nurse should consider these conditions in the assessment.

Children with additional psychiatric disorders or seizures may be receiving multiple medications and require the care of several clinicians. Therefore, assessment should include a careful review of current medications and treating clinicians.

Psychosocial Assessment

Communication, behaviors, and flexibility are critical assessment areas. Direct behavioral observation is important to evaluate the child's ability to relate to others, to verify the selection of age-appropriate activities, and to watch for stereotypic behaviors. Assessment of the child with ASD can be based on the following categories:

- Communication
 - Verbal and nonverbal
 - Use of picture cards, writing, or drawing
 - Comfortable with eye contact
 - Understand emotional cues
 - Presence of pain

- Preoccupation with restricted interests
- Behaviors
 - Items of fixation (how does family manage?)
 - Triggers for agitation
 - Early signs that indicate beginning of agitation
 - Interventions that work when child is overstimulated or agitated
 - Repetitive behaviors
- Flexibility or adherence to routine
 - Home schedule
 - What aggravates or irritates the person
 - Early warning signs of agitation
 - When overagitated, what interventions work best The child's behavior, need for structure, and communication style can affect family functioning. Having a child with ASD is bound to influence family interaction; responding to the child's needs may adversely affect family functioning. For example, sleep disruption in family members who care for these children may increase family stress.

Clinical Judgment

Treatment outcomes need to be individualized to the child, family, and social environment and may change with time. Ensuring physical safety is a priority for the nurse. The nurse will need to develop a plan of care that takes into consideration the child's ability to communicate effectively with others. The child may also have difficulty completing ADLs and may demonstrate poor coping and impaired skills. Determining the need for predictability and stability in routine for the child is also important.

Mental Health Nursing Interventions

Physical Health Interventions

In teaching self-care skills, the nurse needs to consider the child's current adaptive skills and language limitations. Developing a list of activities for the child to post in their bedroom may be effective for some children. Drawings or symbols may be useful for nonverbal children. Physical safety is an important concern for children who are cognitively delayed and may have impaired judgment.

No medication has proved effective at changing the core social and language deficits of autism. However, some atypical antipsychotics (i.e., risperidone, aripiprazole) are approved for the treatment of irritability associated with autism. Weight gain and metabolic syndrome are concerns with these agents. Evidence is minimal that anticonvulsants and traditional mood stabilizers are useful in managing mood lability and aggression (Davico et al., 2018).

Psychosocial Interventions

When working with children with neurodevelopmental disorders, building on their strengths and using positive reinforcement are very important. If these children feel that they are constantly criticized or need “fixing,” their self-esteem will be eroded and they will be unlikely to cooperate and learn.

Promoting Interaction

Structuring interventions for social isolation should fit the child's cognitive, linguistic, and developmental levels. Interventions fostering nonverbal social interactions may be more useful than those based on speech. For higher-functioning children, activities such as getting the mail, passing out snacks, or taking turns in the context of simple games can engage them in social activities without requiring the use of their limited language skills. Structuring social interactions so that the child shares a task with another, such as carrying a load of books, may help boost confidence in relating to others.

ASDs call for extraordinary patience and determination. With help, these children can learn social and communication skills, such as taking turns in conversation and warning the listener before changing the subject in the context of milieu.

Ensuring Predictability and Safety

When children with ASDs are hospitalized, milieu management—a consistent,

structured environment with predictable routines for activities, mealtimes, and bedtimes—is necessary for successful treatment. Changes in routine may provoke disorganization in the child, leading to emotional disequilibrium and explosive behavior. The safety of the inpatient unit offers an opportunity to try behavioral strategies, such as rewards for managing transitions. Health care professionals can pass on successful strategies to parents or primary caretakers (Quiban, 2020).

A structured physical environment will most likely be important to a child with a development disorder. Keeping furniture, dishes, and toys in the same place helps ease anxiety and fosters secure feelings. The nurse should identify the child's individually specific needs for structure.

Behavioral Interventions

Children with ASDs often need specific behavioral interventions to reduce the frequency of inappropriate or aggressive behavior (Kodak & Bergmann, 2020). For example, a child may have angry outbursts in response to routine transitions. If the tantrum is dramatic, the consequence may be that the transition does not take place. By structuring the environment and using visual cues to signal the end of one activity and the start of another, it may be possible to reduce the number and intensity of responses to transitions. Safety is always a concern. Self-injury and aggression are sometimes present, so children may need to be protected from hurting themselves and others. If aggressive or assaultive behavior is a problem, a brief “time out” followed by prompt reentry into activities is usually effective.

Managing the repetitive behaviors of these children depends on the specific behavior and its effects on others or the environment. If the behavior, such as rocking, has no negative effects, ignoring it may be the best approach. If the behavior, such as head banging, however, is unacceptable, redirecting the child and using positive reinforcement are recommended. In some cases, especially in severely delayed children, these strategies may not work, and environmental alterations and perhaps protective headgear will be needed.

Supporting Family

Unfortunately, lack of integration of medical, psychiatric, social, and educational services can add to the family's burden. Parents may manifest denial, grief, guilt, and anger at various points as they adjust to their child's disability. The nurse can offer parents the opportunity to express their frustrations and disappointments and can be alert for indications that parents are in need of additional assistance, such as parent support groups or respite care.

Family interventions include support, education, counseling, and referral to self-help groups. Whenever possible, the nurse provides education to help parents determine appropriate expectations for their child and to meet the child's special needs. The following are examples of potentially useful nursing interventions focusing on the family:

- Interpreting the treatment plan for parents and child
- Modeling appropriate behavior modification techniques
- Including the parents as co-therapists for the implementation of the care plan
- Assisting the family in identifying and resolving their sense of loss related to the diagnosis
- Coordinating support systems for parents, siblings, and family members
- Maintaining interdisciplinary collaboration

Evaluation and Treatment Outcomes

Evaluation of patient and family outcomes is an ongoing process. Short-term outcomes might consist of discrete behavioral improvements, such as reducing self-injurious behavior by 50%. The long-term goal is for the patient to achieve the highest level of functioning.

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

ADHD is one of the most commonly diagnosed disorders in school-aged children (CDC, 2020c). It is almost certainly a heterogeneous disorder with multiple etiologies. The relatively high frequency of ADHD and associated behavior problems virtually guarantees that nurses will meet affected children in

all pediatric treatment settings. ADHD is also diagnosed in adults, but it is less common than in children (Weibel et al., 2020).

Diagnostic Criteria and Clinical Course

A persistent pattern of inattention, hyperactivity, and impulsiveness that interferes with functioning characterizes ADHD (APA, 2013). A diagnosis is made based on school behavior, parents' reports, and direct observation of inattention and hyperactivity–impulsivity that are inconsistent with developmental level. Parents and teachers describe children with ADHD as restless, always on the go, highly distractible, unable to wait their turn, heedless, and frequently disruptive. Indeed, it is often disruptive behavior that brings these children into treatment.

KEYCONCEPT Attention involves concentrating on one activity to the exclusion of others, as well as the ability to sustain focus.

In ADHD, the person finds it difficult to attend to one task at a time and is easily distracted. For some, the lack of attention is related to being unable to filter incoming information, which leads to being unable to screen and select the important information. That is, all incoming stimuli are treated the same (e.g., directions from a teacher elicit the same importance as noise in the hallway). For others, the distractibility may be related to stimuli-seeking behavior. Given the heterogeneity of ADHD, either of these models may explain problems of attention for subgroups of affected children.

Children with ADHD are prone to impulsive, risk-taking behavior and often fail to consider the consequences of their actions (CDC, 2020c). They tend to exercise poor judgment and seem to have more than the usual lumps, bumps, and bruises because of their risk-taking behavior. They often require a high degree of structure and supervision (Daley et al., 2018).

KEYCONCEPT Impulsiveness is the tendency to act on urges, notions, or desires without adequately considering the consequences.

Although hyperactivity is a characteristic often associated with ADHD, controversy is long standing about whether attention-deficit disorder can occur without overactivity. In many cases, the hyperactivity prompts the search for

treatment. Parents typically report that a child's hyperactivity was manifested early in life and is evident in most situations (APA, 2013). Hyperactivity and impulsivity in childhood are associated with conduct disorder ([Chapter 30](#)) and intimate partner violence perpetration in adults (Buitelaar et al, 2020).

KEYCONCEPT **Hyperactivity** is excessive motor activity, as evidenced by restlessness, an inability to remain seated, and high levels of physical motion and verbal output.

ADHD across the Lifespan

ADHD is usually diagnosed in childhood and was traditionally viewed as a problem of children. We now understand that ADHD persists into adulthood and it is sometimes first diagnosed later than in childhood. In adults, symptoms of hyperactivity and impulsivity tend to decline with age and deficit of attention persist and become more varied (Torgersen et al., 2016). However, the majority of the adults with ADHD are undiagnosed and untreated (Ginsberg et al., 2014). Many of the adults with ADHD become the parents of children with the same disorder (Uchida et al., 2020).

Epidemiology and Risk Factors

Although prevalence estimates vary depending on the diagnostic criteria used, the sources of data, and the sampling procedure, ADHD has been diagnosed in as many as 9.4% of children aged 2 to 17 (Danielson et al., 2018). Boys are more likely to be diagnosed than girls (12.9% compared to 5.6%) (CDC, 2020c). Researchers believe that several risk factors may contribute to the development of ADHD, including a family history of ADHD, substance use during pregnancy, exposures to environmental toxins (such as lead) during pregnancy and/or at a young age, low birth weight, and brain injuries (Donzelli et al., 2019; Kim et al., 2020; National Institute of Mental Health [NIMH], 2019a).

Etiology

No single explanation for the occurrence of ADHD exists; instead, this disorder is viewed as having multiple causes. Genetic factors are implicated in the etiology of ADHD. They clearly play a fundamental role in the manifestation of the ADHD behavior (Sciberras et al., 2017). In some children, diet during childhood has been investigated as a potential contributing factor to the development of ADHD, specifically a dietary pattern characterized by high consumption of refined sugars and saturated fat (Del-Ponte et al., 2019).

Biologic Theories

Although the etiology of ADHD is uncertain, evidence about neurobiologic dysfunction is pervasive. Several lines of research have shown that the frontal lobe and functional connections impacted with specific subcortical structures also are dysregulated. One clearly dysfunctional area is the dorsolateral prefrontal cortex, the center of directed attention and the ability to manage emotions or delay emotional reactions. Several neurotransmitters (e.g., dopamine, serotonin) are dysregulated (Hou et al., 2018; Klein et al., 2019; Nilsen & Tolve, 2020). Clinically, the hyperactive-impulsive behavior characteristic of ADHD has been shown to be predominantly related to biologic factors, not psychosocial factors (Nilsen & Tolve, 2020).

Psychosocial Theories

Although genetic endowment is clearly a fundamental element in the etiology of ADHD, psychosocial factors are also important risk factors. Family stress, marital discord, and parental substance use are also associated with exacerbation of ADHD behaviors (Sigfusdottir et al., 2017). Other implicated psychosocial factors are poverty, overcrowded living conditions, and family dysfunction.

Family Response to ADHD

Living with a child who has ADHD is a challenge for all family members,

particularly those members who also have issues similar to those of the affected child. The family will not only be raising a child who needs a structured environment that helps support focus and attention, but the parents have to partner with their children's school system. For some families, the relationship with the school is positive and supportive. For others, the relationship with the school can be strained and lead to additional stress. It is important that the teachers and parents work together and provide consistent directions to the child.

If parents also have problems related to attention, impulse, and hyperactivity, home chaos and ineffective parenting practices can occur (Deater-Deckard, 2017). If the parents also have ADHD, they might not be able to provide a calm structured environment for the child. Effective parenting requires the ability to resist overreacting emotionally, to focus on the child, to keep track of activities, and to provide consistency in discipline (Bowling et al., 2019).

Teamwork and Collaboration: Working toward Recovery

Children with ADHD and their families benefit from symptom management, education, and support from various disciplines to have a high-quality life. Successful recovery efforts involve early recognition and treatment. By recognizing the problem early, family members and teachers can structure the child's interactions, develop meaningful discipline strategies, and modify the physical environment so the child can learn coping skills to deal with impulsivity, distractibility, and hyperactivity. Evidence has accumulated over the years that medication is helpful, especially in the early years, but for long-term effects, a combination of medication management and behavioral approaches results in the best outcomes for the children and their families (Feldman et al., 2018).

ADHD is not an easy disorder to treat or manage. Comorbidity complicates successful recovery. Children with ADHD have more behavior or conduct problems (e.g., run-ins with police), **learning disorders**, anxiety, and depression (CDC, 2020c). Many other problems interfere with recovery efforts, such as family disruptions and economic problems, as well as naturally occurring changes such as maturational issues during their adolescent years. Additionally, children from disadvantaged backgrounds fare worse than those children who

have socioeconomic and educational support (Huang et al., 2018).

Safety Issues

Due to increased impulsivity and inattention, children and adolescents with ADHD are at greater risk for injury than those without ADHD. Research finds that children with ADHD are significantly more likely to experience injury when riding a bike, have more head injuries and injuries to multiple body parts, and are more likely to be hospitalized for unintentional poisoning. Teenagers with ADHD are more likely to break traffic rules and are more likely to be involved in a car accident than those without ADHD (CDC, 2020c).

Individuals of all ages with ADHD are at high risk for mood changes that could lead to risk-taking behavior and suicidal ideation or attempts. Mood lability, the presence of depression, and potential for self-harm should be carefully assessed in these individuals (Claudius & Axeen, 2020; Giupponi et al., 2020; Levy et al., 2020). The risk of suicide attempts in children and adolescents with ADHD may be increased due to possible exposure to certain environmental risk factors, such as poor performance in school, impaired interpersonal relationships, socioeconomic hardship, depression, and substance use (Liu et al., 2020). In a study comparing youth presenting to an emergency department (ED) with suicide attempts versus suicidal ideation, youth with ADHD were more likely to have made an attempt as compared to youth without ADHD (Claudius & Axeen, 2020).

Evidence-Based Nursing Care for Children with Attention-Deficit Hyperactivity Disorder

The planning of nursing interventions must be done within the context of the family, treatment setting, and school environment. With the parents, clinical team members, and school personnel, the nurse participates in designing a plan of care that fits the child's and family's needs. Persons with ADHD and their families will benefit from nursing care at many different times in the course of the disorder. Unless hospitalized for a comorbid mental health problem, most treatment will occur outside the mental health system. School nurses often

provide most of the nursing care and family education.

Mental Health Nursing Assessment

In the school setting, the primary focus of the assessment is the impact of ADHD on classroom behavior and school performance. In the hospital, the nurse tries to determine the contribution of ADHD to the acute psychiatric problem. In both cases, the nurse collects assessment data through direct interview, observation of the child and parent, and teacher ratings. Because children with ADHD may have difficulty sitting through long sessions, interviews are typically brief. Parents and teachers are extremely important sources for assessment data. To this end, the nurse can make use of several standardized instruments ([Box 37.3](#)).

Box 37.3

Standardized Tools for Attention-Deficit Hyperactivity Disorder Diagnosis¹

CONNERS QUESTIONNAIRES

The Conners Parent Questionnaire is a 48-item scale that a parent completes about their child. Each item is a statement that the parent rates on a 4-point scale from 0 (not at all) to 3 (very much). The Conners Teacher Questionnaire is a 28-item questionnaire that the child's teacher completes according to the same 4-point scale as the Parent Questionnaire. Both questionnaires have been standardized by age and gender for a mean of 50 and a standard deviation of 10 (Conners, 1989; Goyette et al., 1978).

CHILD BEHAVIOR CHECKLIST

The Child Behavior Checklist (CBCL) is a 118-item questionnaire that a parent completes. In addition to the 118 questions about specific behaviors and psychiatric symptoms, the CBCL also includes questions concerning the child's competence in social and

academic spheres as well as age-appropriate activities. Normative data are available, allowing the conversion of raw scores to standard scores for age and gender. A teacher version of this scale is also available.

¹Note that the diagnosis of ADHD is not made on the basis of questionnaires alone. Data from these rating scales augment the information gathered through interview and observation. These questionnaires can be especially useful before and after initiating a treatment plan to measure change.

Physical Health Assessment

As with other psychiatric disorders with onset in childhood, the nursing assessment of children with ADHD begins with identification and exploration of the presenting problems, usually hyperactivity, impulsivity, and inattention. This typically entails a review of the child's developmental course, the onset and pattern of the current symptoms, factors that have worsened or improved the child's problems, and prior treatment or self-initiated efforts to remedy the situation. Medical history is also essential, consisting of perinatal course, childhood illnesses, hospital admissions, injuries, seizures, tics, physical growth, general health status, and date of the child's last physical examination.

The behavior of these children is characteristically very active and can often be observed in the office. They cannot sit still. They fidget. Even in sleep, they may be more active than normal children. Thus, a careful assessment of eating, sleeping, and activity patterns is essential. Assessing daily food intake, typical diet, and frequency of eating will help identify any nutritional problems. Caffeinated products can contribute to hyperactivity in some children. Sleep is often disturbed for children with ADHD and consequently also the family. A detailed sleep assessment can provide points for interventions and help the interpretation of drug effects.

Psychosocial Assessment

Data regarding school performance, behavior at home, and comorbid psychiatric

disorders are essential for developing school interventions and behavior plans and establishing the baseline severity for medication. Children with ADHD are more likely to have problems with their cognitive process during changing demands of teachers and parents (cognitive processing, attention, language, and memory) (Korrel et al., 2017; Tamm et al., 2020; Yang et al., 2017). Consequently, they may have more difficulty in school with decision-making. These children are often behind in their work at school because of poor organization, off-task behavior, and impulsive responses.

Dysfunctional interactions can develop within the family. Discipline is frequently an issue because parents may have difficulty controlling their child's behavior, which is disruptive and occasionally destructive. They can exhaust their parents, aggravate teachers, and annoy siblings with their intrusive and disruptive actions. Reviewing the problem behaviors and the situations in which they occur is a way to identify negative interaction patterns.

Because ADHD often occurs in the context of psychosocial adversity, it is important to review the family situation, including parenting style, stability of household membership, consistency of rules and routines, and life events (e.g., divorce, moves, deaths, job loss). Identification of these factors can be useful in shaping a care plan that builds on potential strengths and mitigates the effects of environmental factors that may perpetuate the child's disruptive behavior.

Clinical Judgment

Priorities of nursing care will depend on the severity of the responses, family situation, and school environment. Increased impulsivity and intention puts the child or adolescent at greater risk for injury. Comorbid disorders, such as mood or conduct disorders, may also be present. Sleep deprivation, inadequate nutrition, and the inability to carry out daily routines may require intervention. The child may demonstrate poor coping skills and may not function well in social settings or in structured activities (such as in the school environment). Outcomes should be individualized to the child. Short-term outcomes, such as decreasing the number of classroom ejections within a 2-week period, may be useful for one child, but reducing the frequency and amplitude of angry outbursts at home may be relevant to another child.

Mental Health Nursing Interventions

Physical Health Interventions

Modifying Nutrition

A link between adverse reaction to food (e.g., dietary salicylates and artificially added food colors, flavors, preservatives) and ADHD was suggested many years ago when the Feingold diet was introduced (Feingold, 1975). Over the years, interest in the link between food and behavior continues to spark interest in ADHD as a problem related to food. Agreement exists that in some children the behaviors associated with ADHD can be decreased with diet changes (Uldall & Thomsen, 2020). Study outcomes are mixed. A review of the artificial food color elimination diet (restricted elimination diet), few foods diet, and polyunsaturated fatty acid supplementation diet indicates that the free foods diet provides a contribution to ADHD treatment. The others did not have the research to support their efficacy.

The *few foods diet* includes basic foods that are not likely to produce adverse effects such as lamb, chicken, potatoes, bananas, and apples. Grains, dairy products, and processed foods are avoided in the few foods diet. The *restricted elimination diet* includes all-natural, chemical-free foods. Fruits, vegetables, nuts, nut butters, beans, seeds, gluten-free grains such as rice and quinoa, fish, lamb, wild game meats, organic turkey, and large amounts of water are consumed. This diet is very restricted and consequently difficult to follow all of the time. The *polyunsaturated diet* suggests that children with ADHD have low levels of omega-3 polyunsaturated fatty acids. Supplements are encouraged for these individuals (Pelsser et al., 2017).

Supplementation with free fatty acids has been shown to be helpful for children who have deficiencies in free fatty acid such as omega-3 free fatty acid, omega-6 free fatty acid, and linolenic acid. This supplementation is usually achieved with capsule-containing oils or diets rich in fish products.

If patients adhere to any of these diets, the nurse should support the patient and family in providing the nutritional information needed for the diet. Additionally, the patient and family will need education regarding those foods that are chemical free. A referral to a dietitian will benefit both patient and family.

Children with ADHD seem to be more susceptible to being overweight and developing obesity (Fuemmeler et al., 2020). An estimated 35% of individuals with ADHD are either obese or overweight (Li et al., 2020). Because of the

impulsivity and inattention characteristic of ADHD, these children may be unable to self-regulate and engage in healthy eating behaviors. The nurse can help the family and patient structure the external environment so the child has healthy choices available.

Promoting Sleep

Sleep can be a problem for children with ADHD for many reasons. The overactivity of the disorder itself and the side effects of the psychostimulants contribute to sleep problems. A sleep history should be taken before medications are prescribed. If problems exist, atomoxetine (Strattera) should be considered before the psychostimulants (see next section). If sleep problems arise while taking medications, sleep diaries should be kept. Sleep hygiene and behavior therapy techniques should be implemented (Um et al., 2017). See [Chapter 34](#).

Using Pharmacologic Interventions

Approved medications for ADHD in children as young as 6 years of age include stimulants and nonstimulants. Psychostimulants, including methylphenidate (Ritalin), dextroamphetamine, and mixed amphetamine salts (see [Chapter 12](#)), are by far the most commonly used medications for the treatment of ADHD and are found to be effective in reducing ADHD symptoms in 70% to 80% of children. These medications enhance dopamine and norepinephrine activity which and thereby improve attention and focus, decrease hyperactivity and impulsivity, and decrease disruptive behaviors (CDC, 2020c; Chang et al., 2020; Feldman et al., 2018; NIMH, 2019a).

Methylphenidate has a total duration of action of about 4 hours ([Box 37.4](#)). Thus, parents or teachers often describe a return of overactivity and distractibility as the first dose of medication wears off. This “rebound effect” can often be managed by moving the second dose of the day slightly closer to the first dose. Longer-acting preparations of methylphenidate, such as Concerta, Ritalin LA, and Metadate ER or amphetamine–dextroamphetamine (Adderall XR), do not require such frequent dosing and may be a better fit with a school day schedule. The most common side effects associated with stimulants for ADHD include appetite suppression, insomnia, dry mouth, and nausea (Posner et al., 2020). Drug holidays are sometimes implemented to determine the need for continued medication and to manage side effects (Chang et al., 2020).

Box 37.4

Methylphenidate (Ritalin)

DRUG CLASS: Central nervous system stimulant

RECEPTOR AFFINITY: The mechanisms of pharmacologic effect are not completely clear. At low doses, it provides mild cortical stimulation similar to that of amphetamines. This stimulation results from methylphenidate's ability to promote release and interfere with the reuptake of dopamine in the synaptic cleft. Main sites appear to be the brain stem arousal system and cortex to produce its stimulant effect.

INDICATIONS: Treatment of narcolepsy, attention-deficit disorders, and hyperkinetic syndrome.

ROUTES AND DOSAGE: Available in 5- to 10-mg immediate-release tablets and 20-mg sustained-release tablets (Ritalin-SR). Newer long-acting preparations such as Concerta and Metadate, in various dose strengths, are also available.

Adult Dosage: Must be individualized; range from 10 to 60 mg/day orally in divided doses bid (twice a day) to tid (three times a day), preferably 15 to 30 minutes before meals. If insomnia is a problem, drug should be administered before 6 PM.

Child Dosage: The immediate-release formulation can be started at 5 mg twice or three times daily on a 4-hour schedule with weekly increases depending on response. Starting doses of the long-acting preparations are equivalent to the total tid dose (e.g., 5 TID of short acting would translate into 18 mg of Concerta). Usually given on a tid schedule, with the last dose being roughly half that of the first and second dose. Daily dosage of more than 60 mg is not recommended. Discontinue after 1 month if no improvement is seen.

PEAK EFFECT: 1 hour; half-life: 3 to 4 hours for the immediate-release preparations

SELECT SIDE EFFECTS: Nervousness, insomnia, dizziness, headache, dyskinesias (including tics), toxic psychosis, anorexia, nausea, abdominal pain, increased pulse and blood pressure, palpitations, tolerance, psychological dependence.

WARNING: The drug is discontinued periodically to assess the patient's condition. Contraindications include marked anxiety, tension and agitation, glaucoma, severe depression, and obsessive–compulsive symptoms. Use cautiously in patients with a personal or family history of tic disorders, seizure disorders, hypertension, drug dependence, alcoholism, or emotional instability.

SPECIFIC PATIENT AND FAMILY EDUCATION

- Do not chew or crush sustained-release tablets; they must be swallowed whole.
- Take the drug exactly as prescribed; if insomnia is a problem, the time and dose may need adjustment. The drug is rarely taken after 5 PM.
- Avoid alcohol and over-the-counter products, including decongestants, cold remedies, and cough syrups; these could accentuate side effects of the stimulant.
- Keep appointments for follow-up, including evaluations for monitoring the child's growth and use of parent and teacher ratings to monitor benefit.
- Note that the prescriber may discontinue the drug periodically to confirm effectiveness of therapy.

One major concern with the psychostimulants is the potential for abuse. With the increase in recognition of ADHD, psychostimulant prescriptions have increased, as well as an increase in diversion for cognitive enhancement or appetite suppression. These abused prescription medications are most often acquired from peers who share, sell, or trade their medication. Nurses should caution parents about the potential for abuse and prevent their child's medication from being a source of recreational use (Chaplin, 2018; Molina et al., 2019).

Nonstimulant medications do not work as quickly as stimulants, though they are an alternative for those who do not tolerate stimulants well, when a stimulant is ineffective, or in combination with a stimulant to increase effectiveness. The three Food and Drug Administration (FDA)-approved non-stimulants for ADHD are a norepinephrine uptake inhibitor (atomoxetine [Strattera]), and alpha-2 receptor agonists (guanfacine [Intuniv] and clonidine [Kapvay] (CDC, 2020c; NIMH, 2019a; Posner et al., 2020). Nonstimulants are less likely to be abused or misused than stimulant medications due to a lack of immediacy of effect (a lower speed of action and feeling stimulated) and therefore are often used for those who are more likely to be substance dependent (Feldman et al., 2018). These medications are generally well tolerated in children and adults. Common side effects associated with atomoxetine include gastrointestinal (GI) symptoms, somnolence, headaches, moodiness, and irritability. The more commonly reported adverse effects by individuals taking the alpha-2 receptor agonists include fatigue, sedation, and somnolence (Chang et al., 2020; Feldman et al., 2018).

Teaching Points

Medication can help the child's hyperactivity, impulsiveness, and inattention; therefore, teaching the parent, child, and school personnel about the importance of the medication in ADHD and the potential side effects is a place to begin. Explaining to the child that the medication improves concentration and the ability to sit still can help strengthen patient motivation.

Many times parents are reluctant to initiate treatment with psychostimulants because of the fear that their use in childhood will increase the risk of using substances in adulthood. Studies show that children and adolescents who have taken stimulants medications for ADHD are no more likely to develop later substance use than those who did not take stimulant medications (National Institute on Drug Abuse [NIDA], 2018). Teaching patients and families about the biologic basis of ADHD helps parents understand that these children are not "bad" kids but that they have problems with impulse control and attention. It may be helpful to review the purposes of the medications and assure parents that evidence shows medications help most affected children.

Psychosocial Interventions

Behavioral programs based on rewards for positive behavior, such as waiting turns and following directions, can foster new social skills. Behavioral parent training, behavioral classroom management, and behavioral peer interventions are well-established treatments. Specific cognitive behavioral techniques are helpful in which the child learns to “stop, look, and listen” before doing. These approaches have been refined and several useful recommendations are available (Chang et al., 2020; Feldman et al., 2018; Posner et al., 2020). In general, interactions with children can be guided by the following:

- Set clear limits with clear consequences. Use few words and simplify instructions.
- Establish and maintain a predictable environment with clear rules and regular routines for eating, sleeping, and playing.
- Promote attention by maintaining a calm environment with few stimuli. These children cannot filter out extraneous stimuli and react to all stimuli equally.
- Establish eye contact before giving directions; ask the child to repeat what was heard.
- Encourage the child to do homework in a quiet place.
- Help the child work on one assignment at a time (reward with a break after each completion).

Family treatment is nearly always a component of cognitive behavioral treatment approaches with the child. This may involve parent training that focuses on principles of behavior management, such as appropriate limit setting and use of reward systems, as well as revising expectations about the child's behavior. School programming often involves increasing structure in the child's school day to offset the child's tendency to act without forethought and to be easily distracted by extraneous stimuli. Specific remediation is required for the child with comorbid deficits in learning or language. Some children may require small self-contained classrooms.

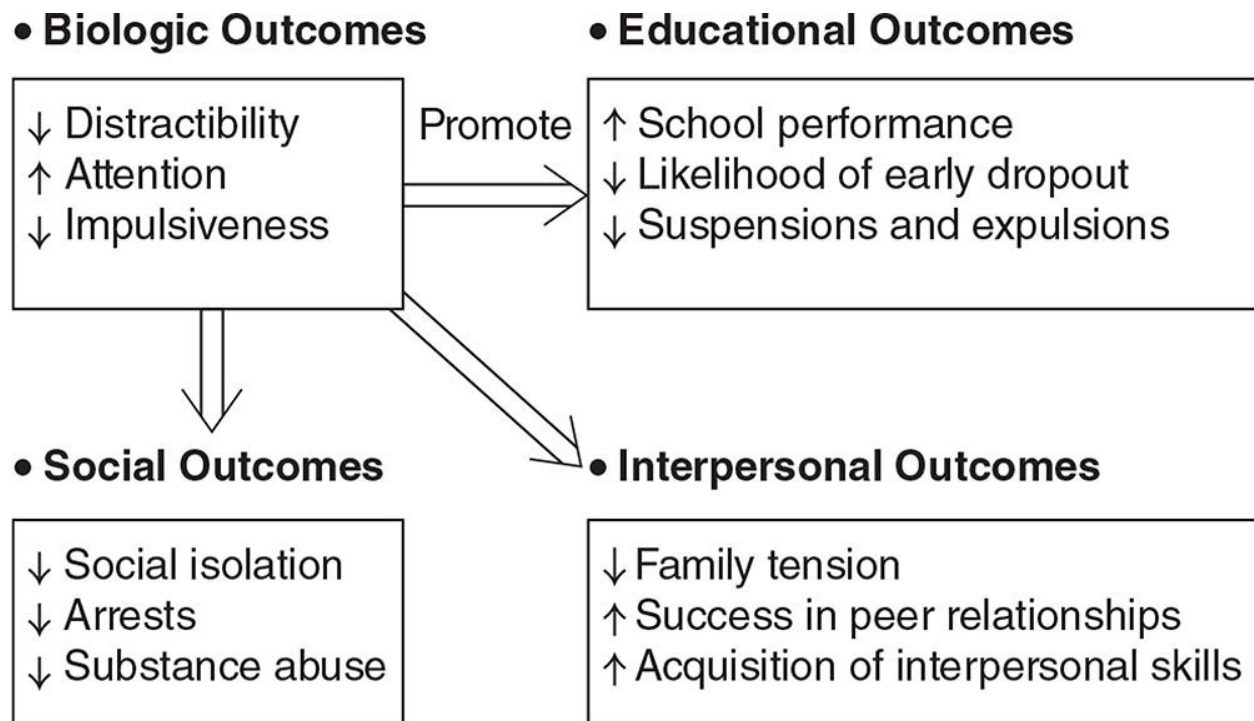

FIGURE 37-2: Long-term outcomes of optimal treatment for patients with attention-deficit hyperactivity disorder.

Evaluation and Treatment Outcomes

Children may not notice any effects after taking medication, but people in their environment do. Often, within 1 to 2 weeks of initiating therapy, children with ADHD become more attentive, less impulsive, and less active. Parents and teachers are often the first to notice improvement. With time, academic achievement also may improve (Figure 37.2).

Continuum of Care

Treatment of ADHD typically is conducted in outpatient settings. Optimal treatment is multimodal (i.e., includes several types of interventions), encompassing four main areas: individual treatment for the child, family treatment, school accommodations, and medication. Parent training and social skills training also help diminish disruptive and defiant behavior.

DISRUPTIVE BEHAVIOR DISORDERS

The **disruptive behavior disorders**, which include oppositional defiant disorder and conduct disorder, are a group of conditions marked by significant problems of conduct. Behaviors associated with these disorders violate the rights of others and/or are in conflict with societal norms (APA, 2013).

Oppositional defiant disorder is characterized by a persistent pattern of disobedience, argumentativeness, angry outbursts, low tolerance for frustration, and tendency to blame others for misfortunes, large and small. Children with oppositional defiant disorder have trouble making friends and often find themselves in conflict with adults. See [Box 37.5](#).

BOX 37.5 CLINICAL VIGNETTE

LEON (CONDUCT DISORDER)

- Leon, a 14-year-old Puerto Rican boy, was admitted to the child psychiatric inpatient service from the emergency department (ED) after a fight with his mother. His mother reported that she and Leon had argued earlier in the evening and that he stormed out of the house screaming and vowing he would never return. Several hours later, Leon came back, yelling and demanding entry into the apartment. Leon's father was working. While his mother was getting up to open the door, Leon continued to yell and scream, waking the neighbors. This led to further arguing between Leon and his mother. Before long, the police were called, and Leon was taken to the ED.
- The admission interview revealed that Leon had run away on several occasions and had even stayed away overnight. Although he strongly denied drug use, he had gotten drunk on several occasions. He had also been in several fights, the latest of which resulted in an expulsion from school. Three months before admission, he was caught trying to steal a CD from a music store. More recently, he boasted that he and his friends had snatched a purse at an outdoor concert and had broken into a car to steal its contents. Leon's school performance has been declining; he was truant on several occasions and will probably have to repeat ninth grade.
- Leon was born in Puerto Rico and is the oldest of three children. His family moved to the mainland shortly after his birth, and the primary language at home is Spanish. His father is employed as a janitor and speaks very little English. His mother works as a secretary and has achieved fairly good command of English. He has received no treatment except for consultation with the school social worker.

What Do You Think?

- When conducting a nursing assessment, what would you want to learn about Leon's school performance?
- What information could you provide Leon's parents about pharmacotherapy? About behavior management?

Conduct disorder is characterized by more serious violations of social norms, including aggressive behavior, destruction of property, and cruelty to animals. Children and adolescents with conduct disorder often lie to achieve short-term ends, may be truant from school, may run away from home, and may engage in petty larceny or even mugging.

Epidemiology

Disruptive behavior disorders are more common in boys and are associated with lower socioeconomic status and urban living (Miranda-Mendizabal et al., 2019). These disorders are relatively common in school-aged children and are frequently presenting complaints in child psychiatric treatment settings.

The prevalence of conduct disorder estimates range from 2% up to 10% with a median of 4%. The disorder appears to be fairly consistent across various countries that differ in race and ethnicity. Prevalence rates rise from childhood to adolescence and are higher among males than among females. Males with conduct disorder frequently are involved in fighting, stealing, vandalism, and school disciplinary problems. Females with the diagnosis are more likely to practice lying, truancy, running away, substance use, and prostitution. Whereas males tend to exhibit both physical aggression and relational aggression (i.e., behaviors that harm social relations of others), females tend to exhibit relatively more relational aggression (APA, 2013). Conduct disorder is one of the most frequently diagnosed disorders in children in mental health facilities. Individuals with conduct disorder are at greater risk for experiencing mood or anxiety disorders and substance-related disorders (APA, 2013).

Etiology

The etiologies of oppositional defiant disorder and conduct disorder are complex. More attention has been paid to conduct disorder, probably because it is the more serious of the two. Models used to understand aggressiveness (see [Chapter 20](#)) are useful in examining these childhood disorders, which appear to have both genetic and environmental components.

Mental Health Nursing Assessment

The nurse gathers data from multiple sources. Adolescents with these disorders are at high risk for physical injury as a result of fighting and impulsive behavior. Sexual promiscuity is common, resulting in an increased frequency of pregnancy and sexually transmitted diseases.

An important aspect of assessment is to rule out comorbid conditions that may partially explain or complicate the person's lack of behavioral control. These conditions include ADHD, learning disabilities, chemical dependency, depression, bipolar illness, or generalized anxiety disorder. Young people who are chronically depressed may be irritable and easily frustrated. Given the tendency of adolescents to act out their frustration, chronic depression may exacerbate their behavior. Conduct problems can also elevate the risk for depression because young people who regularly elicit negative attention from parents and teachers and are constantly at odds with their environment may become despondent.

Adolescents with conduct problems are usually brought or forced into the mental health system by family, school, or the court system because of fighting, truancy, speeding tickets, car accidents, petty crimes, substance abuse, or suicide attempts. These young people may be hostile, sarcastic, defensive, and provocative. At the same time, they may appear calm, outgoing, and engaging. Inconsistencies, distortions, and misrepresentations of the truth are common when interviewing these children, so obtaining a clear history may be difficult. Therefore, instead of asking whether an event or behavior occurred, it may be better to ask when it occurred. These adolescents are adept at changing the subject and diverting discussions from sensitive issues. They often use denial, projection, and externalization of anger as defense mechanisms when asked for self-disclosure. The assessment, which may take several sessions, should be conducted in a nonjudgmental fashion. High levels of marital conflict, parental substance abuse, and parental antisocial behavior often mark family history.

Priority of Care

After patient and staff safety are established, improving communication and coping skills should be the patient's priorities. The nurse can help the patient develop insight into the need for enhanced communication and positive coping.

Nursing Interventions

Children with oppositional defiant disorder or conduct disorder who also have specific neurodevelopmental disorders should be placed in appropriate programs for remediation. If a diagnosis of ADHD or depression emerges from the evaluation, appropriate pharmacotherapy should be considered (see previous discussion of ADHD and after the discussion regarding depression). In planning interventions for patients with oppositional defiant disorder or conduct disorder, the focus is on problem behaviors. Therapeutic progress may be slow, at least partly because these patients often lack trust in authority figures.

Social Skills Training

The nurse should communicate behavioral expectations clearly and enforce them consistently. Consequences of appropriate and inappropriate actions also should be clear. Specific approaches for improving social and problem-solving skills are fundamental features for school-aged children and adolescents. Insofar as children and adolescents with conduct problems fail to recognize the adverse effects of their verbal and nonverbal behavior, their deficit can be formulated as an interpersonal problem. Social skills training teaches adolescents with these behavior disorders to recognize the ways in which their actions affect others. Training involves techniques such as role-playing, modeling by the therapist, and giving positive reinforcement to improve interpersonal relationships and enhance social outcomes.

Problem-Solving Therapy

In contrast to social skills training, which proposes that problems of conduct are the result of poor interpersonal skills, problem-solving therapy conceptualizes conduct problems as the result of deficiencies in cognitive processes. These processes include assessment of situations, interpretation of events, and

expectations of others that are congruent with behavior. These children often misinterpret the intentions of others and may perceive hostility with little or no cause. Problem-solving skills training teaches these children to generate alternative solutions to social situations, sharpen thinking concerning the consequences of those choices, and evaluate responses after interpersonal conflicts.

Parent Management Training and Education

Parent training begins with educating parents about disruptive behavior disorders, focusing particularly on impulsiveness, impaired judgment, and self-control. Children with long-standing problems in these areas often elicit punitive responses and negative attributions about their behavior from their parents. Ironically, because these parental responses focus on the child's failure, they may contribute to the child's behavior problems. An important second step is to clarify parental expectations and interpretation of the child's behavior. Parent management training may be offered to a group of parents or to individuals.

The aims of education are to provide parents with new ways of understanding their child's behavior and to promote improved interactions between parent and child. The most commonly presented techniques include the importance of positive reinforcement (praise and tangible rewards) for adaptive behavior, clear limits for unacceptable behavior, and use of mild punishment (e.g., a time out) (Box 37.6).

Referral to Family Therapy

Family therapy is directed at assisting the family with altering maladaptive patterns of interaction or improving adjustment to stressors, such as changes or loss in family membership. Multisystem family therapy, which considers the child in the context of multiple family and community systems, has shown promise in the treatment of adolescents with conduct disorder.

Evaluation and Treatment Outcomes

The nurse can review treatment goals and objectives to assess the child's

progress with respect to verbal and physical aggression, socially appropriate resolution of conflicts, compliance with rules and expectations, and better management of frustration. As is true for the initial assessment, evaluation of treatment outcomes relies on input from parents, teachers, and other health care team members.

BOX 37.6

Time-Out Procedure

Labeling behavior: Identify the behavior that the child is expected to perform or cease. The aim of this statement is to make clear what is required of the child. It typically takes the form of a simple declarative sentence:

“Threatening is not acceptable.”

Warning: In this step, the child is informed that if they do not perform the expected behavior or stop the unacceptable behavior, they will be given a “time out.” “This is a warning: if you continue threatening to hit people, you’ll have a time out.”

Time out: If the child does not heed the warning, they are told to take a time out in simple straightforward terms: “Take a time out.”

Duration: The usual duration for a time out is 5 minutes for children 5 years of age or older.

Location: The child sits in a designated time-out chair without toys and without talking. The chair should be located away from general activity but within view. A kitchen timer can be used to mark the time, but the clock does not start until the child sits quietly in the designated spot.

Follow-up: The child is asked to recount why they were given the time out. The explanation need not be detailed, and no further discussion of the matter is required. Indeed, long discourse about the child’s behavior is not helpful and should be avoided.

Continuum of Care

Children and adolescents with conduct disorders may be involved with many

different agencies in the community, such as child welfare services, school authorities, and the legal system. Mental health services are requested when a child or adolescent's behavior is out of control or a when comorbid disorder is suspected. Helping the patient and family negotiate their way through this maze of services may be an essential part of the treatment plan.

TIC DISORDERS AND TOURETTE SYNDROME

Tics are a part of several mental health problems. **Motor tics** are usually quick jerky movements of the eyes, face, neck, and shoulders, although they may involve other muscle groups as well. Occasionally, tics involve slower, more purposeful, or dystonic movements. **Phonic tics** typically include repetitive throat clearing, grunting, or other noises but may also include more complex sounds, such as words; parts of words; and in a minority of patients, obscenities. Transient tics by definition do not endure over time and appear to be fairly common in school-aged children. *Tic disorder* is a general term encompassing several syndromes that are chiefly characterized by motor tics, phonic tics, or both.

KEYCONCEPT Tics are sudden, rapid, repetitive, stereotyped motor movements or vocalizations.

Tourette Syndrome, the most severe tic disorder, is defined by multiple motor and phonic tics for at least 1 year. Because no diagnostic tests are used to confirm this disorder, the diagnosis is based on the type and duration of tics present (Gill & Kompoliti, 2020). Early symptoms of Tourette syndrome typically occur in early childhood, with an average onset between the ages of 3 and 9 years (National Institute of Health, National Institute of Neurologic Disorders and Stroke [NIH NINDS], 2020). The average age when symptoms are most severe is 9 years old. Motor tics generally precede phonic tics, and parents often describe the seeming replacement of one tic with another. In addition to this changing repertoire of motor and phonic tics, Tourette syndrome exhibits a waxing and waning course. The child can suppress the tics for brief periods. Thus, it is not uncommon to hear from parents that their child has more frequent tics at home than at school. Older children and adults may describe an urge or a physical sensation before having a tic. The general trend is for tic symptoms to decline by early adulthood.

Epidemiology and Etiology

Studies estimate that 1 out of every 162 children (0.6%) has Tourette syndrome, of which only half are diagnosed. Among those diagnosed, 37 report moderate to severe symptoms. Symptoms generally occur for around 2 years before receiving a formal diagnosis. Tourette syndrome is more common in boys than girls. Though Tourette syndrome is found in all racial and ethnic groups, non-Hispanic White children are twice as likely to have a diagnosis than Hispanic and non-Hispanic Black children. It is not uncommon for children diagnosed with Tourette syndrome to have a comorbid mental, behavioral, or developmental disorder. More than a third of individuals with Tourette syndrome have OCD. Other comorbid diagnoses include ADHD (63%), anxiety (49%), learning disabilities (47%), ASD (35%), developmental delays (30%), behavioral problems (26%), and depression (25%). In addition, over 40% of children with Tourette syndrome have a co-occurring chronic health condition (CDC, 2020e).

The precise nature of the underlying pathophysiology in this primarily inherited disorder is unclear, but the basal ganglia and functionally related cortical areas are presumed to play a central role. Findings from neuroimaging studies are consistent with the presumption that a dysregulation of the cortico-striatal–thalamic circuitry of the brain underlies Tourette syndrome. Additionally, multiple genes on different chromosomes interacting with environmental factors are involved. Several neurotransmitters (dopamine, serotonin, and norepinephrine) have been implicated in the etiology of Tourette syndrome (Kanaan et al., 2017; NIH NINDS, 2020).

Family Response to Disorder

Before evaluation and diagnosis of Tourette disorder, most families struggle with various explanations for the child's tics. Because tics fluctuate in severity with time and may be more prominent in some settings than in others, family members may have difficulty understanding their involuntary nature. Some

parents may be convinced that the tics are deliberate and done to secure attention; others may judge that the tics are “nervous habits” indicative of underlying trouble. Such views require reconciliation with the currently accepted view that tics are involuntary. Some parents may conclude that the child is incapable of controlling any behavior because of Tourette disorder. They may subsequently feel uncertain about setting limits. In these families, delineating the boundaries of Tourette syndrome can be helpful (CDC, 2020e).

On learning that this disorder is probably genetic, some parents may harbor guilt for having passed it on to their child. The nurse can assist such families by listening to these concerns and providing information about the natural history of Tourette disorder—it is not a progressive condition, tics often diminish in adulthood, and it need not restrict what the child can achieve in life.

Evidence-Based Nursing Care for Children with Tourette Syndrome

Mental Health Nursing Assessment

Nursing assessment of a child with tics includes a review of the onset, course, and current level of the symptoms. Goals of the assessment are to identify the frequency, intensity, complexity, and interference of the tics and their effects on functioning; determine the child’s level of adaptive functioning; identify the child’s areas of strength and weakness in general and in school; and identify social supports for the child and family.

Another important aspect of the assessment is to determine the effects of the tic symptoms on the child and family. Some children and families adjust well; however, others are embarrassed or devastated and tend to withdraw socially. Because of the likelihood of comorbid mental, behavioral, or developmental disorders, in addition to inquiring about tics, the nurse should assess the child’s overall development, activity level, and capacity to concentrate and persist with a single task, as well as explore repetitive habits and recurring worries.

Clinical Judgment

Children with Tourette syndrome typically have normal intelligence, but their

tics can interfere with their ability to relate to others and perform well in school. The nurse should determine the degree of anxiety experienced by the child, the impact of the tics on the child's ability to cope, and whether the tics contribute to interference with social relationships and interactions.

Nursing Interventions

The approach to planning nursing interventions depends on the primary source of impairment: tics themselves; OCD symptoms; or the triad of hyperactivity, inattention, and poor impulse control. The nurse can provide counseling and education for the patient, education for the parents, and consultation for the school. Most children and their families need some education about Tourette syndrome. Individual psychotherapy with a mental health specialist (e.g., a psychologist or an advanced practice nurse) may be indicated for some children and adolescents with Tourette syndrome to deal with maladaptive responses to the chronic condition. There is evidence that comprehensive behavior therapy is effective in reducing the tics (Pringsheim et al., 2019).

Medications

Two classes of drugs are commonly used in the treatment of tics: antipsychotics and α -adrenergic receptor agonists. Aripiprazole is replacing the use of older antipsychotics, such as haloperidol and pimozide (Yang et al., 2020). These potent dopamine blockers are often effective at low doses. Attempts to eradicate all tics by increasing the dosages of these antipsychotics almost certainly will result in diminishing therapeutic returns and additional side effects. The most frequently encountered side effects include drowsiness, dulled thinking, muscle stiffness, akathisia, increased appetite and weight gain, and acute dystonic reactions. Long-term use carries a small risk for tardive dyskinesia.

Psychoeducation

Teachers, guidance counselors, and school nurses may need current information about Tourette syndrome and its related problems. Discussions with school personnel often include issues such as how to deal with tic behaviors that are

disruptive in the classroom, how to manage teasing from other children, and how to handle medication side effects. A careful discussion of the boundaries of Tourette syndrome and tic symptomatology usually can resolve these matters. Teachers who understand the involuntary nature of tics can often generate creative solutions, such as excusing the child to do errands. This strategy allows the child to step out of the classroom briefly to release a bout of tics, thereby reducing stress. In some situations, a brief presentation about Tourette syndrome to the class will reduce teasing and help both teachers and classmates tolerate the tic symptoms ([Box 37.7](#)).

Before initiating these interventions with the school personnel, it is essential to identify the child's needs and to pursue these strategies in collaboration with the family and other clinical team members. The Education for the Handicapped Act (Public Law 94–142) ensures that children with conditions such as Tourette Syndrome are eligible for special education services even if they do not meet full criteria for having a learning disability. Thus, if evidence shows that Tourette disorder is hindering academic progress, parents can demand special education services for their child. Nurses can help families negotiate with the school to obtain appropriate services.

Evaluation and Treatment Outcomes

Treatment outcomes will vary over the years and will be influenced by growth and development changes, family interaction and understanding of the disorder, and reduction or elimination of the frequency of the tics. Outcomes should include improvement of the child's quality of life and ability to learn to manage the symptoms of the disorder.

SEPARATION ANXIETY DISORDER

Separation anxiety is normal for very young children, but typically declines between ages 3 and 5 years. When the child's fear and anxiety around separation become developmentally inappropriate, separation anxiety disorder is diagnosed. Separation anxiety disorder is the most common childhood anxiety disorder and occurs at a mean age of 7 years (Vaughan et al., 2017). Although many children experience some discomfort on separation from their attachment figures,

children with separation anxiety disorder suffer great worry or fear when faced with ordinary separations or being away from home, such as when going to school. When separation is about to occur, children often resist by crying or hiding from their parents (Phillips et al., 2020). When asked, most children with separation anxiety disorder will express worry about harm to or permanent loss of their major attachment figure. Other children may express worry about their own safety. For a discussion of other anxiety disorders, see [Chapter 27](#).

A common manifestation of anxiety is school phobia, in which the child refuses to attend school, preferring to stay at home with the primary attachment figure. The term *school phobia* was coined to distinguish it from truancy; whether it is a phobia in the usual sense is a matter of some debate. However, school phobia is common in other disorders such as general anxiety disorder, social phobia, OCD, depression, and conduct disorder. When a comorbid disorder such as depression is identified, it becomes the focus of treatment. In some cases, school phobia may resolve when the primary disorder is successfully treated.

BOX 37.7 • TICS AND DISRUPTIVE BEHAVIORS

INEFFECTIVE APPROACH

Teacher: I see the tics. He jerks his head, makes faces, and flicks his hands.

Nurse: What do you do about them?

Teacher: What can I do? If he isn't disrupting the class, I leave him alone. Even when he is throwing spitballs.

Nurse: Spitballs! He shouldn't be allowed to throw spitballs.

Teacher: Oh, I thought that was a part of his problem.

Nurse: Well, throwing spitballs has nothing to do with tics.

EFFECTIVE APPROACH

Teacher: I see the tics. He jerks his head, makes faces, and flicks his hands.

Nurse: He cannot help the tics that you are seeing. Tic disorders can exhibit a wide range of severity, from mild to severe and from simple to complex. Some complex tics may be difficult to distinguish from habits or

rituals.

Teacher: What about things like throwing spitballs? When he does things like that, I try to ignore that behavior.

Nurse: Sounds like you give him the benefit of the doubt. (Validation) However, throwing a spitball is not a tic behavior.

Teacher: What should I do?

Nurse: How do you usually handle that type of behavior? (A modification of reflection)

Teacher: I'd ask him to stop and sometimes go into the hall.

Nurse: Disruptive behavior that is voluntary in a student with a tic disorder should be handled as you would handle any other child.

CRITICAL THINKING CHALLENGE

- Compare the responses of the nurse in these scenarios. What made the difference in the teacher's responsiveness to the nurse?

Epidemiology and Etiology

Separation anxiety disorder is estimated at 1% to 4% of school-aged children between ages 5 and 11 years (Vaughan et al., 2017). Insecure attachment, difficult temperaments, and genetic factors contribute to the development of separation anxiety disorder. Anxiety disorders are often familial, so it appears that both environmental and genetic factors affect the risk for separation anxiety disorder. For example, separation anxiety may emerge after a move, change to a new school, or death of a family member or pet.

No single etiologic factor, but instead several risk factors are associated with the onset of the disorder. For example, children of parents with at least one anxiety disorder have an increased risk of also having an anxiety disorder. The risk increases even more when two parents are affected (Lawrence et al., 2019).

Family Response to Disorder

There is no single family response to a child who is experiencing separation anxiety. Parenting style, life events, and environmental factors vary from family to family. The family dynamics related to the child's behavior have to be carefully assessed. In some instances, the family may be undergoing a separation of a significant family member through death, divorce, or military deployment. In other situations, the arrival of a new family member may precede the child's separation anxiety. A family assessment is important in determining the relationship of the child's fears and anxiety and the family dynamics.

Teamwork and Collaboration: Working toward Recovery

An interdisciplinary approach is needed for the treatment of separation anxiety disorder. Effective treatment includes child and parent psychoeducation, school consultation, cognitive behavioral therapy, and selective serotonin reuptake inhibitors (SSRIs) (Vaughan et al., 2017).

Evidence-Based Nursing Care for Children with Separation Anxiety Disorder

School refusal is often what prompts the family to seek consultation for the child. Because school refusal can be a behavioral manifestation of several different child psychiatric disorders, it requires careful assessment. Issues to consider are whether the parents have been aware that the child is avoiding school (separation anxiety vs. truancy); what efforts the family has used to return the child to school; the presence of significant subjective distress in the child with anticipation of going to school; and whether the school refusal occurs in the

context of other behavioral, social, or emotional problems. The nurse should also review the purpose and dose of current medications.

The child's developmental history and response to new situations and prior separations provide essential background information for understanding the child's current separation anxiety. The assessment should also include a review of recent life events and the methods the family has used to promote the child's return to school. Finally, the family history with respect to anxiety, panic attacks, or phobias is also informative.

Nursing priorities will depend on the role of the nurse (school nurse, acute care, or community practice) and the relationship with the child and family. In some instances, the nurse will be responsible for education of the child and family. If the child is receiving medication, nursing care related to administration of medications and education should be implemented. Nurses will also be involved in educating teachers and serving as a liaison between treating physicians, family and child, and school.

OBSESSIVE–COMPULSIVE DISORDER

OCD is characterized by intrusive thoughts that are difficult to dislodge (i.e., obsessions) or ritualized behaviors that the child feels driven to perform (i.e., compulsions) (see [Chapter 27](#)). Children tend to exhibit both multiple obsessions and compulsions that relate to fear of catastrophic family event, contamination, sexual or somatic obsessions, and overly moralistic thoughts. Washing, checking, repeating, and ordering are the most commonly reported compulsions (Geller, 2016).

Epidemiology and Etiology

The prevalence rate of OCD is estimated at 1% to 2% with two peaks of incidence across the life span, one occurring in preadolescent children and later a peak in early adult life (Geller, 2016). More than half of the cases of OCD in youth involve a comorbid disorder such as a tic, mood, or anxiety disorder. The etiology of OCD in children is thought to be similar to that of adults (see [Chapter 26](#)). However, there is a subset of children whose OCD behavior that

may be related to an immune response to group A beta hemolytic streptococcal infections that led to inflammation of the basal ganglia (Geller, 2016).

Family Response to Disorder

Parents' responses to their child's obsessions and compulsions depend on their understanding of the thoughts and behaviors. Because OCD is highly familial, if the parents are recovering from their disorder, they may be able to support their child's ability to begin to deal with the symptoms. Conversely, the parents may find their child's thoughts and behaviors tiring so they become easily irritated with the multiple obsessions and compulsions. Parents need education and support to help their child.

Teamwork and Collaboration: Working toward Recovery

Interdisciplinary treatment including school personnel is important for the child and family with OCD. Cognitive behavior therapy (CBT), including psychoeducation, cognitive training, exposure and response preventions, and relapse prevention, is the treatment of choice.

Evidence-Based Nursing Care for Children with OCD

Recurrent worries and ritualistic behavior can occur normally in children at particular stages of development. The first step in the assessment of OCD in children is to distinguish between normal childhood rituals and worries and pathologic rituals and obsessional thoughts. Obsessional thoughts are recurrent, nagging, and bothersome. Although children may describe obsessions as occurring "out of the blue," external events may trigger obsessions. For example,

a child may fear contamination whenever they are in contact with a certain person or object. Likewise, compulsions waste time, cause distress, and interfere with daily life (Box 37.8).

The severity of the child's and family's response to OCD will determine the appropriate interventions. When the obsessions and compulsions emerge, these children or adolescents are in distress because of the disturbing and relentless nature of the symptoms.

Nursing interventions will be guided by the needs of the family and the developmental needs of the child or adolescent. If medication is prescribed, it is important to emphasize safe management of medications. Because the antidepressants have a "black box" warning regarding suicide risk in adolescents, the nurse must discuss with the parents and child the importance of monitoring moods and keeping regularly scheduled mental health appointments.

BOX 37.8 CLINICAL VIGNETTE

KIMBERLY AND OBSESSIVE–COMPULSIVE DISORDER

Kim, an 11-year-old fifth grader, comes for evaluation because her mother and teacher have become increasingly concerned about her repetitive behaviors. In retrospect, Kim's mother recalls first noticing repetitive rituals about 2 years before, but she did not become alarmed about these behaviors until recently when they began to interfere with daily living. At the time of referral, Kim exhibits complicated jumping rituals that involve a specific number of jumps and a particular manner of jumping. She also turns light switches off and on and performs complex movements, such as blinking in patterns and thrusting her arms back and forth a certain number of times. Her mother also reports Kim's near-constant request for reassurance about her own safety. In recent months, her incessant demands for reassurance have been more frequent and elaborate. For example, Kim's mother has to answer three times that everything is all right and then say, "I swear to it."

At the evaluation, Kim expresses fears that some ill fate, such as catastrophic illness or injury, will befall her. This fear is triggered by contact with any individual who seems sick, chance exposures to foul smells or dirt, and minor scrapes or bumps. When the fear is triggered, she becomes increasingly anxious and consumed with the fear that she will develop an illness and die. Sometimes her fears are specific, such as cancer or AIDS. Other times her fears are more ambiguous, as evidenced by statements such as, "Something bad will happen" if she doesn't complete the ritual. Kim acknowledges that the ritual is probably not related to the feared event, but she is reluctant to take a chance. If the ritual does not reduce her anxiety, she seeks reassurance from her mother.

Kim's medical history was negative for serious illness or injury. She was born after an uncomplicated pregnancy, labor, and delivery and achieved developmental milestones at appropriate times. Indeed, her mother could recall no unusual problems in the first few years of life except that Kim was typically

anxious in unfamiliar situations. Kim's mother reports a prior history of panic attacks, but the family history is otherwise negative for anxiety disorders, including OCD.

What Do You Think?

- What assessment information would you want to elicit from Kim?
- What additional information should be considered from Kim's mother about her history of panic attacks?
- What nursing interventions should be considered if Kim were your patient?

OTHER NEURODEVELOPMENTAL DISORDERS

Other neurodevelopmental disorders are characterized by a narrower range of deficits. These include specific neurodevelopmental disorders generally classified as learning, communication, and motor skills disorders. This section focuses primarily on learning and communication disorders.

Specific Learning Disorders

Generally, a learning disorder (also called learning disability) is defined as a discrepancy between actual achievement and expected achievement based on the person's age and intellectual ability. The definition varies depending on the source and state statute. Learning disorders are typically classified as verbal (e.g., reading, spelling) or nonverbal (e.g., mathematics).

Reading disability, also called **dyslexia**, has been recognized for more than 100 years. It is defined as a significantly lower score for mental age on standardized tests in reading that is not the result of low intelligence or inadequate schooling. This relatively common problem affects about 5% of school-aged children, with some studies reporting higher prevalence. In clinical samples, dyslexia affects boys more often than girls. This discrepancy can be explained by slower and variable processing speed and less inhibitory control in males than females. Verbal reasoning is a strength in males (Arnett et al., 2017).

Although it is clear that no single cause will provide a sufficient explanation for reading disability, the underlying problem appears to be a deficit in

phonologic processing, which involves the discrimination and interpretation of speech sounds. A disturbance in the development of the left hemisphere is believed to cause this deficit. Both genetic and environmental factors have been implicated in the etiology of reading disability. Data from family studies show that reading disability is familial and that shared environmental factors alone cannot explain the high rate of recurrence in affected families (Becker et al., 2017).

Less is known about the prevalence of specific learning disorder in mathematics (SLDM), with estimates as high as 6% of school-aged children and no apparent difference between boys and girls. In a study of children with SLDM, 20% also had a diagnosis of a language or communication disorder. An association with autism and ADHD was also noted (Morsanyi et al., 2018).

Communication Disorders

Communication disorders involve speech or language impairments. *Speech* refers to the motor aspects of speaking; *language* consists of higher-order aspects of formulating and comprehending verbal communication. Communication disorders are fairly common and are yet more common in children with ASDs, ADHD, anxiety, and conduct disorders (Beitchman et al., 2014). As with reading disability, undoubtedly multiple causes of speech or language deficit may be present.

A delay in speech or language development can adversely affect the child's socialization and education. For example, peers may rebuff or tease a child with an articulation defect or stutter, contributing to withdrawal and a negative self-image. The resulting isolation could limit opportunities to negotiate rules, take turns, and learn cooperation. These same tasks could also be difficult for children with language delay. Moreover, language appears to play a role in the regulation of behavior and impulses (Lyons et al., 2016).

Evidence-Based Nursing Care for Children with Communication Disorders

Nursing assessment of children with a known specific developmental disorder includes (1) evidence of interference in daily life, (2) determination of the child's

ability (and limitations) to communicate during the interview, (3) assessment of the child's perception about their disability, (4) observation for impaired learning and communication, and (5) past and current interventions for the learning or communication deficit with data gathered through direct interview of the child and significant others such as parents. Several nursing diagnoses can be generated from these data, such as impaired verbal communication and social isolation.

For the child with learning disabilities, nurses can focus on building self-confidence and helping the family connect with guidance and educational resources that support the child's development into adulthood. For the child with communication disorders, the interventions focus on fostering social and communication skills and making referrals for specific speech or language therapy. Modeling appropriate communication in spontaneous situations with the child can be a useful intervention for some children. The following is an overview of nursing interventions for the child with specific developmental difficulties:

- Introduce strategies for increasing communication skills (e.g., initiating conversation, taking turns in conversation, facing the listener).
- Identify and develop specific intervention strategies for problems secondary to learning communication disorders, such as low self-esteem.
- Provide parental support for coping with the disorder.
- Maintain interdisciplinary medical, dental, and speech therapy, and also educational collaboration.
- Refer to learning or speech specialist for evaluation and assistance.

Continuum of Care

Children with learning disabilities obviously require careful psychoeducational and cognitive testing to identify their strengths and deficits. School or clinical psychologists usually perform this type of specialized testing. When a learning disability has been identified, the U.S. Education for All Handicapped Children Act (Public Law 94-142) mandates that public school systems provide remedial services in the least restrictive educational setting. Families occasionally need help in advocating for these services.

The same is true for children with communication disorders, although the services requested may be different. Speech pathologists conduct the diagnostic assessment of speech and language disorder. Nurses may be involved with formal screening for communication disorders. Services such as speech therapy (directed at the motor aspects of speaking) or social skills groups (directed at the social and interpersonal aspects of language) are often available in school districts and can be obtained if a speech or language disorder has been identified. For some children with communication disorders, the services offered by the school may be insufficient. In such cases, the nurse can help the family locate a facility that can provide these needed services.

OTHER MENTAL DISORDERS

Mood Disorders

Mood disorders in children and adolescents are a major public health concern. The prevalence of depression is estimated to be 13.3% (3.2 million) of the U.S. population. Rates of depressive episodes are higher in females (20%) as compared to males (6.8%). Approximately 60% of adolescents with depression report not receiving treatment for their illness (NIMH, 2019b). Lifetime prevalence of bipolar disorder among adolescents aged 13 to 18 is estimated to be 2.9%, of which 2.6% have severe impairment. Bipolar disorder in adolescents is found to be higher in females (3.3%) than in males (2.6%). (See [Chapters 25](#) and [26](#) for a complete discussion of these disorders.)

Children with mood disorders may not spontaneously express feelings (e.g., sadness, irritability) and are more likely to show their suffering through their behavior. These children may act out their feelings rather than discuss them. Thus, behavior problems may accompany depression. Reports from parents are important sources of information about changes in sleep patterns, appetite, activity level and interests, and emotional stability.

Priorities of nursing care for children or adolescents who are depressed are similar to those for adults. Treatment goals include improving the mood and restoring sleep, appetite, and self-care. Interventions for responses to mood disorders in children and adolescents are also similar to those for adults. The

psychiatric nurse develops a therapeutic relationship with the child and provides parent education and support. Developing sensitivity to the influence of environmental events on the child is important for the nurse, parents, and teachers (Box 37.9).

Children and adolescents may be treated with medication. Antidepressant medications are used for depression and mood antipsychotics for bipolar disorder. The controversy surrounding the use of SSRIs in children reminds us that all treatments involve a risk–benefit equation. Given the modest benefit of the SSRIs and the potential for side effects, these medications merit careful monitoring in children and adolescents. Patient monitoring should focus on evidence of benefit and side effects, including sleep problems, hyperactivity, sudden changes in mood or behavior, suicidal ideation, or self-injurious behavior.

Box 37.9

Questions, Choices, and Outcomes

Mrs. S has just returned with her son Jared to the child psychiatric inpatient services facility after an overnight pass. She reports that the visit did not go well because of Jared’s anger and defiance. She remarked that this behavior was distressingly similar to his behavior before the hospitalization. She expressed additional concern because of the upcoming discharge from the hospital. After saying goodbye to Jared, she pulled the nurse aside and stated that she had decided to file for divorce.

Mrs. S indicated that she had not told her husband or the family therapist. When asked whether Jared knew about her decision, Mrs. S suddenly realized that he may have overheard her discussing the matter with her sister on the telephone during this home visit.

How should the nurse approach this situation?

Choice	Possible Outcomes
Discuss her hypothesis about Jared’s behavior and his uncertainty	Mother can see relationship between Jared’s behavior and her plan for divorce. Mother ignores the nurse. Mother is interested but does not see the connection.
Ignore the statement	Child and family did not learn about the connection between Jared’s behavior and the events at home.
Encourage Jared’s mother to sort out her problems.	The focus is then on mother’s problems.

ANALYSIS

The best response is focusing on the possible relationship between Jared's recent behavioral deterioration and his uncertainty about his family's future. If the nurse ignores the statement or focuses on the mother's interpretation of Jared's behavior, the mother is less likely to appreciate the connection between her pending divorce and Jared's behavior. The nurse should also emphasize the importance of discussing the matter in family therapy.

Childhood Schizophrenia

Childhood (early-onset) schizophrenia is diagnosed by the same criteria as those used in adults (see [Chapter 24](#)). Difficulty in diagnosing a psychiatric disorder in children has led to years of debate and controversy regarding whether childhood schizophrenia differs from the adult type or is merely an early manifestation of the same disorder. For many years, it was believed that autism represented the childhood form of schizophrenia. However, today autism and childhood schizophrenia are differentiated. As currently defined, childhood schizophrenia (onset before the age of 13 years) is very rare, but prevalence increases sharply during adolescence, especially in young men (Kodish & McClellan, 2016).

Childhood schizophrenia is usually characterized by poorer premorbid functioning than late-onset schizophrenia. Common premorbid difficulties include social, cognitive, linguistic, attentional, motor, and perceptual delays. Taken together, these findings suggest that early-onset schizophrenia is a more severe form of the disorder.

Nursing care for children with schizophrenia follows an approach similar to that for ASD. Antipsychotic medications are not generally approved for use in children, although the newer atypical antipsychotic medications appear to have a lower risk for neurologic effects; other side effects such as weight gain also warrant careful monitoring.

Development of an individualized care plan for children with schizophrenia begins with a nursing assessment to identify functional problems specific to the child. Similarly, the recognition that childhood schizophrenia is a chronic and severe condition should guide the identification of outcomes. Goals should be realistic; the nurse should pay special attention to the child's support systems. Parent education about the disorder, medications, and long-term management (including use of community resources) is an essential part of the treatment plan. Long-term management also requires monitoring of chronic antipsychotic therapy.

ELIMINATION DISORDERS

Enuresis

Enuresis is the involuntary excretion of urine after the age at which the child should have attained bladder control. It usually involves involuntary bed-wetting at night, but repeated urination on clothing during waking hours can occur (diurnal enuresis). Enuresis is a self-limiting disorder, with most children experiencing a spontaneous remission.

Epidemiology and Etiology

The prevalence of nocturnal enuresis varies with age and gender, being most common in young boys—an estimated 5% to 10% of 5-year-old boys, and 3% to 5% in 10-year-old boys have nocturnal enuresis (Mikkelsen, 2014). The frequency in girls is about half that of boys in each age group. The etiology of enuresis is unknown, with probably no single cause. Most children with nocturnal enuresis are urologically normal. Some evidence has shown that at least some children with nocturnal enuresis secrete decreased amounts of antidiuretic hormone during sleep, which may play a role in enuresis (Mikkelsen, 2014).

Nursing Care

Nursing assessment should include the child's developmental history, the onset and course of enuresis, prior treatment, presence of emotional problems, and medical history. The nurse should also explore the family's home environment, family attitudes about the child's enuresis, and the family's medical history. Routine laboratory tests such as urinalysis and a urine culture are used to identify the presence of infection. The nurse should obtain base-line data regarding toileting habits, including daytime incontinence, urinary frequency, and constipation. They should refer children with persistent daytime enuresis for consultation with a urologist.

In many cases, limiting fluid intake in the evening and treating constipation (if

present) is sufficient to decrease the frequency of bed-wetting. One of the most effective methods is the bell and pad. In this approach, the child sleeps on a pad that has wires on it, and when the child voids, a bell sounds, waking up the child. With use, the child either wakes up to urinate or learns to sleep through the night without voiding. A more temporary solution is the use of desmopressin (DDAVP), a synthetic antidiuretic hormone that actually inhibits production of urine. After medication is withdrawn, the enuresis frequently returns (Mikkelsen, 2014).

Encopresis

Encopresis involves soiling clothing with feces or depositing feces in inappropriate places. Additional diagnostic criteria include that the child is older than 4 years; that the soiling occurs at least once per month; and that the soiling is not the result of a medical disorder, such as congenital aganglionic megacolon (Hirschsprung disease). The most common form of encopresis is fecal impaction accompanied by leakage around the hardened mass of stool. Because of the loss of muscle tone in the lower bowel, the child loses the usual urge to defecate and may not feel the leakage. Surprisingly, the child may not detect the smell of the stool because the olfactory apparatus becomes accustomed to the odor. If left untreated, this problem generally resolves independently by middle adolescence. Nonetheless, the social consequences may be substantial (Mikkelsen, 2014).

Epidemiology and Etiology

As with enuresis, encopresis is more common in boys, and the frequency of the condition declines with age. The current estimate of prevalence is 1.5% of school-aged children aged 7 to 8 years old, with boys three times more likely to have encopresis than girls (Mikkelsen, 2014).

The reasons for withholding stool and starting the cycle of fecal impaction are unclear but are not usually the result of physical causes. However, as noted, when fecal impaction occurs, there is an accompanying loss of tone in the bowel and subsequent leakage.

Nursing Care

Assessment includes a detailed interview with the child and parent regarding the pattern of the encopresis. A calm matter-of-fact approach can help to reduce the child's embarrassment. Physical examination is also necessary; thus, collaboration with the child's primary care provider or consulting pediatric specialist is essential. The presence of encopresis does not necessarily signal severe emotional or behavioral disturbances, but the nurse should inquire about other psychiatric disorders. Diagnosis of encopresis is presumed given a history of intermittent constipation and soiling. Collaboration with primary care consultants is often helpful to rule out rare medical conditions, such as Hirschsprung disease.

Effective intervention begins with educating the parents and the child about normal bowel function and the self-perpetuating cycle of fecal impaction and leakage of stool around the hardened mass of feces. The short-term goal of this educational effort is to decrease the anger and recrimination that often complicate the picture in these families. Because encopresis often results in a loss of bowel tone, it may help to motivate children by emphasizing the need to strengthen their anal muscles.

In many cases, cleaning out the bowel is necessary before initiating behavioral treatment. The bowel catharsis is usually followed by administration of mineral oil, which is often continued during the bowel retraining program. A high-fiber diet is often recommended.

The behavioral treatment program involves daily sitting on the toilet after each meal for a predetermined period (e.g., 10 minutes). The child and parents can measure the time with an ordinary kitchen timer. The parents can encourage the child to read or look at picture books while sitting. They can give the child rewards in the form of stars, stickers, or points for complying with the retraining program and add bonuses for successful defecation. The family can tally stickers or points on a calendar, and the child can "cash in" collected points for small prizes.

Caring for children with encopresis on an inpatient unit is a challenge, because very little research provides direction for positive outcomes. Staff can become frustrated with the child's seemingly unwillingness to cooperate. Possible interventions include maintaining discretion, assisting children with the development of age-appropriate social skills and empathy, and providing positive peer pressure (Shepard et al., 2017).

IMPACT OF THE COVID-19 PANDEMIC ON MENTAL HEALTH

The COVID-19 pandemic has had widespread impact on the lives of children and adolescents across the country and around the world. The combination of the public health crisis, social isolation, and economic recession contributes to the development of psychosocial stressors that may result the development of mental health problems or worsen already existing mental health conditions, including an increased risk of post-traumatic stress disorder (PTSD), depression, and anxiety (Golberstein et al., 2020; Guessoum et al., 2020). School closures have affected the lives of an estimated 55 million students across the country, causing significant disruption in students' day-to-day routines. Social isolation and physical distancing resulting in a lack of regular contact with friends is of particular concern in middle childhood and adolescence. Studies have found that when children are out of school, they are more likely to be less physically active, spend more time on electronics/screens, and have inconsistent eating and sleeping patterns (Nearchou et al., 2020). For quite some time, schools have served as a de facto mental health system for children and adolescents. Data from a nationally representative study of adolescents receiving mental health services found that 35% of them received their mental health services exclusively from school settings (Ali et al., 2019). The closure of schools effectively terminates or significantly reduces the availability of some imperative resources. Fortunately, telehealth services have been found to be similarly effective to in-person services, though not all families and schools have the technology to support this. The coordination and partnership of schools and community mental health agencies may allow students to engage in needed mental health treatment (Golberstein et al., 2020). Strategies to help provide stability and support to children and adolescents include establishing and maintaining a normal routine, encouraging expression of thoughts and concerns, providing honest and accurate information, teaching simple steps to maintain health, being attentive to changes in behavior, and reassurance about the child's safety and well-being (Centers for Disease Control and Prevention [CDC], 2020a).

SUMMARY OF KEY POINTS

- An estimated 20% of American youths are affected by a mental disorder that impairs their ability to function.
- In addressing intellectual disabilities, the emphasis is on determining adaptive behaviors (e.g., conceptual skills, concepts, self-direction), social skills, and practical skills. With guidance and education, many children will no longer have a disability as adults.
- Children with ASD benefit from structure and specific behavioral interventions.
- ADHD is defined by the presence of inattention; impulsiveness; and in most cases, hyperactivity. As currently defined, ADHD is the most common disorder of childhood. This heterogeneous disorder affects boys more often than girls. Nursing interventions involve family and child education and support. The family must partner with the school system to help the child receive the best educational experience. Effective treatment of ADHD often involves multiple approaches, including medication and parental education and support.
- Tourette syndrome is a tic disorder characterized by motor and phonic tics. It is a frustrating disorder that requires patience and understanding. About half of the children with this disorder also have ADHD.
- Separation anxiety is relatively common in school-aged children. OCD becomes more common in adolescents. Treatment of separation anxiety and OCD may include medication, behavioral

therapy, or a combination of these treatments.

- Elimination disorders include encopresis and enuresis. Behavioral therapy approaches are the most effective treatment for these disorders. Medication may also be used.
- Major depression in children is believed to be similar to major depression in adults.
- Childhood schizophrenia is a rare disorder, so other diagnoses should be carefully considered. Nursing care is similar to care of children with ASDs.

CRITICAL THINKING CHALLENGES

1. Interview parents of a child with an intellectual disability. Determine their approach to providing support in education and socialization.
2. Examine the differences and similarities between ASD with and without intellectual and language impairment. Determine whether differences exist in the nursing care according to the diagnoses. Develop a teaching plan for parents of children who have ASD and are trying to understand the underlying problems related to the disorder.
3. Compare and contrast nursing approaches for a child with ADHD with those used for a child with ASD. How are they different? How are they similar?
4. Learning disabilities and communication disorders are more common in children with psychiatric disorders than in the general population. How might a learning disability or a communication disorder complicate a psychiatric illness in a school-aged child?
5. How would you answer these questions from a parent: “What causes ADHD? Is it my fault”?
6. A child is threatening to kill himself. What information is needed in order to keep this child safe?

Movie Viewing Guides

Rain Man: (1988). This classic film stars Dustin Hoffman as Raymond Babbitt, a man who has autism (savant). Tom Cruise plays his brother Charlie, a self-centered hustler who believes that he has been cheated out of his inheritance. Discovering Raymond in an institution, Charlie abducts Raymond in a last-ditch effort to get his fair share of the family estate. The story revolves around the relationship that develops as the brothers drive across the country.

Dustin Hoffman brilliantly portrays the behaviors and symptoms of high-functioning autism, such as the monotone speech, insistence on sameness, and repetitive behavior.

VIEWING POINTS: Identify and describe Raymond's ritualistic behaviors. Observe Raymond's language patterns and any distinct abnormalities. What happens when Raymond's rituals are interrupted?

Mental Health Assessment of Older Adults

Mary Ann Boyd

KEYCONCEPTS

- Normal aging
- Psychiatric–mental health nursing assessment for the older adult

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Compare changes in normal aging with those associated with mental health problems in older adults.
2. Select various techniques in assessing older adults who have mental health problems.
3. Delineate important areas of assessment in the geropsychiatric nursing assessment.

KEY TERMS

- Dysphagia
 - Functional activities
 - Instrumental activities of daily living
 - Polypharmacy
 - Xerostomia
-

INTRODUCTION

The average life span in the United States has increased from 47 years in 1900 to more than 78.7 years in 2018 (National Center for Health Statistics, 2020). Healthcare providers will face new and increased challenges as the Baby Boomers—those born between 1946 and 1964—move into the ranks of the older adult population. Between 2020 and 2060, the number of older adults is projected to increase by 69%, from 56.0 million to 94.7 million. The number of people ages 85 and older is projected to nearly triple from 6.7 million in 2020 to 19.0 million by 2060 (Mather & Kilduff, 2020).

Normal aging is associated with some physical decline, such as decreased sensory abilities and decreased pulmonary and immune function, but many important functions do not change. Intellectual function, capacity for change, and productive engagement with life remain stable. Many myths exist about normal aging. Some people believe that “senility” is normal or that depression or hopelessness is natural for older adults. If family members believe these myths, they will be less likely to seek treatment for their older family members with real problems. For example, although some normal cognitive changes contribute to a slower pace of learning, memory complaints are more likely related to depression than normal aging (Aajami et al., 2020).

The most common mental health problems in older persons are depression, anxiety disorders, and dementia which commonly occur with somatic conditions (Morin et al., 2020). Older adults with mental health problems comprise different population groups. One group consists of those with long-term mental illnesses who have reached the ranks of the older adult population. These individuals usually understand their disorders and treatments. Unfortunately, the changes associated with aging can affect a person’s control of their chronic mental illness. Symptoms may reappear, and medications may need to be adjusted. Another group comprises individuals who are relatively free of mental

health problems until their elder years. These individuals, who may already have other health problems, develop late-onset mental disorders, such as depression, schizophrenia, or dementia. For these individuals and their family members, the development of a mental disorder can be very traumatic.

Mental health problems in older adults can be especially complex because of coexisting medical problems and treatments. Many symptoms of somatic disorders mimic or mask psychiatric disorders. For example, fatigue may be related to anemia, but it also may be symptomatic of depression. In addition, older individuals are more likely to report somatic symptoms rather than psychological ones, making identification of a mental disorder even more difficult.

The coronavirus disease 2019 (COVID-19) pandemic hit the older adult group especially hard. High morbidity and mortality rates of COVID-19 were observed throughout the world. Those over the age of 65 were impacted disproportionately with serious consequences of severed illness and hospitalizations. Within this age group, members of underrepresented minority were disproportionately affected by COVID-19 (CDC, 2021). This pandemic has had profound psychological and social effects on the older adult leading to social isolation, distress anxiety, fear of contagion, depression, insomnia, and suicidal ideation (Sher, 2020).

The purpose of this chapter is to present a comprehensive geropsychiatric–mental health nursing assessment process that serves as the basis of care for older adults. A mental health assessment is necessary when psychiatric or mental health issues are identified or when patients with mental illnesses reach their later years (usually about age 65 years). The assessment generally follows the same format as described in [Chapter 11](#). However, the overall healthcare issues for older adults can be very complex, so it follows that certain components of the geropsychiatric nursing assessment are unique. Thus, the geriatric assessment emphasizes some areas that are less critical to the standard adult assessment.

KEYCONCEPT Normal aging is associated with some physical decline, such as decreased sensory abilities and decreased pulmonary and immune function, but many important functions do not change.

BOX 38.1

Changes That Affect Mental Status in Older Adults

- Acid–base imbalance
- Dehydration
- Drugs (prescribed and OTC)
- Electrolyte changes
- Hypothyroidism
- Hypothermia and hyperthermia
- Hypoxia
- Infection and sepsis

TECHNIQUES FOR DATA COLLECTION

The nurse assesses the patient using an interview format that may take a few sessions to complete. They also may rely on self-report standardized tests, such as depression and cognitive functioning tools. A wide variety of physiologic disorders may cause changes in mental status for older adults; thus, results of laboratory tests often are significant. For example, urinalysis can detect a urinary tract infection that has affected a patient's cognitive status. [Box 38.1](#) contains a representative listing of common physiologic causes of changes in mental status. In addition, medical records from other healthcare providers are useful in developing a complete picture of the patient's health status.

An important source of patient data is family members, who often notice changes that the patient overlooks or fails to recognize. A patient with memory impairment may be unable to give an accurate history. By interviewing family members, the nurse expands the scope of the patient assessment. Moreover, the nurse has an opportunity to evaluate the caregivers themselves to determine whether they can care for the patient adequately and how they are coping with the situation. For example, a husband may be unable to care for his wife but is unwilling to admit it. If the nurse can establish rapport with the husband, the nurse may use the assessment interview as an opportunity to help the husband to examine his wife's care requirements realistically.

PSYCHIATRIC–MENTAL HEALTH NURSING

ASSESSMENT OF THE OLDER ADULT

KEYCONCEPT A psychiatric mental health nursing assessment for the older adult is the comprehensive, deliberate, and systematic collection and interpretation of data based on the special needs and problems of the older adult. The purpose is to determine the current and past health, functional status, and human responses to mental health problems, both actual and potential (Box 38.2).

BOX 38.2

Psychiatric–Mental Health Nursing Assessment for the Older Adult

1. Major reason for seeking help _____

2. Initial information

Name _____

Age _____ Current marital status _____

Gender _____ Caregiver's name _____

Living arrangements _____

3. Level of independence:

High (needs no help) _____

Moderate (lives independently, but needs some help with instrumental activities) _____

Low (relies on others for help in meeting functional and instrumental activities) _____

Physical limitations _____

Level of education completed _____

	Normal	Treated	Untreated
Physical functions: system review	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Activity/exercise	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Sleep patterns	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Appetite and nutrition	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Hydration	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>

Sexuality	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>
Existing physical illnesses	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>

List any chronic illnesses _____

Presence of pain (use standardized instrument if pain is present.) No _____ Yes _____

Score _____ Treatment of pain _____

4. Responses to mental health problems

Major concerns regarding mental health problem

Major loss/change in past year: No _____ Yes _____

Fear of violence: No _____ Yes _____

Strategies for managing problems/disorder _____

5. Mental status examination

General observation (appearance, psychomotor activity, attitude) _____

Orientation (time, place, person) _____

Mood, affect, emotions (GDS should be used if evidence of depression) Speech (verbal ability, speed, use of words correctly) _____

Thought processes (hallucinations, delusions, tangential, logic, repetition, rhyming of words, loose connections, disorganized) *(Describe content of hallucinations, delusions.)*

Cognition and intellectual performance *(Use standardized test scores as well as observations.)*

Attention and concentration _____

Abstract reasoning and concentration _____

Memory (recall, short-term, long-term) _____

Judgment and insight _____

6. Significant behaviors (psychomotor, agitation, aggression, withdrawn) *(use standardized test if behaviors are problematic.)*

When did problem behavior begin? Has it gotten worse?

7. Self-concept beliefs about self-body image, self-esteem, personal identity) _____

8. Risk assessment

Suicide: High _____ Low _____ Assault/homicide: High _____ Low _____

Suicide thoughts or ideation: No _____ Yes _____

Current thoughts or harming self _____ Plan _____

Means _____

Means available

Assault/homicide thoughts: No _____ Yes _____

What do you do when angry with a stranger? _____

What do you do when angry with family or partner? _____

Have you ever hit or pushed anyone? No ____ Yes ____

Have you ever been arrested for assault? No ____ Yes ____

Current thoughts of harming others _____

9. Functional status (*use standardized test such as FAQ*) _____

10. Cultural assessment

Cultural group _____

Cultural group's view of health and mental illness _____

By what cultural rules do you try to live? _____

Special, cultural foods that are important to you _____

11. Stresses and coping behaviors

Social support _____

Family members _____

Which members are important to you? _____

On whom can you rely? _____

Community resources _____

12. Spiritual assessment _____

13. Economic status _____

14. Legal status _____

15. Quality of life _____

16. Summary of significant data that can be used in formulating clinical judgment.

SIGNATURE/TITLE _____ Date _____

At the beginning of the assessment, the nurse should determine the patient's ability to participate. A key component in a successful interview with an older adult is the formation of an atmosphere of respect for the person. Use of childlike language with the older adult signifies an ageist attitude and often results in poor communication. For example, if a patient is using a wheelchair, they may have physical limitations that prevent full participation in the assessment. However, physical limitations should not be assumed to indicate decreased mental capacity. The patient must be able to hear the nurse. For a patient with compromised hearing, the nurse must attend to voice projection and volume. Shouting at the older patient is unnecessary. The nurse should remember to lower the pitch of their voice because higher pitched sounds are often lost

with presbycusis (loss of hearing sensitivity associated with aging). The nurse should eliminate distracting noises, such as from a television or radio, and ensure that the patient's hearing aid is in place and turned on. Facing the patient and using distinct enunciation will help lip-reading patients understand what is being said. Sometimes deafness is mistaken for cognitive dysfunction. If a patient's hearing is questionable, the nurse should enlist the help of a speech and language specialist. Generally, the pace of the interview should mirror the patient's ability to move through the assessment. Usually, the pace will be slower than the nurse uses with younger populations.

Physical Assessment

Collecting and analyzing data for the physical assessment include areas similar to those discussed in [Chapter 11](#). The assessment components include present and past health status, physical examination results, physical functioning, and pharmacology review. When focusing on physical health, the nurse pays special attention to the patient's general physical appearance as well as any observable manifestations of illness. The nurse should assess how all physical problems affect the patient's mental well-being. For example, pain and immobility are physical problems that can negatively affect mental health. A low-energy level may be immediately apparent. Women with obvious osteoporosis are experiencing pain most of the time. Men undergoing radiation for prostate cancer worry about sexual functioning and urinary incontinence.

Present and Past Health Status

A review of the patient's current health status includes examining health records and collecting information from the patient and family members. The nurse must identify chronic health problems that could affect mental healthcare. For example, the patient's management of diabetes mellitus could provide clues to the likelihood of complications such as retinopathy or neuropathy, which in turn will affect the patient's ability to follow a mental health treatment regimen. The nurse must document a history of psychiatric treatment.

Physical Examination

The psychiatric nurse reviews the physical examination findings, paying special attention to recent laboratory values, such as urinalysis, white and red blood cell

counts, thyroid studies, and fasting blood glucose data (see [Chapter 8](#)). Results of neurologic tests could indicate compromise of the neuromuscular systems. Many psychiatric medications lower the seizure threshold, making a history of seizures, which can cause behavior changes, an important assessment component. The nurse should note any evidence of movement disorders, such as tremors, abnormal movements, or shuffling. If a patient has been taking antipsychotics, the nurse should consider assessment for symptoms of tardive dyskinesia using one of the appropriate assessment tools (see [Chapter 24](#) for an additional discussion of tardive dyskinesia).

The nurse should take routine vital signs during the assessment. They should note any abnormalities in blood pressure (i.e., hypertension or hypotension) because many psychiatric medications affect blood pressure. Generally, these medications may cause orthostatic hypotension, which can lead to dizziness, an unsteady gait, and falls. A baseline blood pressure is needed for future monitoring of medication side effects. Lying, sitting, and standing blood pressures are especially useful in assessing for orthostatic hypotension.

Physical Functions

The nurse must consider the patient's physical functioning within the context of the normal changes that accompany aging and the presence of any chronic disorders. The nurse should note the patient's use of any personal devices, such as canes, walkers, or wheelchairs; oxygen; or environmental devices, such as grab bars, shower benches, or hospital beds. Specific areas to consider are nutrition and eating, elimination, and sleep patterns.

Nutrition and Eating

Assessment of the type, amount, and frequency of food eaten is standard in any geriatric assessment. Weight loss of more than 10 pounds should be noted. The nurse must consider such nutrition changes in light of mental health problems. For example, is a patient's weight loss related to an underlying physical problem or to the patient's belief that she is being poisoned, which makes her afraid to eat?

Eating is often difficult for older patients, who may experience a lack of appetite. The nurse must assess eating and appetite patterns because many psychiatric medications can affect digestion and may impair an already compromised gastrointestinal tract. A common problem of older adults who live

in nursing homes is dysphagia, or difficulty swallowing. **Dysphagia** can lead to dehydration, malnutrition, pneumonia, or asphyxiation. People who have been exposed to conventional antipsychotics (e.g., haloperidol, chlorpromazine) may have symptoms of tardive dyskinesia, which can make swallowing difficult. Thus, the nurse should evaluate any patient who has been exposed to the older psychiatric medications for symptoms of tardive dyskinesia.

Xerostomia, or dry mouth, which is common in older adults, also may impair eating. The nurse should pay particular attention to those who are currently receiving treatment for mental illnesses, particularly with medications that have anticholinergic properties. Dry mouth is also a side effect of many other anticholinergic medications, such as cimetidine, digoxin, and furosemide. Frequent rinsing with a nonalcohol-based mouthwash will help to correct the dry condition. Observe for the frequent use of candy- or sugar-based gum for these clients because dental caries and gum disease provide a portal of entry for sepsis in older adults. Decreased taste or smell is common among older adults and may reduce the pleasure of eating so that the patient may eat less. Making meal times social and relaxing experiences can help the patient compensate for some of the loss of pleasure associated with decreased taste or smell. Preparing favorite foods will also enhance the quality of meals and meal times.

Substance Use

Alcohol use is common in the older adult population and is the substance of choice. Older adults are more vulnerable to the effects of alcohol because of the physiologic changes associated with aging, increases in chronic diseases, and medication use. Alcohol use in older adults has been associated with functional impairments, falls, delirium, and increased mortality. Substance abuse in the older adults is expected to increase as the Baby Boomer generation ages with its higher rates of substances use compared to preceding generation. There is a substantially increased mortality risk for heavy drinkers and a slightly reduced risk for lighter drinkers (Bares & Kennedy, 2020). Indications of alcohol or drug use include observable changes in sleep patterns and unusual fatigue, changes in mood, jerky eye movement, seizures, unexplained complaints about chronic pain or vision problems, poor hygiene and self-neglect, unexplained nausea or vomiting, and slurred speech. Use of an assessment tool such as the CAGE questionnaire (discussed in [Chapter 31](#)) may be helpful in this area.

Elimination

The nurse must assess the patient's urinary and bowel functions. Older adults are more likely to experience constipation caused by a change in eating or activity patterns or intentional reduction in fluid intake. Medications with anticholinergic properties can cause constipation, leading to fecal impaction. Abuse of laxatives is common among older adults and requires evaluation. Although the addition of fiber is recommended for constipation, such measures may cause bloating and excessive gas production. Older patients are also more likely to experience urinary frequency because the strength of the sphincter muscles decreases. Because many older adults drink fewer fluids to manage urinary incontinence, fluid intake also becomes an important factor in assessing urinary functioning and constipation. The nurse should remember that urinary incontinence is not a normal age-related finding but a symptom of a disorder that requires follow-up and treatment.

Sleep

During the normal aging process, sleep patterns change, and patients may sleep more or less than they did when younger. The nurse must assess any recent changes in sleep patterns and evaluate whether they are related to normal aging or are symptomatic of an underlying disorder. Insomnia, the inability to fall or remain asleep throughout the night, may be the result of depression or can lead to an increased risk for depression and regular use of sleep medications. Sleep disturbances such as waking after onset of sleep and spending time in bed are associated with apathy, one of the early signs of Alzheimer dementia (Lloret et al., 2020). Disturbed sleep patterns are also associated with interpersonal stress and loneliness (Griffin et al., 2020; Pye et al., 2020). If a patient reports sleep problems, the nurse should ask about the patient's use of alcohol, over-the-counter (OTC) medications, and prescription drugs, which can interfere with sleep ([Box 38.3](#)).

Pain

Older adults are more likely to experience persistent pain than younger adults because they are at increased risk for chronic illness and may be experiencing the consequences of a lifetime of injuries. For many older adults, chronic pain is a constant companion and contributes to unexplained behavior and personality

changes. Chronic pain assessment is more difficult because of the person's perception of pain or cognitive impairment, which interferes with communication. Older persons are often reluctant to report pain or believe that they have to be stoic about pain and “not make a big deal” about it.

BOX 38.3

Perceptions and Beliefs about Sleep

McPhillips, M. V., Dickson, V. V., Cacchione, P. Z., Li, J., Gooneratne, N., & Riegel, B. (2020). Nursing home eligible, community-dwelling older adults' perceptions and beliefs about sleep: A mixed-methods study. *Clinical Nursing Research*, 29(3), 177–188. <https://doi.org/10.1177/1054773819849348>

THE QUESTION: Do nursing home eligible, community dwelling older adults have dysfunctional beliefs about sleep that perpetuate sleep disturbances.

METHODS: Forty Black females over the age of 55 years participated in the study. Qualitative data were obtained by semi-structured interviews and prioritized according to the perceptions and beliefs about sleep. Quantitative measures were obtained by actigraphy (a non-invasive method of monitoring rest/activity cycles).

FINDINGS: The majority of the sample had poor sleep quality and did not get the recommended amount of sleep, regardless of self-perceptions of sleep quality. Despite objective sleep disturbances, qualitative interviews revealed those participants believed their sleep was good.

IMPLICATIONS FOR NURSING: Older adults may not be accurately perceiving their sleep disturbances. Clinicians should proactively assess sleep in this group through qualitative measures. Based on this study, older adults may not recognize a sleep problem making them higher risk for nursing home placement.

While an in-depth discussion of pain assessment is beyond the scope of this text, it is important for the mental health nurse to understand the pain assessment approaches. A common practice of asking a patient if they are experiencing pain

on a scale of 1 to 10 is being replaced with a more meaningful assessment of the impact of the pain on the person. The emerging trend in pain assessment is to determine the intensity of the pain and the extent to which the pain interferes with movement (physical activity) and function (performance of daily or overall function). It is important to understand how pain limits their functional ability and mobility. A movement-based pain assessment involves assessing the pain intensity and interference on function during movement or physical activities (Booker et al., 2020).

Pharmacologic Assessment

One of the most important aspects is the pharmacologic assessment. **Polypharmacy**, the use of duplicate medications, interacting medications, or drugs used to treat adverse drug interactions, is common in older adults. The nurse must ask the patient and family to list all medications and times that the patient takes them. Asking family members to bring in all the medications the patient is taking, including OTC medications, vitamins, and herbal supplements, allows for a careful assessment of polypharmacy. Because older adults are more sensitive than younger people to medications, the possibility of drug-to-drug interactions is greater. When considering potential drug interactions, the nurse should ask the patient about their consumption of grapefruit juice, which contains naringin, a compound that inhibits the CYP3A4 enzyme involved in the metabolism of many medications (e.g., antidepressants, antiarrhythmics, erythromycin, and several statins).

Psychological Assessment

The psychological assessment provides the nurse with the opportunity to identify limitations, behavior symptoms, and reactions to illness. The nurse assesses many of the same areas as in other adult assessments, but again, the emphasis may be different. The following discussion focuses on the responses of older patients to mental health problems, mental status examination, behavior changes, stress and coping patterns, and risk assessments.

Responses to Mental Health Problems

Many older patients are reluctant to admit that they have psychiatric symptoms, particularly if their culture stigmatizes mental illness, and may deny having

mental or emotional problems. They may also fear that if they admit to any symptoms, they may be placed outside their home. If patients do not recognize or admit to having psychiatric symptoms, their vulnerability to being taken advantage of or injured increases.

Throughout the assessment, the nurse evaluates the patient's verbal reports, obvious symptoms, and family reports. If a patient flatly denies any psychiatric symptoms (e.g., depression, mood swings, outbursts of anger, memory problems), the nurse should respectfully accept the patient's answer and avoid arguments or confrontation (Box 38.4). If the patient's family members contradict the patient's report or symptoms are obvious during the interview, the nurse can approach the issue while planning care. Nurses may need to use conflict resolution strategies in helping families and patients arrive at mutually agreed on reports.

Mental Status Examination

The areas of special interest in the mental status examination are mood and affect, thought processes, and cognitive functioning. The nurse should interpret the results in light of any accompanying physical problems, such as chronic pain, or life changes, such as loss of a spouse.

Mood and Affect

Depression in older adults is common and associated with the following risk factors: loss of spouse, physical illness, low socioeconomic status, impaired functional status, and heavy alcohol consumption. In older people, other disorders may mask depression. When symptoms are present, they may be attributed to normal aging or atherosclerosis or other age-related problems. Older patients are less likely to report feeling sad or worthless than are younger patients. As a result, family members and primary care providers often overlook depression in older patients.

BOX 38.4 • ASSESSMENT INTERVIEW

Tom, 79 years old, is being seen for the first time in a geropsychiatric clinic because of recent changes in his behavior and his accusations that family members are trying to steal his house and car. He locked his wife out of the house, accusing her of being unfaithful. When Susan, the psychiatric nurse

assigned to his case, is conducting the assessment interview, Tom cooperates and is very pleasant until the nurse begins the psychological assessment.

INEFFECTIVE APPROACH

Nurse: Have there been times when you have had problems with any members of your family?

Patient: No. (Silence)

Nurse: Have you noticed that lately you have been getting more upset than usual?

Patient: No. Who has been talking to you?

Nurse: Your wife seems to think that you may be getting a little more upset than usual.

Patient: You are just like her. She keeps telling me something is wrong with me. (Getting very agitated)

Nurse: Please, I'm trying to help you. I understand that you locked your wife out of the house last week.

Patient: Leave me alone. (Gets up and leaves)

EFFECTIVE APPROACH

Nurse: How have things been going at home?

Patient: All right.

Nurse: (Silence)

Patient: Well, my wife and I sometimes argue.

Nurse: Oh. Most husband and wives argue. Any special arguments?

Patient: No. Just the usual. I don't pick up after myself enough. I don't dress right to suit her. But, lately, she's gone a lot.

Nurse: She is gone a lot?

Patient: Yeah! A lot.

Nurse: The way you say that, it sounds like you have some feelings about her being gone.

Patient: You're damned right I do—and you would, too.

Nurse: I'm missing something.

Patient: Well, if you must know, I think she's having an affair with the man next door.

Nurse: Really? That must upset you to think your wife is having an affair.

Patient: I am devastated. I feel so bad.

Nurse: Would you say that you are depressed?

Patient: Well, wouldn't you be? Yes, I'm feeling pretty low.

CRITICAL THINKING CHALLENGE

- How do the very first questions differ in the two interviews?
- What therapeutic techniques did the nurse use in the second interview to avoid the pitfalls the nurse encountered in the first scenario?
- How did the nurse in the second scenario elicit the patient's delusion about his wife's affair?
- From the data that the second nurse gathered, how many patient problems can be identified?

The term *late-onset depression* refers to the development of depression or depressive symptoms that impair functioning after 60 years of age. In late-onset depression, the risk for recurrence is relatively high. Emerging evidence suggests that late-life depression is associated with changes in the cortical network (Li et al., 2020).

The Geriatric Depression Scale (GDS) is a useful screening tool with demonstrated validity and reliability (Hyer & Blount, 1984). The GDS was designed as a self-administered test, although it also has been used in observer-administered formats. One advantage of the test is its “yes/no” format, which may be easier for older adults than the Hamilton Rating Scale for Depression (HAM-D), which uses a scale from 0 to 4 (see [Chapter 25](#)). This tool is easy to administer and provides valuable information about the possibility of depression ([Box 38.5](#)). If results are positive, the nurse should refer the patient to a psychiatrist or advanced practice nurse for further evaluation. Among nursing home residents, the usefulness of the GDS depends on the degree of cognitive impairment. Residents who are mildly impaired may be able to answer the yes/no questions; however, moderate to severely impaired patients will be unable to do the same. The best validated scale for patients with dementia is the Cornell Scale for Depression in Dementia (CSDD) (Alexopoulos et al., 1998). The CSDD is an interview-administered scale that uses information both from the patient and an outside informant.

Box 38.5

Geriatric Depression Scale (Short Form)

1. Are you basically satisfied with your life?	Yes	No
2. Have you dropped many of your activities and interests?	Yes	No
3. Do you feel that your life is empty?	Yes	No
4. Do you often get bored?	Yes	No
5. Are you in good spirits most of the time?	Yes	No
6. Are you afraid that something bad is going to happen to you?	Yes	No
7. Do you feel happy most of the time?	Yes	No
8. Do you often feel helpless?	Yes	No
9. Do you prefer to stay at home rather than go out and do new things?	Yes	No
10. Do you feel you have more problems with memory than most?	Yes	No
11. Do you think it is wonderful to be alive now?	Yes	No
12. Do you feel pretty worthless the way you are now?	Yes	No
13. Do you feel full of energy?	Yes	No
14. Do you feel that your situation is hopeless?	Yes	No
15. Do you think that most people are better off than you are?	Yes	No

Score:—/15. One point for “No” to questions 1, 5, 7, 11, 13; one point for “Yes” to other questions.

Normal	3 ± 2
Mildly depressed	7 ± 3
Very depressed	12 ± 2

From Sheikh, J. I. & Yesavage, J.A. (1986). Geriatric Depression Scale (GDS): recent evidence and development of a shorter version. *Clinical Gerontologist*, 5(1–2), 165–173. Reprinted by permission of Taylor & Francis Ltd, <https://www.tandfonline.com>.

Anxiety is another important mood for nurses to assess in older adults because it can interfere with normal functioning. In dementia, anxiety is common (Hwang et al., 2020). The Rating Anxiety in Dementia (RAID) scale was developed as a global scale to assess anxiety in patients with dementia (Shankar et al., 1999). The domains that the RAID scale assesses include worry, apprehension and vigilance, motor tension, autonomic hyperactivity, and phobias and panic attacks.

Thought Processes

Thought processes and content are critical in the assessment of older patients.

Can the patient express ideas and thoughts logically? Can the patient understand questions and follow the conversation of others? If the patient shows any indication of hallucinations or delusions, the nurse should explore the content of the hallucination or delusion. If the patient has a history of mental illness, such as schizophrenia, these symptoms may be familiar to family members, who can validate whether they are old or new problems. If this is the first time the patient has experienced these abnormal thought processes, the nurse should further evaluate the content. Suspicious and delusional thoughts that characterize dementia often include some of the following beliefs:

- People are stealing my things.
- The house is not my house.
- My relative is an impostor.

Cognition and Intellectual Performance

Cognitive functioning includes parameters such as orientation, attention, short- and long-term memory, consciousness, and executive functioning. Intellectual functioning, also considered a cognitive measure, is rarely formally assessed with a standardized intelligence test in older adults. Considerable variability among individuals depends on lifestyle and psychosocial factors. Some changes in cognitive capacity may accompany aging, but important functions are spared. Normal cognitive changes during aging include a slowing of information processing and memory retrieval. Abnormalities of consciousness, orientation, judgment, speech, or language are not related to age but to underlying neuropathologic changes. Cognitive changes in older adults are associated with delirium or dementia (see [Chapter 39](#)) or with schizophrenia (see [Chapter 24](#)).

The assessment includes the number of years of education. An inverse relationship between Alzheimer disease and the number of years of education exists. Evidence suggests that severe cognitive deterioration may occur in older adults with schizophrenia. An easy to administer and easily accessible screening tool is the SLUMS (Saint Louis University Mental Status Examination) (see [Chapter 39](#)).

Behavior Changes

Behavior changes in older adults can indicate neuropathologic processes and

thus require nursing assessment. If such changes occur, it is most likely that family members will notice them before the patient does. Apraxia (an inability to execute a voluntary movement despite normal muscle function) is not attributed to age but indicates an underlying disease process, such as Alzheimer disease, Parkinson disease, or other disorders. Various other behavior problems are associated with psychiatric disorders in older adults, including irritability, agitation, apathy, and euphoria. Other behaviors in older adults who are experiencing psychiatric problems include wandering and aggressive behaviors.

The Neuropsychiatric Inventory (NPI) was developed in 1994 to assess behavior problems associated with dementia. The scale assesses 10 behavior problems: delusions, hallucinations, dysphoria, anxiety, agitation or aggression, euphoria, inhibition, irritability or lability, apathy, and aberrant motor behavior (Cummings et al., 1994). This very popular tool is used in many medication clinical trials. There are two versions. The standard version is used when the patient is still at home; the second version (NPI-NH) is used when the patient is in a nursing home.

Stress and Coping Patterns

Identifying stresses and coping patterns is just as important for older patients as it is for younger adults. Unique stresses for older patients include living on a fixed income, handling declining health, losing partners and friends, and ultimately confronting death. Coping ability varies, depending on patients' unique circumstances. For example, some patients respond to stressful events with amazing adaptability, but others become depressed and suicidal.

Bereavement, a natural response to the death of a loved one, includes crying and sorrow, anxiety and agitation, insomnia, and a loss of appetite. These symptoms, although overlapping with those of major depression, do not constitute a mental disorder. Although bereavement is a normal response, the nurse must identify it and develop interventions to help the individual successfully resolve the loss. Bereavement is an important and well-established risk factor for depression (see [Chapter 21](#)).

Risk Assessment

Suicide is a major mental health risk for older adults. An average of one older adult dies by suicide every 57.3 minutes. Older adults make up 16.9% of 2019 population but 19.4% of suicides (AAS, 2020). Depression is the greatest risk

factor for suicide and is crucial in maintaining a desire to die. Hopelessness is also a strong factor related to death by suicide. Hopelessness is driven by a low mood, perceptions of poor physical health, and social isolation (Hernandez et al., 2020). The social isolation associated with COVID-19 contributes to the risk of suicide in the older adult (Sher, 2020). Individuals who are suicidal often believe that they are a burden to their family who would be better off without them (see [Chapter 22](#)). In assessing an older patient, the nurse should consider the following characteristics as indications of high risk for committing suicide:

- Depression
- Attempted suicide in the past
- Family history of suicide
- Firearms in the home
- Abuse of alcohol or other substances
- Unusual stress
- Burden to family
- Chronic medical condition (e.g., cancer, neuromuscular disorders)
- Social isolation

NCLEXNOTE Suicide assessment is a priority for the older adult experiencing mental health problems. It is important to carefully assess recent behavior changes and loss of support.

Social Assessment

The social assessment includes determining the patient's interactions with others in their family and community. The nurse targets social support because it is so important to the well-being of the older adult's functional status and because of the potential physical changes that can affect this area and social systems, which encompasses all community resources.

Social Support

Remaining active throughout one's life is one of the best predictors of mental

health and wellness in an older patient. People obtain their sense of self-worth through their interactions with others in their environment. A sense of “who one is” is closely tied to the roles that a person play in life. When older adults relinquish such roles because of physical disabilities, become isolated from friends and family, or begin to sense that they are a burden to those around them rather than contributing members of society, a sense of hopelessness and helplessness often follows.

The role of social support is critical to assess in this age group. Social support is a reciprocal concept, meaning that simply receiving assistance increases the person’s sense of being a burden. Those older adults who believe that they contribute to the welfare of others are most likely to remain mentally healthy. For this reason, pets are often “life savers” for older adults who live alone. Nothing can be more understanding and accepting of an older adult’s behavior or disabilities than a beloved pet.

The nurse should assess the patient’s number of formal and informal social contacts. The nurse should ask about the frequency of contacts with others (in person and through telephone calls, letters, and cards). Determining whether these contacts are actually satisfying and supporting to the patient is essential. If family members are important to the patient’s well-being, the nurse should complete a more in-depth family assessment (see [Chapter 15](#)).

The nurse can use the following questions to focus on social support:

- In the past 2 weeks, how often would you say that family members or friends let you know that they care about you?
- In the past 2 weeks, how often has someone provided you with help, such as giving you a ride somewhere or helping around the house?
- Do you have a family member or a special person you could call or contact if you needed help? Who?
- In general, other than your children, who do you consider a close friend or companion?

For patients who are isolated with few social contacts, the nurse can develop interventions to improve social support.

Functional Status

As part of a complete assessment, the nurse will need to assess the older adult's functional status. **Functional activities** or activities of daily living (ADLs) are the activities necessary for self-care (i.e., bathing, toileting, dressing, and transferring). **Instrumental activities of daily living (IADLs)** include those that facilitate or enhance the performance of ADLs (i.e., shopping, using the telephone, using transportation). These aspects are critical to consider for any older adult living alone. The most common tools used to assess functional status are the Index of Independence in the ADLs and the IADLs (Katz & Akpom, 1976).

Social Systems

Community resources are essential to an older adult's ability to maintain mental health and wellness, as well as to their ability to remain at home throughout the later years. Senior centers are federally funded community resources that provide a wide array of services to the nation's older population. They provide daily balanced meals at a nominal cost. In addition, they provide opportunities for socialization, which is a key to combating loneliness and social isolation. Many senior centers provide annual influenza and pneumonia vaccination clinics and education on such topics as fall prevention and recognition and prevention of elder abuse. Additional community resources that are specific to older adults include geriatric assessment clinics and adult day care centers.

During the assessment, the nurse must determine which community resources are available and if the older patient uses them. Lack of transportation to and from these community resources may be a barrier to use. Most communities have buses available for older or disabled individuals. The nurse may need to assist the older adult in accessing this important resource.

Many older citizens rely on the Social Security Administration for their monthly income. For many, this financial support, although less than adequate in most instances, is their only source of income. In addition to Social Security, the federal government provides basic healthcare coverage in the form of the state-administered Medicare program. Together, these programs contribute to the patient's ability to live independently and receive healthcare. The nurse should assess a patient's sources of financial support. Sometimes nurses are uncomfortable asking for financial information, fearing that they are invading the patient's privacy. However, such data are important for the nurse to determine whether a patient's resources adequately meet their needs. The source of financial support is also important. For example, a patient whose income is

adequate and from personal resources is more likely to be independent than the patient who depends on family members for income.

The nurse should ask the patient about accessible clinics, support groups, and pharmaceutical services. Information about available healthcare resources can provide useful data regarding the patient's ability to access services and can also provide potential referral sources. In urban areas that are likely to have adequate healthcare resources, cultural and language barriers may prohibit access. People who live in rural areas where healthcare resources are limited are less likely to enjoy the full range of healthcare resources than are those in urban areas. Overall, the use of mental health services by older adults with mental illnesses is low (Knight & Winterbotham, 2020). If older adults are married and have insurance, they are more likely to seek mental health services.

Spiritual Assessment

Spiritual needs are basic for all age groups and are requirements for establishing meaning and purpose, love and relatedness, and forgiveness. With advanced age, many people begin to reflect on their successes and failures. During such reflection, many seek out God or a higher being to make sense of the past and establish hope for the future.

The process of spiritual assessment involves active listening, thoughtful observing, and sensitive questioning. The nurse may simply ask if the person would find comfort from a visit from a spiritual leader. Many forms of religion use various rituals that are important to the person's daily routine. The nurse should explore and honor these aspects to the extent possible.

Legal Status

A growing trend in the United States is to view older adults as a special population whose rights deserve increased attention. Instances of elder abuse are far too common. Every nurse must consider themselves a patient advocate and be vigilant in recognizing the signs of neglect or abuse, such as unexplained injuries. At times, abuse can take the form of another individual usurping the rights of the older person. Unless the older person is determined to be incompetent, they have the same rights to personal decision-making as any other adult, including the right to refuse treatment.

Quality of Life

A sense of quality of life is closely tied to values and beliefs. For many older adults, quality of life is not reflected in material possessions or physical health. At this stage, quality of life is connected more with contentment over how the person has lived life and the extent to which their life has had meaning and purpose. Keeping close personal contacts with friends and family and having the opportunity to share stories of lifetime experiences are essential to maintaining mental health and wellness for older adults. For older adults, physical illnesses may affect the quality of life more than psychiatric disorders. The assessment of quality of life becomes especially important when assessing a patient living in a nursing home or isolated in their own home. The assessment of quality of life of older adults is similar to that for younger adults (see [Chapter 11](#)).

SUMMARY OF KEY POINTS

- Normal aging is associated with some physical decline, but most functions do not change. Intellectual functioning, capacity for change, and productive engagement with life remain stable.
- Mental health assessments are necessary when older patients face psychiatric or mental health issues. The biopsychosocial geropsychiatric nursing assessment examines many sources of data, including self-reports, laboratory test results, and reports from family members.
- The psychiatric–mental health nursing assessment for the older adult is based on the special needs and problems of the older adult. This assessment examines current and past health, functional status, and human responses to mental health problems.
- The physical assessment involves collecting data about past and present health status, physical examination findings, physical functions (i.e., nutrition and eating, elimination patterns, sleep), pain, and pharmacologic information.
- The psychological assessment includes the patient’s responses to mental health problems, mental status examination, behavioral changes, stress and coping patterns, and risk assessment.

- The social assessment includes social systems, spiritual assessment, legal information, and quality of life.
- When conducting an assessment, the nurse may find several tools useful. For patients with possible depression, the GDS may be helpful. For patients with anxiety, nurses can use the RAID scale.
- Coping with the stresses of aging varies among patients. Determining stresses and coping skills for dealing with stresses is important.
- Social support is critical to patients in this age group and requires assessment.
- Determination of the patient's ability to perform functional and instrumental ADLs is critical in the assessment of the older adult.

Unfolding Patient Stories: George Palo

Part 2 (90 years, independent living—when to move to higher level of care)

Recall from [Chapter 21](#) George Palo, a 90-year-old, is diagnosed with minor neurocognitive disorder, Alzheimer's type, and living independently in a retirement community since his wife died 3 years ago. His daughter has noticed some cognitive decline and social isolation after the recent loss of his dog. What assessments should the nurse perform during a home visit? How can the nurse determine if he is receptive to community resources for supporting his independent living and involvement in activities? Considering his neurocognitive disorder and response to recent loss, how would the nurse approach a discussion on his ability to maintain independence and when he should transfer to a higher level of care?

CRITICAL THINKING CHALLENGES

1. The director of your church's senior center has asked you to be the guest speaker at the monthly meeting

of the Retired Active Citizens group. The subject is to be “Maintaining Your Mental Health After Retirement.” What key points will you touch on in your presentation? What activities or handouts will you use to highlight your talk?

2. When asking about current illnesses, a patient begins telling you her whole life story. What approach would you take to elicit the most important needed to develop an individualized plan of care for your older patient?
3. A caregiver tells you that her mother has become suspicious of the neighbors and other family members. How would you assess this perceptual experience? What other data should you gather from this patient?
4. A caregiver brings a sack of medications to the patient’s assessment interview. What information should you obtain from the caregiver regarding the patient’s use of these medications?
5. A woman brings her father, who has a long history of frequent psychiatric hospitalizations for depression, to the clinic. The patient’s wife recently died, and the daughter fears that her father is becoming depressed again. What approach would you use in assessing for changes in mood?
6. Obtain a listing of the social services available in your community. Examine the list for areas of duplication and omission of services needed by an older adult living alone in their own home.

Movie Viewing Guides

Dad (1989): Looking like death warmed over, Jack Lemmon plays Jake Tremont, the aging father of John Tremont (Ted Danson). Always proud of being able to fend for himself, Lemmon despises being dependent on others, but his increasingly frequent periods of confusion do not allow him his old independence. For his part, Danson resents having to care for his dad as he would for an infant. To make matters even worse, Lemmon is diagnosed with cancer. As the reality of his imminent death strikes everyone around him, Lemmon retreats into fantasy, recalling the past happy events of his life as though they're happening here and now. The rest of the family humors their

dying dad, and in so doing draws closer together than they've been in years.

VIEWING POINTS: Identify the physical impairments that are obvious throughout the movie. Identify specific memory problems that Jake experiences. Are these problems part of normal aging? If you were Jake Tremont's nurse, what key assessment areas would you explore?

Neurocognitive Disorders

Mary Ann Boyd Rebecca Luebbert

KEYCONCEPTS

- Cognition
- Delirium
- Dementia
- Memory

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of cognition and memory in neurocognitive disorders.
2. Distinguish the clinical symptoms and course of delirium and Alzheimer disease.
3. Analyze the primary theories of delirium and dementia and their relations to cognition and memory.
4. Develop strategies to establish a patient-centered therapeutic relationship with a person with Alzheimer disease.
5. Apply a person-centered nursing process for persons with delirium and Alzheimer disease.
6. Identify medications used to treat people with Alzheimer disease and evaluate their effectiveness.
7. Differentiate types of mental health care provided in inpatient-focused care and community mental health care for persons with Alzheimer disease.
8. Discuss the importance of integration of primary health care for persons with Alzheimer disease.

). Describe other types of neurocognitive disorders.

KEY TERMS

- Acetylcholine (ACh)
- Acetylcholinesterase (AChE)
- Acetylcholinesterase inhibitors (AChEIs)
- Agnosia
- Amyloid precursor protein (APP)
- Aphasia
- Apraxia
- Beta-amyloid plaques
- Catastrophic reactions
- Cortical dementia
- Disinhibition
- Disturbance of executive functioning
- Hypersexuality
- Hypervocalization
- Illusions
- Impaired consciousness
- Neurocognitive disorders
- Neurofibrillary tangles
- Oxidative stress
- Subcortical dementia

INTRODUCTION

Most mental disorders occur in people of all ages and are not unique to the older adult. The first disorder discussed in this chapter, delirium, can occur at any time in a person's life, but it frequently occurs in the older adult. The other disorders discussed in this chapter are unique to the older adult. This chapter focuses on changes in cognitive functioning and **neurocognitive disorders** that are associated with the older adult.

Cognition is an intellectual process of acquiring, using, or manipulating

perceptions and information. It involves the perception of reality and an understanding of its representations. Cognitive functions to be noted include the acquisition and use of language, the orientation of time and space, and the ability to learn and solve problems. Cognition also is the basis of judgment, reasoning, attention, comprehension, concept formation, planning, and the use of symbols (e.g., numbers and letters used in mathematics and writing).

KEYCONCEPT Cognition is based on a system of interrelated abilities, such as perception, reasoning, judgment, intuition, and memory, that allow one to be aware of oneself and one's surroundings. Impairments in these abilities can result in a failure of the afflicted person to recognize that they are ill and in need of treatment.

Memory, a facet of cognition, refers to the ability to recall or reproduce what has been learned or experienced. It is more than simple storage and retrieval; it is a complex cognitive mental function that includes most areas of the brain, especially the hippocampus, which is believed to be essential to the transfer of some memories from short- to long-term storage. Defects of memory are an essential feature of many cognitive disorders, particularly dementia.

KEYCONCEPT Memory is a facet of cognition concerned with retaining and recalling past experiences, whether they occurred in the physical environment or internally as cognitive events.

Neurocognitive disorders are characterized by a decline in cognitive function from a previous level of functioning. These disorders are acquired and have not been present since early life. The diagnosis of a neurocognitive disorder is based on deficits in the following cognitive domains: *attention* (distractibility with multiple stimuli), *executive function* (planning, decision-making, working memory), *learning and memory* (recall and recognition), *language* (expressive including naming, word finding, fluency, grammatical syntax, and receptive language), *perceptual-motor* (visual perception, visuoconstructional, perceptual-motor), and *social cognition deficits* (recognition of emotions, ability to consider another's mental state) (American Psychiatric Association [APA], 2013).

The neurocognitive disorders discussed in this chapter include delirium, a disorder of acute cognitive impairment usually caused by a medical condition (e.g., infection) and dementia, characterized by chronic cognitive impairments. Dementia is differentiated from delirium by underlying cause, not by symptom patterns, which are often similar.

KEYCONCEPT Delirium is a disorder of acute cognitive impairment that is caused by a medical

condition (e.g., infection), substance abuse, or multiple etiologies.

KEYCONCEPT Dementia is characterized by chronic cognitive impairments and is differentiated by underlying cause, not by symptom patterns. Dementia can be further classified as cortical or subcortical to denote the location of the underlying pathology.

Cortical dementia results from a disease process that globally afflicts the cortex. **Subcortical dementia** is caused by dysfunction or deterioration of deep gray- or white-matter structures inside the brain and brain stem. Symptoms of subcortical dementia may be more localized and tend to disrupt arousal, attention, and motivation, but they can produce a variety of clinical behavioral manifestations. In this chapter, one type of cortical dementia, Alzheimer disease (AD), is highlighted because it is the most prevalent form of dementia.

DELIRIUM

Clinical Course

Delirium is a disturbance in consciousness and an acute change in cognition and mental status that develops over a short time. It is usually reversible if the underlying cause is identified and treated quickly. It is a serious disorder and should always be treated as a medical emergency.

EMERGENCY CARE ALERT ! Individuals with delirium are in a state of confusion and disorientation that develops during a period of a few hours or days. If delirium is not treated in a timely manner, irreversible neurologic damage can occur. Delirium is a common complication in patients admitted to intensive care units and inpatient psychiatric units (Jin et al., 2020).

Diagnostic Criteria

Impaired consciousness is the key diagnostic criterion for delirium. The patient becomes less aware of their environment and loses the ability to focus, sustain, and shift attention. Cognitive changes include problems with memory, orientation, and language. The patient may not know where they are, may not recognize familiar objects, or may be unable to carry on a conversation. This problem developed during a short period (compared with dementia, which develops gradually) (APA, 2013). Impaired alertness, apathy, anxiety, disorientation, and hallucinations commonly occur. Delirium can be categorized as *hyperactive* with agitation, increased psychomotor activity, and heightened level of arousal; *hypoactive* with somnolence and psychomotor retardation; or *mixed* with alternating hypoactive and hyperactive states. Hyperactive delirium is easily recognized, but hypoactive delirium is most common (Shenvi et al., 2020). Delirium is different than dementia, although the presenting symptoms are often similar. [Table 39.1](#) highlights the differences between delirium and dementia.

TABLE 39.1 DIFFERENTIATING DELIRIUM FROM DEMENTIA

Characteristics	Delirium	Dementia
Onset	Sudden	Insidious
24-hr course	Fluctuating	Stable
Consciousness	Reduced	Clear
Attention	Globally disoriented	Usually normal
Cognition	Globally disoriented	Globally impaired
Hallucinations	Visual auditory	Possible
Orientation	Usually impaired	Often impaired
Psychomotor activity	Increased, reduced, or shifting	Often normal
Speech	Often incoherent; slow or rapid	Often normal
Involuntary movement	Often asterixis or coarse tremor	Rare
Physical illness or drug toxicity	One or both	Rare

Source: Lee, L., Weston, W. W., Heckman, G., Gagnon, M., Lee, F. J., & Stoke, S. (2013). Structured approach to patients with memory difficulties in family practice. *Canadian Family Physician*, 59(3), 249–254.

NCLEXNOTE Delirium and dementia have similar presentations. Because delirium can be life threatening, identifying the potential underlying cause for the symptoms is a priority.

■

Although delirium may occur in any age group, it is most common among older adults. In this age group, delirium is often mistaken for dementia, which in turn leads to inappropriate treatment. Patients with delirium have a reduced ability to focus, difficulty in sustaining or shifting attention, changes in cognition, or perceptual disturbances (Mattison, 2020).

Epidemiology and Risk Factors

Statistics concerning prevalence are based primarily on older adults in acute care settings. Estimated prevalence rates range from 10% to 50% of patients. Delirium is particularly common in older postoperative patients. In some groups, such as those with dementia, the prevalence may be higher. Preexisting cognitive impairment is one of the greatest risk factors for delirium (Mattison, 2020; see [Boxes 39.1](#) and [39.2](#)).

Etiology

Delirium in the older adult is associated with medications, infections, fluid and electrolyte imbalances, metabolic disturbances, hypoxia, or ischemia. The probability of the syndrome developing increases if some predisposing factors, such as advanced age, brain damage, or dementia, are also present. Sensory overload or underload, immobilization, sleep deprivation, COVID-19, and psychosocial stress also contribute to delirium (Duggan et al., 2021).

Box 39.1

Risk Factors for Delirium

- Advanced age
- Preexisting dementia
- Functional dependence
- Endocrine and metabolic disorders
- Bone fracture

Infection (pneumonia, urinary tract)
Medications (anticholinergic side effects)
Changes in vital signs (including hypotension and hyper- or hypothermia)
Electrolyte or metabolic imbalance (dehydration, renal failure, hyponatremia)
Admission to a long-term care institution
Postcardiotomy
AIDS
Pain
Acute or chronic stress
Substance use and alcohol withdrawal

Box 39.2

Delirium

Margaret, a widowed 72-year-old woman living in her own home, has been having trouble sleeping. Her daughter visits her and suggests that she try an OTC sleeping medication. Margaret also takes antihistamines for allergies and the antidepressant amitriptyline. Three nights later, a neighbor calls the daughter, concerned because Margaret is wandering the streets, unable to find her home. When the neighbor approached Margaret to help her home, she began to scream and strike out at the neighbor.

The daughter visits immediately and discovers that her mother does not know who she is, does not know what time it is, appears disheveled, and is suspicious that people have been in her home stealing the things she cannot find. Margaret does not recall taking any medication, but when her daughter investigates, she finds that 10 pills of the new sleeping aid have already been used.

WHAT DO YOU THINK?

- Identify risk factors that may have contributed to Margaret's experiencing delirium.

- How could the addition of an OTC sleeping medication interact with the antihistamine and antidepressant to be responsible for Margaret's delirium?

RECOVERY-ORIENTED CARE FOR PERSONS WITH DELIRIUM

Delirium is a medical emergency that is easily misdiagnosed as a dementia. Prompt treatment leads to recovery.

Teamwork and Collaboration: Working Toward Recovery

Although delirium may be recognized and diagnosed in any health care setting, appropriate intervention usually requires that the patient be admitted to an acute care setting for rigorous assessment and rapid treatment. Priority in care is identifying the underlying cause of the delirium. Interdisciplinary management of delirium includes two primary aspects: (1) elimination or correction of the underlying cause and (2) symptomatic and supportive measures (e.g., adequate rest, comfort, maintenance of fluid and electrolyte balance, and protection from injury).

Safety Issues

If possible, the use of all suspected medications should be stopped and vital signs should be monitored at least every 2 hours. Close observation of the patient with particular regard to changes in vital signs, behavior, and mental status is required. Patients are monitored until the delirium subsides or until discharge. If the delirium still exists at discharge, it is critical that referrals for post-discharge follow-up assessment and care be implemented.

EVIDENCE-BASED NURSING CARE FOR

PERSONS WITH DELIRIUM

The best management is prevention or early recognition of delirium. Special efforts should be made to include family members in the nursing process.

Mental Health Nursing Assessment

The onset of symptoms is typically signaled by a rapid or acute change in behavior. Delirium is underdiagnosed, and symptoms are easily missed in persons with mental disorders when it is assumed that the cognitive and behavioral changes are related to the mental disorder. An underlying medical cause should always be the first consideration.

Assessing the symptoms requires knowing what is normal for the individual. Caregivers, family members, or significant others should be interviewed because they can often provide valuable information. Family members may be the only resource for accurate information.

Physical Health Assessment

History should include a description of the onset, duration, range, and intensity of associated symptoms. Recent physical illness, dementia, depression, or other psychiatric illnesses should be identified. A physical examination should be conducted. Vital signs are crucial. Changes in activities of daily living (ADLs), use of sensory aids (eyeglasses and hearing aids), pain, and sleep should be documented. Recent laboratory results that might indicate hypoxia, hypoglycemia, and ST-segment elevation myocardial infarction (STEMI) should be considered. Assessment for infections that commonly underlie delirium, such as urinary tract infection, pneumonia, and sepsis from other sources, should be included. An abnormal neurological assessment would suggest a TIA (transient ischemic attack), stroke, intracranial hemorrhage or mass).

Medication Assessment

Many medications are associated with delirium (see [Table 39.2](#)). Medications and recent changes in the type and number, including over-the-counter (OTC) medications, should be documented. Combinations of medications can interact and cause delirium. Cold medications, taken in sufficient quantities, may cause confusion, especially in older adults. A substance use history (including alcohol

intake and smoking history) should be taken.

Psychosocial Assessment

Mental Status

Rapid onset of global cognitive impairment that affects multiple aspects of intellectual functioning is the hallmark of delirium. Mental status evaluation reveals several changes:

- Fluctuations in level of consciousness with reduced awareness of the environment
- Difficulty focusing and sustaining or shifting attention
- Severely impaired memory, especially immediate and recent memory

Patients may be disoriented to time and place but rarely to person. Environmental perceptions are often disturbed. The patient may believe shadows in the room are really people. Thought content is often illogical, speech may be incoherent or inappropriate to the context. Mental status tends to fluctuate over the course of the day.

Behavior

Persons with delirium exhibit a wide range of behaviors, complicating the process of making a diagnosis and planning interventions. At times, the individual may be restless or agitated and at other times lethargic and slow to respond.

TABLE 39.2 **EXAMPLES OF DRUGS THAT CAN CAUSE DELIRIUM**

Class	Specific Drugs
Anticholinergic	Antihistamines Chlorpheniramine Antiparkinsonian drugs (e.g., benztropine [Cogentin], biperiden [Akineton], or trihexyphenidyl) Atropine Belladonna alkaloids Diphenhydramine Phenothiazines

	Scopolamine
	Tricyclic antidepressants
Anticonvulsant	Phenobarbital
	Phenytoin (Dilantin)
	Sodium valproate (Depakene, Depakote)
Antiinflammatory	Corticosteroids
	Ibuprofen (Motrin, Advil)
	Indomethacin (Indocin)
	Naproxen (Naprosyn)
Antiparkinsonian	Amantadine
	Carbidopa (Sinemet)
	Levodopa (Larodopa)
Antibiotics	Isoniazid
	Rifampin
Analgesic	Opioids
	Salicylates
	Synthetic narcotics
Cardiac	Beta-blockers
	Propranolol (Inderal)
	Clonidine (Catapres)
	Digitalis (Digoxin, Lanoxin)
	Lidocaine (Xylocaine)
	Methyldopa (Aldomet)
	Quinidine
	Procainamide (Pronestyl)
Sedative—hypnotic	Barbiturates
	Benzodiazepines
Sympathomimetic	Amphetamines
	Phenylephrine
	Phenylpropanolamine
Over-the-counter medications	Compoz
	Excedrin PM
	Sleep-Eze
	Sominex
Miscellaneous	Acyclovir (antiviral)
	Aminophylline
	Amphotericin (antifungal)
	Bromides
	Cephalexin (Keflex)
	Chlorpropamide (Diabinese)
	Cimetidine (Tagamet)
	Disulfiram (Antabuse)
	Lithium
	Metronidazole (Flagyl)
	Theophylline
	Timolol ophthalmic

Clinical Manual of Drug Interaction: Principles for Medical Practice.
Arlington, VA: American Psychiatric Publishing, Inc.

Family Environment

An assessment of living arrangements may provide information about sensory stimulation or social isolation. Assessing family interactions, support for the patient, and family members' ability to understand delirium is also important. The behaviors exhibited by the person experiencing delirium may be frightening or at least confusing for family members. Some family members may actually contribute to the patient's increased agitation. At the same time, however, the family's presence may help to calm and reassure the patient.

CLINICAL JUDGMENT

If delirium is established as the medical diagnosis, the nurse must address any life-threatening issues related to respiration and cardiovascular impairment. If the patient is combative, de-escalation becomes a priority. Because there are many potential issues that could be underlying delirium, other priorities will be based on the identified causes.

MENTAL HEALTH NURSING INTERVENTIONS

Important interventions include providing a safe and therapeutic environment, maintaining fluid and electrolyte balance and adequate nutrition, and preventing aspiration and decubitus ulcers, which are common complications. Other interventions relate to individual symptoms and underlying causes.

Complementary and Nonpharmacological

Interventions

There is strong evidence that complementary and nonpharmacological medicine interventions are effective in reducing agitation and delirium in older adults. Aromatherapy, massage, acupuncture, and therapeutic touch have been used successfully in reducing agitation and aggressive behavior (Leng et al., 2020).

Medications

There is no medication for delirium, but as the underlying medical problem is treated, the person may be given medication to treat the symptoms associated with delirium, such as agitation, inattention, combativeness, insomnia, and psychosis. Dosages are usually kept very low, especially with older adults and the medication is selected in light of the potential side effects (particularly anticholinergic effects, hypotension, and respiratory suppression). Antipsychotics are often used for a targeted group of patients who experience hallucinations or delusions associated with delirium (Ostuzzi et al., 2020). Recent research suggests that supportive measures and treatment of precipitating factors are more effective than antipsychotics (Ali & Cascella, 2020). Benzodiazepines are also used when the delirium is related to alcohol withdrawal. In some patients, benzodiazepines may further impair cognition because of the sedation.

Patients should be monitored for sedation, hypotension, or extrapyramidal symptoms. Although mental status often fluctuates during delirium, it may also be influenced by these medications, so any changes or worsening of mental status after administration of the medication should be reported immediately to the prescriber. Some side effects may also be confused with the symptoms of delirium. For example, akathisia (see [Chapter 11](#)), a side effect of antipsychotics, may appear as agitation or restlessness. Medications for treating symptoms related to delirium should be discontinued as soon as possible.

Psychosocial Interventions

Patients with delirium need frequent interaction and support if they are confused or hallucinating. Patients should be encouraged to express their fears and discomforts that result from frightening or disconcerting psychotic experiences. Adequate lighting, easy-to-read calendars and clocks, a reasonable noise level,

and frequent verbal orientation may reduce this frightening experience. If the patient wears eyeglasses or uses a hearing aid, these devices should be used. Including familiar personal possessions in the environment may also help. These interventions have been shown to reduce the need for antipsychotic medication and reduced length of hospitalization (Hshieh et al., 2020).

A safe environment is important to protect the patient from injury. A predictable, orienting environment will help to reestablish order to the patient's life. That is, a calendar, clocks, and other items may be provided to help orient the patient to time, place, and person. If the patient is agitated, de-escalation techniques should be used (see [Chapter 14](#)). Physical restraint should be avoided.

Families can also be encouraged to work with staff to reorient the patient and provide a supportive environment. Families need to understand that important decisions requiring the patient's input should be delayed if at all possible until the patient has recovered. Although patients may be able to participate in decision-making, they may not remember the decision later.

Psychoeducation

To prevent future occurrences, provide education to the patient and family about the underlying cause of the delirium. If the delirium is not resolved before discharge, family members need to know how to care for the patient at home.

Promoting Safety

Behaviors exhibited by the person with delirium, such as hallucinations, delusions, **illusions**, aggression, or agitation (restlessness or excitability), may pose safety problems. Because individuals with delirium are more likely to fall or injure themselves during a confused state, special precautions and safety measures should be considered. The patient must be protected from physical harm by using low beds, guardrails, and careful supervision. Delirium management and fall prevention may be implemented for any patient at risk for falls.

Therefore, it is important to have several witnesses present.

Evaluation and Treatment Outcomes

The primary treatment goal is prevention or resolution of the delirious episode with return to previous cognitive status. Outcome measures include the following:

- Correction of the underlying physiologic alteration
- Resolution of confusion
- Family member verbalization of understanding of confusion
- Prevention of injury

Resolution of confusion is the primary goal; however, the nursing care provided makes important contributions to all four of these outcomes. The end result of delirium may be full recovery, incomplete recovery, incomplete recovery with some residual cognitive impairment, or a downward course leading to death.

BOX 39.3

Delirium

When caring for the patient with delirium, be sure to include the caregivers, as appropriate, and address the following topic areas in the teaching plan:

- Psychopharmacologic agents, if used, including drug action, dosage, frequency, and possible adverse effects
- Underlying cause of delirium
- Mental status changes
- Safety measures
- Hydration and nutrition
- Avoidance of restraints
- Decision-making guidelines

Continuum of Care

Patients with delirium may present in a number of treatment settings (e.g., home, nursing home, ambulatory care, day treatment, outpatient setting, hospital). Patients usually are admitted to an acute care setting for rapid evaluation and treatment of the underlying etiology. For more information on caring for patients with delirium, see [Box 39.3](#).

ALZHEIMER DISEASE

Clinical Course

AD is a degenerative, progressive, neuropsychiatric disorder that results in cognitive impairment, emotional and behavioral changes, physical and functional decline, and ultimately death. Gradually, the patient's ability to carry out ADLs declines, although physical status often remains intact until late in the disease. Although primarily a disorder of older adults, AD has been diagnosed in patients as young as age 35 years.

Two subtypes have been identified: early onset AD (age 65 years and younger) and late onset AD (age older than 65 years). Late-onset AD is much more common than early-onset AD, but early-onset AD has a more rapid progression. AD is also routinely conceptualized in terms of three stages: mild, moderate, and severe. Signs and symptoms of AD change as the patient passes from one phase of the illness to another ([Figure 39.1](#)).

Diagnostic Criteria

The diagnosis of AD is made on clinical grounds, but verification is only confirmed during autopsy. The essential feature of AD is cognitive decline from a previous level of functioning in one or more cognitive domains (attention, executive function, learning and memory, language, perceptual-motor or social cognition) (APA, 2013). These deficits interfere with independence in ADLs. Typical deficits include **aphasia** (i.e., alterations in language ability), **apraxia** (i.e., impaired ability to execute motor activities despite intact motor

functioning), **agnosia** (i.e., failure to recognize or identify objects despite intact sensory function), or a **disturbance of executive functioning** (i.e., ability to think abstractly, plan, initiate, sequence, monitor, and stop complex behavior).

Mild neurocognitive impairment (MCI) is diagnosed if a modest cognitive decline from a previous level of function is found in one or more of the cognitive domains, but the cognitive deficits do not interfere with independence in daily activities (APA, 2013). MCI is thought to be related to multiple causes and some, but not all, progress to AD. MCI is categorized according to type of memory loss. In *amnesic MCI*, an individual may start to forget important information such as appointments, conversations, or events. In *nonamnesic MCI*, impairment in visual perception, the ability to make sound decisions, or the capacity to judge the time or sequence of steps needed to complete a complex task occurs (Alzheimer's Association, 2021a).

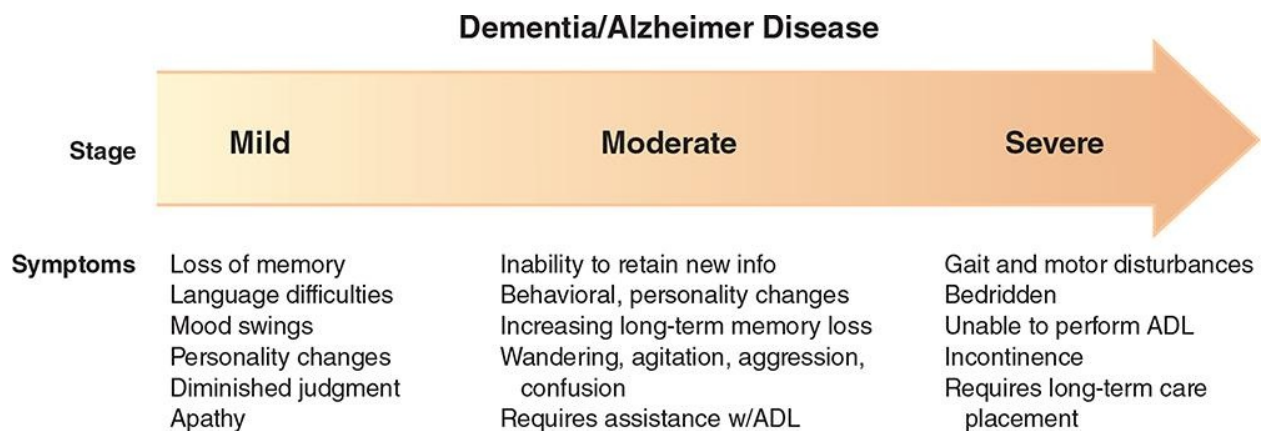

FIGURE 39-1: Alzheimer disease progression.

Epidemiology and Risk Factors

In 2020, an estimated 5.8 million Americans had AD, 1 in 10 older than 65 years old. By 2050, the population of America over the age of 65 is projected to grow from 56 million to 88 million. With this increase in population, the number of those with AD will also grow. Almost two thirds of Americans with AD are women. Dementia appears to affect all groups, but studies in the United States reveal a higher incidence in Black or African American individuals and Hispanic or Latinx individuals than in White individuals. Currently, AD is the fifth leading cause of death among older adults in the United States (Alzheimer's Association, 2020).

General Risk Factors

AD can run in families. Compared with the general population, first-degree biologic relatives of individuals with early-onset AD are more likely to experience the disorder. Studies show that those with fewer years of education or those who have had a prior head injury are at higher risk of developing AD (Alzheimer's Association, 2020).

Down Syndrome

People with Down syndrome are at higher risk of developing AD than others, most likely because of the additional copy of chromosome 21. The **amyloid precursor protein (APP)** is a gene found on this chromosome that is involved in the formation of neurons and their survival. This gene is cut into smaller fragments (peptides) by enzymes. The extra copy of chromosome 21 increases the amount of amyloid beta (A-beta) fragments in the brain, which in turn increases the possibility of formation of **beta-amyloid plaques**. By age 40, most people with Down syndrome have increased levels of beta-amyloid plaques and tau tangles in their brain (Alzheimer's Association, 2020).

Metabolic Syndrome

Individuals with metabolic syndrome have a greater risk of developing AD (Alzheimer's Association, 2020). Metabolic syndrome, a cluster of conditions (hypertension, hyperglycemia, abdominal obesity, and hyperlipidemia) that occur together, increases the risk of heart disease, stroke, and diabetes. Metabolic syndrome is associated with microvascular changes in the brain, which in turn appear to cause mitochondrial dysfunction. Insulin resistance is thought to play a key role in the neuroinflammation and loss of synapses (Kellar & Craft, 2020).

Etiology

Researchers have yet to identify a definitive cause of AD, but a combination of genetic, environmental, and lifestyle factors influences a person's risk for developing the disease. There are multiple factors involved in the development and progression of this disorder (National Institute on Aging [NIH], 2019).

Amyloid Precursor Protein

The APP located on the cell membrane appears to have a neuroprotective role in situations of metabolic stress. During an acute stroke, cardiac arrest, or chronic hypoxic–ischemic condition, the APP can promote neuronal survival. Damage to DNA prevents repair of the APP. When APP is cut or cleaved by the beta-site APP Cleaving Enzyme 1, neurotoxic amyloid-beta is released. These peptides can accumulate as amyloid plaques, promoting neurodegeneration (Lin et al., 2020).

Beta-Amyloid Plaques

One piece of the puzzle is partially explained by a leading theory that beta-amyloid plaques, made up of proteins, clump together in the brain and destroy cholinergic neurons. Research suggests that beta-amyloid deposits impair the normal function of pericytes, which are cells important for controlling the removal of protein from the brain. This leads to further accumulation of the protein. Beta-amyloid is hypothesized to interfere with the process of storing memories through interrupting synaptic connection. Symptoms such as aphasia and visuospatial abnormalities are attributable to plaque formation (Sengoku, 2020).

Neurofibrillary Tangles

Neurofibrillary tangles are made of abnormally twisted protein threads found inside the brain cells. The main component of the tangles is *tau*, a protein that stabilizes the microtubules of transport cells. In AD, tau separates from the microtubules. Loose tau proteins tangle with each other, causing the characteristic neurofibrillary tangles. When microtubules disintegrate, the neuron's transport system collapses, resulting in cell death (Sengoku, 2020) ([Figure 39.2](#)).

Synaptic Micron RNA and Neurotransmission

In patients with AD, neurotransmission is reduced, neurons are lost, and the hippocampal neurons degenerate. Several major neurotransmitters are affected, such as **acetylcholine (ACh)**, norepinephrine, and serotonin important, in cognitive functioning and memory. Researchers hypothesize that microRNA (molecules involved in gene expression) alterations, occur impacting synaptic

transmission (see [Chapter 6](#)). See [Figure 39.3](#) are also affected (Kumar & Reddy, 2020).

FIGURE 39-2: Series comparison of older control subjects (*top row*) and patients with Alzheimer disease (AD) (*bottom row*). Although some decreases in metabolism are associated with age, in most patients with AD, marked decreases are seen in the temporal lobe, an area important in memory functions. (Courtesy of Monte S. Buchsbaum, MD, *The Mount Sinai Medical Center and School of Medicine*, New York.)

One of the early hypotheses was that cholinergic dysfunction contributed to cognitive deficits associated with aging and AD. This hypothesis was based on evidence that alterations in the cholinergic systems induced cognitive deficits similar to those in AD and aging. When cholinergic functioning was increased, there were beneficial effects. We now understand that the pathogenesis of AD is much more complicated than a single cause, even though the primary medications for AD target the cholinergic system (Barfejani et al., 2020).

Genetic Factors

Mutations on three genes are identified as causing AD through altering A-beta processing and are transmitted through genetic inheritance—*APP*, *PSEN1*, and *PSEN2*. These mutations explain 5% to 10% of the occurrence of early-onset AD. The majority of early-onset AD cases do not have a clear genetic pattern of inheritance. However, genetic predisposition is estimated to be a factor in 60% to 80% of AD cases, including late-onset AD (Bellenguez et al., 2020).

The *APOE* gene transports cholesterol in the bloodstream. Three forms of the *APOE* gene (e2, e3, and e4) are inherited from each parent. The e3 form is the most common and is believed to neither increase or decrease the risk of AD. e4 is the next most common and is found to increase the risk of developing AD. People with one copy of the e4 form are three times as likely to develop AD compared with those who have the e3 form, and those with two copies of the e4 form have an 8 to 12 times greater risk. The least common *APOE* gene, e2, is relatively rare and may actually decrease one's risk of AD (Alzheimer's Association, 2020).

Oxidative Stress, Free Radicals, and Mitochondrial Dysfunction

It is hypothesized that in AD-affected brains, there is a rapid increase in formation of free radicals (i.e., highly reactive molecules), which can lead to **oxidative stress** that damages other cellular molecules such as proteins, lipids, and nucleic acid. Recent studies suggest that oxidative stress may result in changes in chromatin (a complex of DNA and proteins), which may lead to dysfunctional gene expression (Tadokoro et al., 2020).

FIGURE 39-3: Metabolic activity in a subject with Alzheimer disease (*left*) and control subject without AD (*right*). (Courtesy of Monte S. Buchsbaum, MD, The Mount Sinai Medical Center and School of Medicine, New York.)

Inflammation

Inflammation is now considered as one of the many factors that contribute to the development of AD. The hypothesis is that inflammation may damage small blood vessels and brain cells, initiating a cascade of pathologic events related to oxidative damage and dysregulated amyloid metabolism (Kacířová et al., 2020).

Gut–Brain Axis Alteration

The gut microbial composition is thought to influence several age-related neurological disorders including AD. It is proposed that alterations in gut microbial composition contributes to the pathogenesis of AD. Normally, the gastrointestinal (GI) tract epithelium and the blood–brain barrier are protective physiological barriers. After aging, these protective barriers become more permeable. If repeated chronic infection occurs, exposure to exotoxins such as lipopolysaccharides (LPS) and bacterial amyloids occurs because they pass more easily through compromised GI tract and blood–brain barrier. Evidence reveals

that aging together with repeated chronic infections lead to altered activation of microglial cells that aggravates inflammatory responses, A-beta fibrillation, and the aggregation of amyloid-beta. in the brain (Kesika et al., 2021).

Family Response to Disorder

Families are the first to be aware of the cognitive problem, often before the patient, who can be unaware of the extent of memory impairment. When finally confirmed, the actual diagnosis can be devastating to the family. Unlike delirium, a diagnosis of AD means long-term care responsibilities while the essence of a family member diminishes day by day. Most families keep their relative at home as long as possible to maintain contact and to avoid costly nursing home placement. The two symptoms that often result in nursing home placement are incontinence that cannot be managed and behavioral problems, such as wandering and aggression.

RECOVERY-ORIENTED CARE FOR A PERSON WITH ALZHEIMER DISEASE

AD has a long clinical course—at least 20 years. AD research is quickly advancing, and it is likely that treatment will provide more options to reduce or reverse the illness trajectory. Hope for the future should be instilled in patients and families. Recovery is an important focus for persons with AD, reminding families that wellness is possible despite the presence of a chronic disease.

Teamwork and Collaboration: Working toward Recovery

The nature and range of services needed by patients and families throughout the illness can vary dramatically at different stages. As with any other patient, the person with AD should be the center of the decision-making process. The plan

should include educational and supportive programs individualized for the person's self-identified needs. Ideally, plans should be designed to support self-awareness, self-esteem, maintenance of abilities, and management of behavioral symptoms and health promotion.

Treatment efforts currently focus on managing cognitive symptoms, delaying cognitive decline (e.g., memory loss; confusion; and problems with learning, speech, reasoning), treating the noncognitive symptoms (e.g., psychosis, mood symptoms, agitation), and supporting the caregivers to improve the quality of life for both patients and their caregivers.

Safety Issues

The priority of care changes throughout the course of AD. Initially, the priority is delaying cognitive decline and supporting family members. Later, the priority is protecting the patient from injury because of the patient's lack of judgment. Near the end, the physical needs of the patient are the focus of care.

EVIDENCE-BASED NURSING CARE FOR PERSONS WITH ALZHEIMER DISEASE

Development and implementation of appropriate, effective, and safe nursing services for the care and support of patients with AD and their families is a particular challenge because of the complex nature of the illness. See [Nursing Care Plan 39.1](#).

NCLEXNOTE Needs and problematic behaviors of patients with AD vary throughout the course of the disorder. Early in the disorder, the nurse focuses on support, education, and cognitive interventions for depression. As AD progresses, priority care becomes safety interventions.

Mental Health Nursing Assessment

Physical Health Assessment

A review of body systems must be conducted on each patient suspected of having AD. The neurologic function of the patient with AD is usually preserved through the early and middle stages of the disease, although seizures, gait disturbances, and tremors may occur at any time. In the later stages of the disease, neurologic signs, such as flexion contractures and primitive reflexes, are prominent features.

Physical Functions

Assessment of physical functions includes ADLs, recent changes in functional abilities, use of sensory aids (e.g., eyeglasses, hearing aids), activity level, and assessment of pain. Eyeglasses and hearing aids may need to be in place before other assessments can be made.

At first, limitations may primarily involve instrumental activities of daily living (IADLs) (e.g., shopping, preparing meals, performing other household chores). Later in the disease process, basic physical dysfunctions occur, such as incontinence, ataxia, dysphagia, and contractures. Incontinence can be a major source of stress and a considerable burden to family caregivers. Evaluation of the patient's functional abilities includes bathing, dressing, toileting, feeding, nutritional status, physical mobility, sleep patterns, and pain.

Self-Care

Alterations in the central nervous system (CNS) associated with AD impair the patient's ability to collect information from the environment, retrieve memories, retain new information, and give meaning to current situations. Therefore, patients with AD often neglect self-care activities. Periodically, biologic assessment parameters need to be reevaluated because patients with AD may neglect activities such as bathing, eating, or skin care.

Sleep–Wake Disturbances

Patients with AD have frequent daytime napping and nighttime periods of wakefulness, with little rapid eye movement (REM) sleep. Circadian rhythms are disrupted as the amyloid beta (A-beta) increases. Tau pathology and increases in beta-amyloid plaques are associated with restlessness, irritability, and general sleep impairment (Uddin et al., 2021).

Activity and Exercise

One of the earliest symptoms of AD is withdrawal from normal activities. Motor activity is affected in the mild stages of AD and can lead to early problems in functional performance (Alzheimer's Association, 2020). As the disease progresses, the patient may just sit staring at a blank wall.

Nutrition

Nutritional assessment is very important in light of the recent understanding that changes in gut microbiota could affect the brain's physiological, behavioral, and cognitive functions (Lin et al., 2018). Foods high in fat content and foods highly processed are detrimental to the support of a healthy gut microbiome.

NURSING CARE PLAN 39.1

The Patient with Dementia

Lorine is a 76-year-old widow who lives independently. Recently, her children have noticed that she is becoming more forgetful and seems to have periods of confusion. She has agreed to have someone help her during the day. Her oldest son lives with her and is with her during the evening and night. Lorine refuses to see a health care provider but did agree to go in for a routine checkup. Her daughter helped her get dressed and took her to the primary care office.

Setting: Primary Care Office

Baseline Assessment: A well-groomed woman is accompanied by her daughter. Lorine says there is nothing wrong, but her daughter disagrees. A review of body systems reveals poor hearing and vision but is otherwise unremarkable. Her daughter reports that Lorine has become very suspicious of her neighbors and has changed her locks several times.

Associated Psychiatric Diagnosis	Medications
Probable Alzheimer disease	Galantamine (Razadyne) 4 mg twice a day (BID); titrate to 8 mg BID over 4 weeks.

Priority of Care: Changes in Memory

Important Characteristics

Inability to recall information

Inability to recall past events
Observed instances of forgetfulness
Forgets to perform daily activities (e.g., grooming)

Associated Considerations

Neurocognitive changes associated with dementia

Outcomes

Initial

Maintain or improve current memory

Long-term

Delay cognitive decline associated with dementia

Interventions

Interventions

Develop memory cues in home. Have clocks and calendars clearly displayed. Make lists for the patients.

Teach the patient and family about taking an acetylcholinesterase inhibitor. Review expected effects and side effects. Develop a titration schedule with the family to decrease the appearance of side effects.

Observe patient for visuospatial impairment. If

Rationale

Maintaining current level of memory involves providing cues that will help the patient recall information.

Confidence and self-esteem improve when a person looks well groomed.

Visuospatial

Ongoing Assessment

Contact family members for the patient's ability to use memory cues.

Monitor response to suggestions.

Observe for

present, sequence habitual activities such as eating, dressing, and bathing.	impairment is one of the symptoms of dementia.	appropriate dress, bathing, eating, and so on.
--	--	--

Evaluation

Outcomes	Revised Outcomes	Interventions
Lorine did have some improvement in memory. Suspiciousness and behavioral symptoms improved.	Continue maintaining memory.	Continue with memory cues and galantamine.

Eating can become a problem for a patient with AD and is associated with rapid cognitive decline. As the disease progresses, patients may lose the ability to feed themselves or recognize that what is being offered is food. Some patients with AD are bulimic or hyperoral (eating or chewing almost everything possible and sometimes with an insatiable appetite). Other patients with AD experience anorexia and have no appetite.

Pain

Although AD is not usually considered a physically painful disorder, patients often have other comorbid physical diseases that may be painful. In the early stages of AD, the patient can usually respond to verbal questions regarding pain. Later, it may be difficult to assess the comfort level objectively, especially if the patient cannot communicate. Some patients in the end stage of AD become hypersensitive to touch.

Subtle behavioral changes, such as lethargy, anxiety, or restlessness, or more obvious physical signs, such as pyrexia, tachypnea, or tachycardia, may be the only indications of actual or impending illness. Observing for changes in patterns of nonverbal communication, such as facial expressions, may help in identifying indicators of pain. **Hypervocalizations** (disturbed vocalizations), restlessness, and agitation are other possible signs of pain.

Psychosocial Assessment

Personality changes almost always accompany AD. Researchers have identified two contrasting patterns. One is marked by apathy, lack of spontaneity, and

passivity. The other involves growing irritability, sarcasm, self-preoccupation, and intolerance of and lack of concern for others.

Mental Status and Appearance

The mental status assessment can be difficult for the patient with AD because cognitive disturbance is the clinical hallmark of AD. However, family members should also be a part of any assessment, especially early in the disease process. There are several screening instruments that can be used in detecting symptoms of dementia. The Mini-Cog is used by clinicians in assessing whether an individual has symptoms of AD (Borson et al., 2003). The AD8 Dementia Screening Interview, which is given to a family member, is a brief, sensitive measure that differentiates between those with and without dementia (Galvin et al., 2005, 2006). The AD8 contains eight questions asking the family member to rate any change (“yes” or “no”) in memory, problem-solving abilities, orientation, and ADLs. The higher the number of changes, the more likely dementia is present (Figure 39.4). The nurse should suspect delirium in instances where cognitive deterioration occurs rapidly.

Memory

The most dramatic and consistent cognitive impairment is in memory. Patients with dementia appear mildly forgetful and repetitive in conversation. They misplace objects, miss appointments, and forget what they were just doing. They may lose track of a conversation or television show. Initially, they may complain of memory problems, but rapidly in the course of the illness, insight is lost, and they become unaware of what is lost. Sometimes, they may confabulate, making what appears to be an appropriate explanation of why the information or object is missing. Eventually, all aspects of memory are impaired and even long-term memories are affected. During the interview, short-term memory loss is usually readily evident by the patient’s inability to recall three or four words given to them at the beginning of the assessment. Often, the earliest symptom of AD is the inability to retain new information.

Language

Language is also progressively impaired. Individuals with AD may initially have agnosia (difficulty finding a word in a sentence or in naming an object). They

may be able to talk around it, but the loss is noticeable. Later, fluent aphasia develops; comprehension diminishes; and, finally, they become mute and unresponsive to directions or information.

Visuospatial Impairment

Deficits in visuospatial tasks that require sensory and motor coordination develop early, drawing is abnormal, and the ability to write may change. An inaccurate clock drawing is diagnostic of impairment in this area ([Figure 39.5](#)). Sequencing tasks, such as cooking or other self-care skills, become impaired. The individual becomes unable to complete complex tasks that require calculations, such as balancing a checkbook.

Executive Functioning

Judgment, reasoning, and the ability to problem solve or make decisions are also impaired later in the disorder, closer to the time of nursing home placement. It is hypothesized that as the disease progresses, the degeneration of neurons is spread diffusely throughout the neocortex.

Remember, “Yes, a change” indicates that there has been a change in the last several years caused by cognitive (thinking and memory) problems.	YES, A change	NO, No change	N/A, Don’t know
1. Problems with judgment (e.g., problems making decisions, bad financial decisions, problems with thinking)			
2. Less interest in hobbies/activities			
3. Repeats the same things over and over (questions, stories, or statements)			
4. Trouble learning how to use a tool, appliance, or gadget (e.g., VCR, computer, microwave, remote control)			
5. Forgets correct month or year			
6. Trouble handling complicated financial affairs (e.g., balancing checkbook, income taxes, paying bills)			
7. Trouble remembering appointments			
8. Daily problems with thinking and/or memory			
TOTAL AD8 SCORE

The AD8® Administration and Scoring Guidelines

A spontaneous self-correction is allowed for all responses without counting as an error.

The questions are given to the respondent on a clipboard for self-administration or can be read aloud to the respondent either in person or over the phone. It is preferable to administer the AD8 to an informant, if available. If an informant is not available, the AD8 may be administered to the patient.

When administered to an informant, specifically ask the respondent to rate change in the patient.

When administered to the patient, specifically ask the patient to rate changes in his/her ability for each of the items, *without* attributing causality.

If read aloud to the respondent, it is important for the clinician to carefully read the phrase as worded and give emphasis to note changes due to cognitive problems (not physical problems). There should be a one second delay between individual items.

No timeframe for change is required.

The final score is a sum of the number items marked “Yes, A change”.

Interpretation of the AD8

(Adapted from Galvin JE et al, The AD8, a brief informant interview to detect dementia, *Neurology* 2005;65:559-564)

A screening test in itself is insufficient to diagnose a dementing disorder. The AD8 is, however, quite sensitive to detecting early cognitive changes associated many common dementing illness including Alzheimer disease, vascular dementia, Lewy body dementia and frontotemporal dementia.

Scores in the impaired range (see below) indicate a need for further assessment. Scores in the “normal” range suggest that a dementing disorder is unlikely, but a very early disease process cannot be ruled out. More advanced assessment may be warranted in cases where other objective evidence of impairment exists.

Based on clinical research findings from 995 individuals included in the development and validation samples, the following cut points are provided:

0 – 1: Normal cognition

2 or greater: Cognitive impairment is likely to be present

Administered to either the informant (preferable) or the patient, the AD8 has the following properties:

Sensitivity > 84%

Specificity > 80%

Positive Predictive Value > 85%

Negative Predictive Value > 70%

Area under the Curve: 0.908; 95%CI: 0.888-0.925

Receiver Operator Characteristics (ROC) curve for AD8

FIGURE 39-5: Clock drawing by a patient with moderate Alzheimer disease. The patient was asked to draw a clock at 3:00 PM.

Psychotic Symptoms

Delusional thought content and hallucinations are common in people with AD. These psychotic symptoms differ from those of schizophrenia.

Suspiciousness, Delusions, and Illusions

Illusions, or mistaken perceptions, are also common in patients with AD. For example, a woman with AD mistakes her husband for her father. He resembles her father in that he is roughly her father's age when the father was last alive. If an illusion becomes a false fixed belief, it is a delusion.

As the disease progresses, delusions develop in 34% to 50% of the people with AD. These characteristic delusions are different from those discussed in the psychotic disorders. Common delusional beliefs include the following:

- Belief that their partner is engaging in marital infidelity
- Belief that other patients or staff are trying to hurt them
- Belief that staff or family members are impersonators
- Belief that people are stealing their belongings
- Belief that strangers are living in their home
- Belief that people on television are real and not actors

Hallucinations

Visual, rather than auditory, hallucinations are the most common in AD. A frequent complaint is that children, adults, or strange creatures are entering the house or the patient's room. These hallucinations may not seem unusual to the patient. If possible, the content and form of hallucination should be ascertained because this information may suggest a treatable disorder. For example, an auditory hallucination commanding the patient to commit suicide may be caused by a treatable depression, not AD. In some cases, hallucinations may be pleasant, such as children being in the room, or the hallucinations may be frightening and uncomfortable.

Mood Changes

A depressed mood is common, but major depression and AD appear to be separate disorders. Many people with AD experience one or more depressive episodes with symptoms such as psychomotor retardation, anxiety, feelings of guilt and worthlessness, sadness, frequent crying, insomnia, loss of appetite, weight loss, and suicidal rumination. Depressive symptoms are most prevalent in the early stages of AD, which may be attributed to the patient's awareness of cognitive changes, memory loss, and functional decline (Kuo et al., 2020).

Anxiety

Moderate anxiety is a natural reaction to the fear engendered by gradual deterioration of intellectual function and the realization of impending loss of control over one's life. Failure to complete a task formerly regarded as simple creates a source of anxiety in patient with AD. As patients with AD become unsure of their surroundings and the expectations of others, they frequently react with fear and distress. It is thought that anxious behavior occurs when the patient is pressed to perform beyond their ability.

Catastrophic Reactions

Catastrophic reactions are overreactions or extreme anxiety reactions to everyday situations. Catastrophic responses occur when environmental stressors are allowed to continue or increase beyond the patient's threshold of stress tolerance. Behaviors indicative of catastrophic reactions typically include verbal or physical aggression, violence, agitated or anxious behavior, emotional outbursts, noisy behavior, compulsive or repetitive behavior, agitated night awakening, and other behaviors in which the patient is cognitively or socially inaccessible. Factors that contribute to catastrophic responses in patients with progressive cognitive decline include fatigue, a change in routine (e.g., faster pace, caregiver), demands beyond the patient's ability, overwhelming sensory stimuli, and physical stressors (e.g., pain, hunger).

Behavioral Responses

Apathy and Withdrawal

Apathy, the inability or unwillingness to become involved with one's environment, is common in AD, especially in the moderate to late stages. Apathy leads to withdrawal from the environment and a gradual loss of empathy for others. This lack of empathy is very difficult for families and friends to understand.

Restlessness, Agitation, and Aggression

Restlessness, agitation, and aggression are relatively common in the moderate to late stages of AD. Restlessness should be further evaluated to determine its underlying cause. If the restlessness occurs during medication change or adjustment, side effects should be suspected.

Aberrant Motor Behavior

Symptoms such as fidgeting, picking at clothing, wringing hands, loud vocalizations, and wandering may all be signs of such underlying conditions as dehydration, medication reaction, pain, or infection (suggesting delirium). One of the most difficult behaviors for which to determine an underlying cause is *hypervocalization*, a term that refers to the screams, curses, moans, groans, and verbal repetitiveness that are common in the later stages of AD in cognitively impaired older adults, often occurring during a hospitalization or nursing home placement. In the assessment of these hypervocalizations, it is important to identify when the behavior is occurring; antecedents of the behavior; and any related events, such as a family member leaving or a change in stimulation.

Disinhibition

One of the most frustrating symptoms of AD is **disinhibition**, acting on thoughts and feelings without exercising appropriate social judgment. In AD, the patient may decide that they are more comfortable naked than with clothes. Or the patient may not be able to find their clothes and may walk into a room of people without any clothes on. This behavior is extremely disconcerting to family members and can also lead to nursing home placement.

Hypersexuality

A closely related symptom is **hypersexuality**, which is inappropriate and socially unacceptable sexual behavior. The patient begins talking and behaving in ways that are uncharacteristic of premorbid behavior. This behavior is very

difficult for family members and nursing home staff.

Stress and Coping Skills

Patients with AD seem extremely sensitive to stressful situations and often do not have the coping abilities to deal with such situations. A careful assessment of the triggers that precede stressful situations will help in understanding a provoking event.

Social Network and Support System

AD interferes with a person's ability to interact socially as much as it disrupts intellectual functioning. The patient's whole social network is affected by AD, and the primary caregiver of a person with AD (usually the partner or offspring in a community setting) is often considered a copatient. It is important to assess the family caregiver's ability to use supportive mechanisms to maintain their own integrity throughout the disease process.

If the patient still resides in the community, a home visit will prove useful because it provides information about the patient in the natural environment. From this assessment, the situational and psychosocial stressors that affect the family and patient can be identified, so interventions to strengthen coping strategies, including the ability to seek help from appropriate community resources, can be developed.

CLINICAL JUDGMENT

The unique and changing needs of these patients present a challenge for nurses in all settings. Priorities of care vary according to the stage of the disease. Early on, memory impairment and confusion may be present. An individual may begin to feel less connected and engaged in usual activities. As the disease progresses, the patient may have difficulty with their ADLs. Safety concerns may be present, especially if the patient is agitated, aggressive, or prone to wandering. In late stages of AD, the patient may be completely reliant on others in meeting basic health care needs.

MENTAL HEALTH NURSING INTERVENTIONS

Self-Care Interventions

Patients should be encouraged to maintain as much self-care as possible. If eyeglasses and hearing aids are needed but not used, patients are more likely to have false perceptual experiences (hallucinations).

Oral hygiene can be a problem and requires excellent basic nursing care. Aging and many medications reduce salivary flow, which can lead to a painfully dry and cracking oral mucosa. Periodontal disease (a persistent low-grade inflammatory condition caused by pathogenic microorganisms) has been linked to increase in the amyloid beta (A-beta) load (Sadrameli et al., 2020). For patients with xerostomia (dry mouth), hard candy or chewing gum may stimulate salivary flow or modification of the drug regimen may be necessary. Glycerol mouthwash can provide as much relief from xerostomia as artificial saliva.

During later stages of AD, bathing can be problematic for the patient and nursing staff. Bath time is a high-risk time for agitation and aggression. The person-centered approach focuses on personalizing care to meet residents' needs, accommodating to residents' preferences, attending to the relationship and interaction with the resident, using effective communication and interpersonal skills, and adapting the physical environment and bathing procedures to decrease stress and discomfort.

Physical Health Interventions

Supporting Bowel and Bladder Function

Urinary or bowel incontinence affects many patients with AD. During the middle phases of the disease, incontinence may be caused by the patient's inability to communicate the need to use the toilet or locate a toilet quickly, undress appropriately to use the toilet, recognize the sensation of fullness signaling the need to urinate or defecate, or apathy with lack of motivation to remain continent.

For the patient who is incontinent because of an inability to locate the toilet, orientation may be helpful. Signs and active training should help to modify

disorientation. Displaying pictures or signs on bathroom doors provides visual cues; words should use appropriate terminology.

Sleep Interventions

Sedative–hypnotic agents may be prescribed for a short time for restlessness or insomnia, but they may also cause a paradoxical reaction of agitation and insomnia (especially in older adults). Sleep hygiene interventions are appropriate for patients with AD, although morning and afternoon naps (or rest periods for patients who do not nap) may be the most effective intervention for a patient with altered diurnal rhythms.

Activity and Exercise Interventions

Activity and exercise are important nursing interventions for patients with AD. To promote a feeling of success, any activity or exercise plan must be culturally sensitive and adapted to the patient's functional ability and interests. The activity or exercise must be designed to prevent excess stress (both physical and psychological), which means that it must be individualized for each patient with AD based on their relative strengths and deficits.

Nutritional Interventions

Maintenance of nutrition and hydration are essential nursing interventions. The patient's weight, oral intake, and hydration status should be monitored carefully. Patients with AD should eat well-balanced meals appropriate to their activity level and eating abilities, with special attention given to electrolyte balance and fluid intake. A Mediterranean diet (vegetables, whole grains and olive oil, fermented dairy products, nuts, seeds and herbs/spices, plant protein and seafood) supports a healthy gut and brain (Flanagan et al., 2020).

Watch for swallowing difficulties that may put the patient at risk for aspiration and asphyxiation. Swallowing difficulties may result from changes in esophageal motility and decreased secretion of saliva.

Pain and Comfort Management

Nursing care of noncommunicative patients who have AD and who also have pain can be challenging. Because of the difficulty in identifying and monitoring the pain, the patients are often undertreated. However, several measures may be used to assess the efficacy of pharmacologic interventions, such as decreased

restlessness and agitation. Small doses of oral morphine solution appear to reduce discomfort during routine nursing procedures. The main side effect of morphine is constipation.

Relaxation

Approaching patients in a calm, confident, unhurried manner; maintaining a soothing, quiet environment; avoiding unnecessary noise or chatter around patients and lowering vocal tone and rate when addressing them; maintaining eye contact; and using touch judiciously are likely to promote a sense of security conducive to patient relaxation and comfort. Simple relaxation exercises can be used to reduce stress and should be performed by the patient.

Medication Interventions

Medications have two goals: restoration or maintenance of cognitive function and treatment of related psychiatric and behavioral disturbances that cause discomfort for the patient, interfere with treatment, or worsen the individual's cognitive status. Doses must be kept extremely low, and patients should be monitored closely for any side effects or worsening of cognitive status. "Start low and go slow" is the principle guiding the administration of psychopharmacologic agents in older patients.

Cholinesterase Inhibitors.

Acetylcholinesterase inhibitors (AChEIs) are the mainstay of pharmacologic treatment of AD because they inhibit **acetylcholinesterase (AChE)**, an enzyme necessary for the breakdown of acetylcholine. Inhibition of AChE results in an increase in cholinergic activity. Because these medications have been shown to delay the decline in cognitive functioning but generally do not improve cognitive function after it has declined, it is important that this medication be started as soon as the diagnosis is made. The primary side effect of these medications is gastrointestinal distress, including nausea, vomiting, and diarrhea.

Cholinesterase inhibitors are indicated for the treatment of AD. These drugs may help to delay or prevent symptoms from becoming worse (see [Table 39.3](#)). Cholinesterase inhibitors are oral medications usually taken once or twice a day. The earlier in the disease process these medications are initiated, the more likely they will delay cognitive decline. Although there are no special monitors for the

cholinesterase inhibitors, the prolonged concurrent use of nonsteroidal antiinflammatory drugs (NSAIDs) with them can increase the risk of stomach ulcers.

TABLE 39.3 MEDICATIONS TO TREAT ALZHEIMER DISEASE

Drug	Drug Type and Use	Dose	Common Side Effects	Drug–Drug Interactions
<i>Donepezil</i> (Aricept)				
Prevents the breakdown of acetylcholine in the brain	Cholinesterase inhibitor treats symptoms of mild, moderate, and severe Alzheimer	5 mg once a day Increase after 4–6 wk to 10 mg/day	Nausea, diarrhea, vomiting	None observed in laboratory studies. NSAIDs should be used with caution in combination with this medication
<i>Galantamine</i> (Razadyne)				
Prevents breakdown of acetylcholine and modulates nicotinic receptors that release acetylcholine in the brain	Cholinesterase inhibitor treats symptoms of mild and moderate Alzheimer	4 mg BID Titrate to 16–24 mg/day over 8 wk	Nausea, vomiting, diarrhea, weight loss	Some antidepressants, such as paroxetine, amitriptyline, fluoxetine, fluvoxamine, and other drugs with anticholinergic action, may cause retention of excess galantamine in the body. NSAIDs should be used with caution in combination with this medication
<i>Memantine</i> (Namenda)				
Blocks toxic effects of excess glutamate and regulates glutamate activation	NMDA antagonist to treat moderate to severe symptoms of Alzheimer	Initial dose 5 mg once a day; may increase to 10 mg/day, 15 mg/day, 20 mg/day at weekly intervals	Dizziness, headache, diarrhea, constipation, confusion	A total of 174 drugs (1,401 brand and generic names) are known to interact with memantine. Other prescribed medications and substances should be checked for interactions
<i>Memantine Extended Release and Donepezil</i> (Namzaric)				
Blocks the toxic effects associated	NMDA antagonist and	28-mg memantine	Headache, nausea,	Combined use with NMDA antagonists, anticholinergic

with excess glutamate and prevents the breakdown of acetylcholine in the brain	cholinesterase inhibitor to treat symptoms of moderate to severe Alzheimer	extended release mg donepezil once a day	vomiting, diarrhea, dizziness	medications, succinylcholine, similar neuromuscular blocking agents, or cholinergic agonists
--	--	--	-------------------------------	--

Rivastigmine (Exelon)

Prevents the breakdown of acetylcholine and butyrylcholine in the brain	Cholinesterase inhibitor treats symptoms of mild to moderate Alzheimer (patch is also for severe)	1.5 mg BID Titrate to 24 mg/day by increasing 3 mg/day every 2 wk	Nausea, vomiting, weight loss, upset stomach, muscle weakness	None observed in laboratory studies; NSAIDs should be used with caution in combination with this medication
---	---	---	---	---

Note. BID, twice a day; NMDA, *N*-methyl-D-aspartic acid; NSAIDs, nonsteroidal antiinflammatory drug.

Adapted from USDHHS. (2018). *Treatment of Alzheimer's Disease*. Washington, DC: Alzheimer's Disease Education & Referral (ADEAR) Center, National Institute on Aging, National Institutes of Health, NIH Publication N. 08–3431. Retrieved February 5, 2021, from <https://www.nia.nih.gov/alzheimers/publication/alzheimers-disease-medications-fact-sheet#treatment>

N-Methyl-D-Aspartic Acid Antagonists.

In AD, it is hypothesized that the chronic release of glutamate leads to neuronal degeneration. Memantine (Namenda XR) is an *N*-methyl-d-aspartic acid (NMDA) receptor antagonist that has been shown to improve cognition and ADLs in patients with moderate to severe symptoms of AD (Yiannopoulou & Papageorgiou, 2020).

Memantine and Donepezil Combination

Patients stabilized on daily donepezil may be prescribed Namzaric, a combination of memantine and donepezil in one capsule (Box 39.4). This medication is formulated in various strengths of memantine (7, 14, 21, and 28 mg) combined with 10-mg donepezil.

Amyloid Beta-Directed Antibody

In AD, there is a build-up of the amyloid-beta plaque which interferes with neurotransmission. Aducanumab-avwa (ADUHELM®) was approved for the treatment of Alzheimer disease on an accelerated basis by the US Food and Drug Administration in 2021. This medication is a human, immunoglobulin gamma-1 (IgG1) monoclonal antibody that reduces the amyloid-beta plaques. Aduhelm is administered as an intravenous infusion over approximately 1 hour for every 4 weeks and at least 21 days apart. Patients can experience symptoms such as headache, confusion, dizziness, vision changes, or nausea. There can be temporary swelling in areas of the brain that usually resolves over time. Continued approval of this drug will depend on verification of clinical benefits in clinical trials (US FDA, 2021).

Other Medications

Even though antipsychotics are not approved for the use in dementia-related psychosis and have a boxed warning for this population, off-label use of antipsychotics for psychosis is common. There is evidence for the use of antidepressants for treating symptoms of depression and in reducing agitation (Magierski et al., 2020). Benzodiazepines should be used with caution and only on a short-term basis to treat anxiety in older adults. Anticholinergic medications should be avoided in patients with AD if at all possible. See [Box 39.5](#) for examples of medications that are commonly prescribed in older adults that have anticholinergic properties.

Psychosocial Interventions

The therapeutic relationship is the basis for interventions for the patient and family with dementia. Care of the patient entails a long-term relationship needing much support and expert nursing care. Interventions should be delivered within the relationship context.

Box 39.4

Memantine and Donepezil (Namzaric)

DRUG CLASS: N-methyl-D-aspartate (NMDA) receptor antagonist and

cholinesterase inhibitor

RECEPTOR AFFINITY: Low to moderate affinity uncompetitive (open-channel) NMDA receptor antagonist, which binds preferentially to the NMDA receptor, a reversible inhibitor of the enzyme acetylcholinesterase.

INDICATIONS: For treatment of moderate to severe dementia of the Alzheimer type in patients stabilized on 10 mg of donepezil hydrochloride once daily

ROUTES AND DOSAGE: 7-, 14-, 21-, and 28-mg tablets

For patients stabilized on donepezil hydrochloride 10 mg and not currently on memantine hydrochloride, the recommended starting dose of Namzaric is 7/10 mg, taken once a day in the evening. The dose should be increased in 7-mg increments of the memantine hydrochloride component to the recommended maintenance dose of 28/10 mg once daily. The minimum recommended interval between dose increases is 1 week. The dose should only be increased if the previous dose has been well tolerated. The maximum dose is 28/10 mg once daily.

HALF-LIFE (PEAK EFFECT): Terminal half-life, 60–80 hours (peak effect, 3–7 hours). Excreted predominantly in the liver.

SPECIFIC PATIENT AND FAMILY EDUCATION: Caregivers should be instructed in the recommended administration (twice per day for doses above 5 mg) and dose escalation (minimum interval of 1 week between dose increases).

- This drug does not alter the Alzheimer disease process, and the efficacy of the medication may decrease over time.
- Continue using other medications for dementia as prescribed by the health care provider.
- Review the patient information.
- Instruct patients and caregivers to take Namzaric only once daily in the evening, or as prescribed.
- If a patient misses a single dose of Namzaric, the patient should not double up on the next dose. The next dose should be taken as scheduled.
- Instruct patients and caregivers that Namzaric capsules should be swallowed

whole. Alternatively, Namzaric capsules may be opened and sprinkled on applesauce and the entire contents consumed. The capsules should not be divided, chewed, or crushed. Warn patients and caregivers not to use any capsules of Namzaric that are damaged or show signs of tampering.

- Advise patients and caregivers that Namzaric may cause headache, diarrhea, dizziness, anorexia, vomiting, nausea, and ecchymosis.
- Do not discontinue the drug or change the dose unless advised by the health care provider.
- Do not increase the dose of memantine if Alzheimer disease symptoms do not appear to be improving or appear to be getting worse; notify the health care provider.
- Namzaric may cause drowsiness or dizziness. Use caution while driving and performing other activities requiring mental alertness and coordination until tolerance is determined.
- Do not use any prescription or over-the-counter medications, dietary supplements, or herbal preparations unless advised by the health care provider.
- Follow-up visits may be required to monitor therapy and to keep appointments.

Box 39.5

Medications with Anticholinergic Effects

Amitriptyline

Captopril (Capoten)

Codeine

Cimetidine (Tagamet)

Citalopram (Celexa)

Digoxin (Lanoxin)

Diphenhydramine
Dipyridamole (Trental)
Donepezil (Aricept)
Escitalopram (Lexapro)
Furosemide (Lasix)
Fluoxetine (Prozac)
Isosorbide (Ismotic)
Mirtazapine (Remeron)
Nifedipine (Procardia)
Oxybutynin ER
Paroxetine (Paxil)
Phenytoin (Dilantin)
Prednisolone
Ranitidine (Zantac)
Theophylline
Triamterene and hydrochlorothiazide
Tolterodine (Detrol LA)
Warfarin (Coumadin)

Memory Enhancement

The sooner patients begin taking AChEIs, the slower the cognitive decline will be. However, pharmacologic agents are only a small part of the intervention picture. The nursing goal is to maintain memory function as long as possible. When caring for a patient with AD, a concerted effort should be made to reinforce short- and long-term memory. For example, reminding patients what they had for breakfast, which activity was just completed, or who their visitors were a few hours ago will reinforce short-term memory. Encouraging patients to tell the stories of their earlier years will help bring long-term memories into focus. In the earlier stages of AD, there is considerable frustration when the patient realizes that they have short-term memory loss. In a matter-of-fact manner, help “fill in the blanks” and then redirect to another activity. Pictures of familiar people, places, and activities are also important tools in memory retrieval. Using scents (perfume, shaving lotions, spices, different foods) to stimulate memory retrieval and asking patients to relate their memories are also

useful. Formalized reminiscence groups also help patients relive their earlier experiences and support maintenance of long-term memories.

Orientation Interventions

To enhance cognitive functioning, attempts should be made to remind patients of the day, time, and location. However, if the patient begins to argue that they are really at home or falsely believes that it is 1992, the patient need not be confronted by facts. Any confrontation could easily escalate into an argument. Instead, either redirect the patient or focus on the topic at hand ([Box 39.6](#)).

Maintaining Language

Losing the ability to name an object (i.e., agnosia) is frustrating. For example, the patient may describe a flower in terms of color, size, and fragrance but never be able to name the flower. When this happens while interacting with a patient, immediately say the name of the item. This reinforces cognitive functioning and prevents disruption in the interaction. Referral to speech therapists may also be useful if the language impairment impedes communication.

Supporting Visuospatial Functioning

The patient with visuospatial impairments loses the ability to sequence automatic behaviors, such as getting dressed or eating with silverware. For example, patients often put their clothes on backward, inside out, or with undergarments over outer garments. After they are dressed, they become confused as to how they arrived at their current state. If this happens, it may help to place clothes for dressing in a sequence for the patient so they patient can move from one article to the next in the correct sequence. This same technique can be used in other situations, such as eating, bathing, and toileting.

Interventions for Suspiciousness, Illusions, and Delusions

Delusions often occur when patients are placed in a situation they cannot master cognitively. The principle of nonconfrontation is most important in dealing with formation of suspiciousness and delusion. Efforts should be directed at determining the circumstances that trigger suspicion or delusion formation and creating a means of avoiding these situations.

Frequent causes of suspicion occur when changes in daily routine occur. The common accusations that “someone has entered my room,” or “someone has changed my room” can be managed by asking, “Do you want to see if anything is missing?” Such accusations usually arise when a patient cannot remember what the room looked like or when the room was rearranged or cleaned.

Patients with AD often have delusions that a spouse, child, or other significant person is an impostor. If this situation occurs, it is important to assert in a matter-of-fact manner, “This is your wife, Barbara” or “I am your daughter Jenny.” More vigorous assertions, such as offering various types of proof, tend to increase puzzlement as to why a person would go so far to impersonate the spouse or child.

BOX 39.6 • **Therapeutic Dialogue: The Patient with Dementia of the Alzheimer Type**

Lois’s daughter has told the home health agency nurse that on several occasions Lois has been found cowering and fearful under the kitchen table, saying she was hiding from voices. The nurse also knows that Lois denies having any difficulty with her memory or her ability to care for herself.

INEFFECTIVE APPROACH

Nurse: I’m here to see you about your health problems.

Lois: I have no problems. Why are you here?

Nurse: I’m here to help you.

Lois: I do not need any help. I think there is a mistake.

Nurse: Oh, there is no mistake. Your name is Ms. W, isn’t it?

Lois: Yes, but I don’t know who you are or why you are here. I’m very tired; please excuse me.

Nurse: OK. I will return another day.

EFFECTIVE APPROACH

Nurse: Hello, my name is Susan Miller. I’m the home health nurse, and I will be spending some time with you.

Lois: Oh, alright. Come in. Sit here.

Nurse: Thank you.

Lois: There is nothing wrong with me, you know.

Nurse: Are you wondering why I am here? (Open-ended statement)

Lois: I know why you are here. My children think that I cannot take care of myself.

Nurse: Is that true? Can you take care of yourself? (Restatement)

Lois: Of course I can care for myself. When people get older, they slow down. I'm just a little slower now, and that upsets my children.

Nurse: You are a little slower? (Reflection)

Lois: I sometimes forget things.

Nurse: Such as ... (open-ended statement)

Lois: Sometimes I cannot remember a telephone number or a name of a food.

Nurse: Does that cause problems?

Lois: According to my children, it does!

Nurse: What about you? What causes problems for you?

Lois: Sometimes the radio says terrible things to me.

Nurse: That must be frightening. (Acceptance)

Lois: It's terrifying. Then, my daughter looks at me as if I am crazy. Am I?

Nurse: It sounds like your mind is playing tricks on you. Let's see if we can figure out how to control the radio. (Validation)

Lois: Oh, OK. Will you tell my daughter that I am not crazy?

Nurse: Sure, I would be happy to meet with both you and your daughter if you would like. (Acceptance)

CRITICAL THINKING CHALLENGE

- In the first scenario, how did the nurse's underlying assumption that the patient would welcome the nurse lead to the nurse's rejection by the patient?
- What communication techniques did the nurse use in the second scenario to open communication and set the stage for the development of a sense of trust?

When patients experience illusions, find the source of the illusion and remove it from the environment if possible. For example, if a patient is watching a television program featuring animals and then verbalizes that the animal is in the

room, switch the channel and redirect the conversation.

Some patients with AD may no longer recognize the reflections in the mirror as themselves and become agitated, thinking that a stranger is staring at them. Potentially misleading or disturbing stimuli, such as mirrors or art work, can be easily covered or removed from the environment.

Interventions for Hallucinations

Reassurance and distraction may be helpful for the hallucinating patient. For example, an 89-year-old patient with AD in a residential care facility would get up each night, walk to the nursing station, and whisper to the nurses, “There’s a man in my bed who won’t let me sleep. You should patrol this place better!” If the hallucination is not too disturbing for the patient, it can often be dismissed calmly with diversion or distraction. Because this patient did not seem too concerned by the “man” in her bed, the nurse may gently respond by saying, “I’m sorry you have to put up with so much. Just wait here (or come with me) and I’ll make sure your room is ready for you.” The nurse should then take the patient back to her room and help her into bed.

Frightening hallucinations and delusions usually require antipsychotic medications to dampen the patient’s emotional reactions, but they can also be dealt with by optimizing perceptual cues (e.g., cover mirrors, turn off the television) and by encouraging patients to stay physically close to their caregivers. For example, one patient complained to her visiting nurse that she was being poisoned by deadly bugs that crawled up and down her arms and legs while she tried to sleep at night. Antipsychotic medication may help this patient sleep at night, and she would also likely benefit from reassurance and protection.

Interventions for Mood Changes

Strategies for Depression

Psychotherapeutic nursing interventions for depression that accompanies AD are similar to interventions for any depression. It is important to spend time alone with patients and to personalize their care as a way of communicating the patient’s value. Encouraging expression of negative emotions is helpful because patients can talk honestly to a nonjudgmental person about their feelings. Although depressed patients with AD are likely to be too disorganized to attempt

suicide, it is wise to remove potentially harmful objects from the environment.

Coping with Stress and Anxiety

Cognitively impaired patients are particularly vulnerable to anxiety. Patients with AD become unsure of their surroundings or of what is expected of them and then tend to react with fear and distress. They may feel lost, insecure, and left out. Failure to complete a task formerly regarded as simple creates anxiety and agitation. Often, they cannot explain the source of their anxiety. In many cases, lowering the demands, simplifying routines, and reducing the number of choices alleviates the anxiety.

Interventions for Catastrophic Reactions

If a patient reacts catastrophically, remain calm, minimize environmental distractions (quiet the environment), get the patient's attention, and softly assure the patient that they are safe. Give information slowly, clearly, and simply, one step at a time. Let the patient know that you understand the fear or other emotional response, such as anger or anxiety.

As nursing skills are developed in identifying antecedents to the patient's catastrophic reactions, it becomes possible to avoid situations that provoke such reactions. Patients with AD respond well to structure but poorly to change. Attempts to argue or reason with them will only escalate their dysfunctional responses.

Interventions for Apathy and Withdrawal

As the patient withdraws and becomes more apathetic, it becomes more challenging to engage the patient in meaningful activities and interactions. Providing this level of care requires knowing the premorbid functioning level of the patient. Close contact with family helps provide ideas about meaningful activities.

Using Behavioral Interventions

Strategies for Restlessness and Wandering

Restlessness and wandering are major concerns for caregivers, especially in the

community (home) or long-term care setting. The principal means of dealing with restless patients who wander into other patients' rooms or out the door is to have an adequate number of staff (or caregivers in the home setting) to provide supervision, as well as electronically controlled exits. Wandering behavior may be interrupted in more cognitively intact patients by distracting them verbally or visually. Patients who are beyond verbal distraction can be distracted by physically joining them on their walk and then interrupting their course of action and gently redirecting them back to the house or facility. Many times, wandering is a result of a patient's inability to find their own room or may represent other agenda-seeking behaviors such as trying to find a bathroom.

Interventions for Agitated Behavior

Agitated behavior is likely to occur when patients are pressed to assist in their own care. A calm, unhurried, and undemanding approach is usually most effective. Attempts at reasoning may only aggravate the situation and increase the patient's resistance to care. If unable to determine the source of the patient's anxiety, the patient's restless energy can often be channeled into activities such as walking. Relaxation techniques also can be effective for reducing behavioral problems and anxiety in patients with AD.

TABLE 39.4 MESSAGES, MEANINGS, AND MANAGEMENT STRATEGIES

Possible Underlying Meanings	Related Management Strategies
"I'm hurt!" (e.g., from arthritis, fractures, pressure ulcers, degenerative joint disease, cancer)	<ul style="list-style-type: none"> • Observe for pain behaviors (e.g., posture, facial expressions, and gait in conjunction with vocalizations). • Treat suspected pain judiciously with analgesics and nonpharmacologic measures (e.g., repositioning, careful manipulation of patient during transfers and personal care, warm or cold packs, massage, relaxation).
"I'm tired." (e.g., sleep disturbances possibly related to altered sleep–wake cycle with day–night reversal, difficulty falling asleep, frequent night awakenings)	<ul style="list-style-type: none"> • Increase daytime activity and exercise to minimize daytime napping and promote nighttime sleep. • Promote normal sleep patterns and biorhythms by strengthening natural environmental cues (e.g., provide light exposure during the day; avoid bright lights at night), provide large calendars and clocks. • Establish a bedtime routine. • Reduce night awakenings: avoid excess fluids, diuretics, caffeine at bedtime, minimize loud noises, consolidate nighttime care activities (e.g., changing, medications,

“I’m lonely.”

“I need ...” (e.g., food, a drink, a blanket, to use the toilet, to be turned or repositioned)

“I’m stressed.” (e.g., Inability to tolerate sensory overload)

“I’m bored.” (e.g., lack of sensory stimulation)

“What are you doing to me?” (e.g., personal boundaries are invaded)

“I don’t feel well.” (e.g., a urinary or upper respiratory tract infection, metabolic abnormality, fecal impaction)

“I’m frustrated—I have no control.” (e.g., loss of autonomy)

“I’m lost.” (e.g., memory impairment)

“I feel strange.” (e.g., side effects from medications that may include psychotropics, corticosteroids, beta-blockers, NSAIDs)

treatments).

- Encourage social interactions between patients and their family, caregivers, and others.
- Increase time the patient spends in group settings to minimize time in isolation.
- Provide opportunity to interact with pets.
- Anticipate needs (e.g., assist the patient to toilet soon after breakfast when the gastrocolic reflex is likely).
- Keep patient comfort and safety in mind during care (e.g., minimize body exposure to prevent hypothermia).
- Promote rest and quiet time.
- Minimize “white noise” (e.g., vacuum cleaner) and background noise (e.g., televisions and radios).
- Avoid harsh lighting and busy, abstract designs.
- Limit patient’s contacts with other agitated people.
- Reduce behavioral expectations of patient, minimize choices, and promote a stable routine.
- Maximize hearing and visual abilities (e.g., keep external auditory canals free from cerumen plugs, ensure that glasses and hearing aids are worn, provide reading material of large print, soften lighting to reduce glare).
- Play soft classical music for auditory stimulation.
- Offer structured diversions (e.g., outdoor activities).
- Avoid startling patients by approaching them from the front.
- Always speak before touching the patient.
- Inform patients what you plan to do and why before you do it.
- Allow for flexibility in patient care.
- Identify the etiology through patient history, examination, possible tests (e.g., urinalysis, blood work, chest radiography, neurologic testing).
- Treat underlying causes.
- When possible, allow patient to make their own decisions.
- Maximize patient involvement during personal care (e.g., offer the patient a washcloth to assist with bathing).
- Treat patients with dignity and respect (e.g., dress or change patients in private).
- Maintain familiar routines.
- Label the patient’s room, bathroom, drawers, and possessions with large name signs.
- Promote a sense of belonging through displays of familiar personal items, such as old family pictures.
- Minimize the overall number of medications; consider nondrug interventions when possible.
- Begin new medications one at a time; start with low doses and titrate slowly. Suspect a drug reaction if the patient’s behavior (e.g., vocal) changes.
- Educate caregivers about the patient’s medications.

“I need to be loved!”

- Provide human contact and purposeful touch.
- Acknowledge or verify the patient’s feelings.
- Encourage alternative, nonverbal ways to express feelings, such as through music, painting, or drawing.
- Confirm a sense of purpose in life, acknowledge achievement, and reaffirm that the patient is still needed.

Note. NSAID, nonsteroidal antiinflammatory drug.

Interventions for Aberrant Behavior

When patients are picking in the air or wringing hands, simple distraction may work. Hypervocalizations are another story. Direct care staff tend to avoid these patients, which only makes the vocalizations worse. In reality, these vocalizations may have meaning to the patient. Instead, develop strategies to try to reduce the frequency of vocalizations ([Table 39.4](#)).

Reducing Disinhibition

Anticipation of disinhibiting behavior is the key to nursing interventions for this problem. Disinhibition can take many forms, from undressing in a public setting to touching someone inappropriately to making cruel but factual statements. This behavior can usually be viewed as normal by itself but abnormal within its social context. Keen behavioral assessment of the patient increases the ability to anticipate the likely socially inappropriate behavior and redirect the patient or change the context of the situation. If the patient starts undressing in the dining room, offering a robe and gently escorting them to another part of the room might be all that is needed. If a patient is trying to fondle a staff member, having the staff member leave the immediate area or redirecting the patient may alleviate the situation.

Psychoeducation for Families

Especially in AD, the needs of family members should also be considered. Caring for a family member with dementia takes its toll. Eighty percent of the home care is provided by family caregivers. Two thirds of the caregivers are women, and 34% are over the age of 65 years. Caregivers' health often declines and directly affects their ability to provide care (Alzheimer's Association, 2020). Caregivers are faced with extreme pressures and often feel isolated, frustrated, and trapped. The potential for patient abuse is significant, especially if agitated and aggressive behaviors are present in the relative.

Caregivers should be encouraged to attend support groups and carve out personal time. Educational and training programs may help in understanding the complex nature of the disorder (Boxes 39.7 and 39.8). Community resources, such as day care centers, home health agencies, and other community services, can be an important aspect of nursing care for the patient with dementia.

Promoting Safety

In the early stages of the illness, safety may not seem to be a prime issue because the individual is cognitively intact. However, early behaviors suggesting AD are often related to safety, such as the patient getting lost while driving or going the wrong way on the highway. Patients may be prevented from driving even though they can continue to live at home. Safety continues to be an issue in the home when patients engage in unsupervised cooking, cleaning, or household tasks. Day care centers provide a structured yet safe environment for these individuals. Family members should be encouraged to assess continually the abilities of members to live at home safely.

Tips for Caregivers

When caring for the patient with dementia, be sure to include the caregivers, as appropriate, and address the following topic areas in the teaching plan:

- Psychopharmacologic agents, if used, including drug action, dosage, frequency, and possible adverse effects
- Rest and activity
- Consistency in routines
- Nutrition and hydration
- Sleep and comfort measures
- Protective environment
- Communication and social interaction
- Diversional measures
- Community resources

During hospitalizations or nursing home care, the safety issues are different. Most geropsychiatric units are kept locked and a dementia unit often has an electronic alarm system to alert staff about patients attempting to leave the secured floor. Staff and visitors need to be vigilant for perilous situations.

Box 39.8

Caregiver Burden and Quality of Life

Zeliha, T., Baykal, D., Erturk, S., Bilgic, B., Hanagasi, H., & Gurvit, I. H. (2020). *Caregiver burden, quality of life and related factors in family caregivers of dementia patients in Turkey. Issues in Mental Health Nursing*, 41(8), 741–749, DOI:10.1080/01612840.2019.1705945

THE QUESTION: What are the caregiver burdens and quality of life in dementia caregivers?

METHODS: Family caregivers of persons with dementia ($N = 102$) attending an outpatient dementia clinic were assessed for their caregiver burden and quality of life.

FINDINGS: Caregiver burden was related to quality of life. Compared to the general population with the same age, caregivers of dementia patients had

poorer quality of life. Polypharmacy, cognitive function, age of the caregiver, and having limited space at home were predictors of caregiver burden. Having any disease and having limited space at home were predictors for poorer quality of life of the caregivers.

IMPLICATIONS FOR NURSING: Caregivers are at high risk for poorer quality of life than the general population. Nurses should assess caregivers and provide them support as they care for persons with Alzheimer disease.

Implementing Milieu Therapy

Overstimulating activities (e.g., social outing, family visit) can result in an outburst of delusional accusations or agitation. The nurse should attempt to determine each patient's optimal level of stimulation at various times of the day. It may be that stimulating environments can be tolerated early in the morning but not in the afternoon, when the patient is tired.

Socialization Activities

Overlearned social skills are rarely lost in patients with AD. It is not unusual for patients with dementia to respond appropriately to a handshake or smile well into the disease process. Even patients who are no longer able to communicate coherently will carry on long discussions with people who are willing to listen and respond (to language that does not make sense). The risk for social isolation is strong in patients with AD because of communication difficulties. Reinforcing social remarks and gestures, such as eye contact, smiling, greetings, and farewells, can promote a sense of competency and self-esteem. Pet therapy and "stuffed animal" therapy can also enhance social interaction in cognitively impaired individuals. It is important to remember that patients with AD do not lose their ability to laugh and play, and the psychosocial benefits of humor are well known.

Activities that elicit pleasant memories from an earlier time in the patient's life (reminiscence) may produce a soothing effect. Eliciting pleasant memories may be enhanced by gentle stimulation of the patient's senses, for example, viewing and discussing photo albums, looking at personal memorabilia, providing a favorite food item, playing a musical instrument, or listening to

music the person preferred in younger years. It may be useful to incorporate movement or dance along with a singing exercise.

If the patient with AD resists structured exercise, it may be because of a fear of falling or injury or of demonstrating to others that their health is failing. Patients with AD often forget how to move or how to coordinate their movements in relation to objects. Therefore, exercise should be light and enjoyable. Encourage the patient to take rest periods at intervals throughout the activity in an effort to minimize stress.

Evaluation and Treatment Outcomes

The objectives of nursing interventions are to help the patient with AD remain as independent as possible and to function at the highest cognitive, physical, emotional, spiritual, and social levels. The maximum level of functional ability can be promoted when nursing care is related to and based on the remaining abilities of the patient.

Continuum of Care

The goal of in-home and community-based long-term care services is to maintain patients in a self-determining environment that provides the most home-like atmosphere possible, allows maximum personal choice for care recipients and caregiver, and encourages optimal family caregiving involvement without overwhelming the resources of the family network. All services for patients with AD and their families must be provided within a context of continuity of care, a concept that mandates access to various health and supportive services over an unpredictable and changing clinical course.

Nurses working with patients with AD are especially knowledgeable about all aspects of the illness and care. These nurses are often involved in local organizations, such as the Alzheimer's Association. Issues of care and safety and reimbursement for services often require professional expertise and influence.

Inpatient-Focused Care

Comprehensive admission assessment followed by the development of an individualized (and constantly updated) care plan that involves the patient, significant others, and diverse health care professionals is the foundation of an

effective and efficient post-discharge plan. Attention to all aspects of this process is necessary to ensure that the goal of continuity of care is achieved. The hospital-based nurse may initiate family education and counseling as part of discharge planning.

Community Care

It is estimated that more than 60% to 70% of older adults with AD live at home, with 86% of home care provided by family and friends. In 2019, unpaid caregivers provided \$244 billion of economic worth (Alzheimer's Association, 2020). Use of community-based services (e.g., home health aides, home-delivered meals, adult day care centers, respite care, caregiver support groups) often extends the amount of time an individual with AD or a related disorder can safely remain in the home.

Nursing Home

As the AD progresses, many patients are placed in a nursing home for care. Nursing care in a nursing home is usually delivered by nurses' aides, who need support and direction. Interestingly, people with AD require complex nursing care, but the skill level of people caring for these individuals often is minimal. Education and support of the direct caregiver is the focus of most nursing homes.

Integration with Primary Care

Persons with AD usually have multiple physical health issues and are most likely to be treated by primary care providers. Dementia is often treated in the primary care health care settings until behavioral disturbances emerge. Persons with advancing dementia are then referred to mental health or specialized geriatric providers for treatment of these psychiatric symptoms. The other health care needs continue to be treated by primary care. The mental health specialist integrates care, with the medical health care being provided by the primary care nurse or physicians. If patients are treated with medications, the primary care nurse must be monitoring the patient for changes in target symptoms, side effects and drug-drug interactions.

OTHER DEMENTIAS

Dementia symptoms may occur as a result of a number of disorders and underlying etiologies. The subsequent sections provide a brief description of some of the dementias listed in the *DSM-5*. In each case, the classic symptoms of dementia (e.g., memory impairment with a number of other cognitive deficits) must be present. Nursing interventions for all dementias are similar to those described for individuals with AD.

Vascular Neurocognitive Disorder

Vascular neurocognitive disorder (also known as *vascular dementia*) is a decline in thinking skill caused by conditions that block or reduce blood flow to the brain and the second most common type of dementia. Slightly more men than women are affected. Vascular dementia results when a series of small strokes damage or destroy brain tissue. These are commonly referred to as “ministrokes” or TIAs; several TIAs may occur before the affected individual becomes aware of the symptoms of vascular dementia. Most often, a blood clot or plaques (fatty deposits) block the vessels that supply blood to the brain, causing a stroke. However, a stroke can also occur when a blood vessel bursts in the brain (Alzheimer’s Association, 2021b).

Symptoms of vascular neurocognitive disorder usually begin more suddenly rather than in AD. Often, the neurologic symptoms associated with a TIA are minimal and may last only a few days, including slight weakness in a limb, dizziness, or slurred speech. Thus, the clinical progression is often described as intermittent and fluctuating or of step-like deterioration, with the patient’s cognitive and functional status improving or plateauing for a period of time followed by a rapid decline in function after another series of TIAs. Treatment aims to reduce the primary risk factors for vascular dementia, including hypertension, diabetes mellitus, and additional strokes.

Dementia Caused by Parkinson Disease

In individuals with Parkinson disease, 75% will develop neurocognitive dementia (APA, 2013). Although investigators do not know why, pathologic

overlap is considerable between Parkinson disease and AD. The evidence consistently suggests that low cerebrospinal fluid levels of amyloid-beta predict future cognitive decline and dementia in Parkinson disease. Cognitive-enhancing medications have some effect, but there is no convincing evidence that the progression of dementia can be delayed (Kyle & Bronstein, 2020).

Dementia Caused by Huntington's Disease

Huntington's disease is a progressive, genetically transmitted, autosomal dominant disorder characterized by choreiform movements and mental abnormalities. The onset is usually between the ages of 30 and 50 years, but onset occurs before 5 years of age in the juvenile form or as late as 85 years of age in the late-onset form. The disease affects men and women equally. A person with Huntington's disease usually lives for approximately 15 years after diagnosis (APA, 2013). The dementia syndrome of Huntington's disease is characterized by insidious changes in behavior and personality. Typically, the dementia is frontal, which means that the person demonstrates prominent behavioral problems and disruption of attention.

FRONTOTEMPORAL NEUROCOGNITIVE DISORDER

Progressive development of behavioral and personality change and/or language impairment characterizes frontotemporal neurocognitive disorder, which has distinct patterns of brain atrophy and distinctive neuropathology. Individuals with this disorder have varying degrees of apathy or disinhibition. They may lose interest in socialization, self-care, and personal responsibilities. Family members report socially inappropriate behaviors, but afflicted individuals show little insight. The cognitive deficits are typically in the area of planning, organization, and judgments. They are easily distracted (APA, 2013).

NEUROCOGNITIVE DISORDER WITH LEWY BODIES

Progressive cognitive decline with visual hallucination, REM sleep disorder, and spontaneous parkinsonism characterizes dementia with Lewy bodies, a major neurocognitive disorder. Cognitive symptoms occur several months before motor symptoms. These symptoms fluctuate and may resemble delirium. These individuals are at high risk for falls because of periods of syncope and transient episodes of consciousness. Orthostatic hypotension and urinary incontinence may occur. The cause is unknown, but evidence implies genetic factors and neuroinflammation (Hinkle & Pontone, 2020). The pathology involves Lewy bodies found in the cortical location in the brain, which are thought to be responsible for the disorder.

The estimated prevalence of this dementia ranges from 0.1% to 5% of the general older population, with men slightly more affected (APA, 2013). This onset of disorder is typically in the sixth to ninth decades and is progressive with a 5- to 7-year survival rate. These individuals are more functionally impaired than those with other types of dementia (e.g., AD) and are very sensitive to psychotropic medication, especially antipsychotics.

NEUROCOGNITIVE DISORDER DUE TO PRION DISEASE

Neurocognitive disorder due to prion-related symptoms comprises a group of spongiform encephalopathies including Creutzfeldt–Jakob disease, a rare, rapidly fatal, brain disorder, and mad cow disease, which is a bovine disorder. A prion is a small infectious particle composed of abnormally folded protein that causes progressive neurodegeneration. Many of the symptoms seen in Creutzfeldt–Jakob disease are similar to those found in AD and other dementias. However, changes in the brain tissue are different in Creutzfeldt–Jakob disease and are best differentiated with surgical biopsy or during autopsy (APA, 2013). Common symptoms include fluctuating fever, difficulty swallowing, incontinence, tremors, seizures, and sensitivity to touch and environmental noise.

At present, no effective treatment for the disease exists and nothing has been found to slow progression of the illness, although antiviral drug studies are ongoing. Person-to-person transmission of Creutzfeldt–Jakob disease is rare (but possible), and it can be transmitted from people to animals and between animals.

Because of the transmissible nature of Creutzfeldt–Jakob disease and because the virus is not easily destroyed, strict criteria for the handling of infected tissues and other contaminated materials have been developed.

NEUROCOGNITIVE DISORDER DUE TO TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) affects about 1.4 to 1.7 million people in the United States each year, resulting in various symptoms including neurological, cognitive, behavioral, and emotional impairments (APA, 2013). Repeated concussions can lead to brain injury with long-term TBI. Evidence suggests that even mild TBI is a significant risk factor of developing dementia (Maigler et al., 2021).

SUBSTANCE- OR MEDICATION-INDUCED NEUROCOGNITIVE DISORDER

If dementia results from the persisting effects of a substance (e.g., drugs of abuse, a medication, exposure to toxins), substance-induced neurocognitive disorder is diagnosed. Other causes of dementia (e.g., dementia caused by a general medical condition) must always be considered even in a person with a dependence on or exposure to a substance. For example, head injuries often result from substance use and may be the underlying cause of the neurocognitive changes (APA, 2013). Prescription drugs are the most common toxins in older adults.

SUMMARY OF KEY POINTS

- Neurocognitive disorders are characterized clinically by significant deficits in cognition or memory that represent a clear-cut change from a previous level of functioning. In some disorders, the loss of cognitive function is

progressive, such as in AD. It is important to recognize the differences because the interventions and expected outcomes of the two syndromes are different.

- Delirium is characterized by a disturbance in consciousness and a change in cognition that develops over a short period of time. It requires rapid detection and treatment.
- The primary goal of treatment of individuals with delirium is prevention or resolution of the acute confusion episode with return to previous cognitive status and interventions focusing on (1) elimination or correction of the underlying cause and (2) symptomatic and safety and supportive measures.
- Dementia is characterized by the gradual onset of decline in cognitive function, especially memory, usually accompanied by changes in behavior and personality.
- AD is an example of a progressively degenerative dementia. Treatment efforts currently focus on reduction of cognitive symptoms (e.g., memory loss; confusion; and problems with learning, speech, and reasoning) in attempts to improve the quality of life for both patients and their caregivers.
- Research efforts continue to focus on understanding the relationship among the development of the beta-amyloid plaques, neurofibrillary tangles, and cell death.
- Nursing care of a person with dementia depends on the stage of the disease and the availability of family caregivers.
- Educating and supporting families and caregivers through the progressive cognitive decline and behavior changes is essential to ensuring proper care.
- Several mental health strategies (exercise, education, cognitive stimulation) support and protect a person's cognitive reserve. A healthy cognitive reserve is thought to be protective against neuropathologic insults.
- Other neurocognitive disorders may be related to specific brain changes (Lewy bodies), infections (prion disease), genetic diseases (Huntington's disease), and substances/medications.

CRITICAL THINKING CHALLENGES

1. What factors should be considered in differentiating AD from vascular dementia?
2. Suggest reasons that older adults are particularly vulnerable to the development of neurocognitive disorders.
3. Compare the nursing care of a person with delirium versus one with dementia. What are the similarities and differences in the care?
4. The physical environment is particularly important to the patient with dementia. Visualize your last experience in a health care setting (e.g., hospital, nursing home, day care program, home care setting). Identify environmental factors that could be misleading or stress producing to a person with impaired cognition (dementia) and identify ways to modify this environment to alleviate some of the stressors or misleading stimuli.
5. Mr. J. has been recently diagnosed with mild AD and is asking for advice about deciding on his care in the future. His wife and daughter believe that he does not have the ability to make these decisions and asks for the nurse's advice. How should the nurse respond? Explain the rationale.

Movie Viewing Guides

Iris (2001): This film tells the story of British novelist Iris Murdoch (played by Kate Winslet and then by Judi Dench when Iris is much older) and her relationship with her husband, John Bayley (played by Hugh Bonneville and Jim Broadbent) during the last 5 years of her life. Based on Bayley's memoir, *Elegy for Iris*, the film depicts Ms. Murdoch's decline into dementia and the stress associated with caregiving. This wonderful movie shows the suffering of a person with AD but also shows the strength of relationships. The film contrasts their relationship at the start, when Iris was an outgoing but dominant individual and John was a timid, shy, scholarly partner, with that between the two older

adults who created a loving bond that provided the fabric of the last days of Iris's life.

VIEWING POINTS: Identify the symptoms of the progressive illness throughout the film. Were there any “breaking points” for the caregiver? Were there aspects of Iris's personality that were sustained throughout the course of her life that were evident at the end? What nursing interventions would have been helpful to support her cognitive functioning?

Unit IX: Care of Special Populations

40

Care of Veterans with Mental Health Needs

Mary Ann Boyd

KEY CONCEPTS

- Military Sexual Trauma
- Military Veteran
- Moral Injury
- Veteran Identity

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the military culture.
2. Trace the mental health needs of veterans during various military campaigns.
3. Describe the changing role of women in the military.
4. Discuss the inclusion of underrepresented groups in the military.
5. Analyze mental health needs of veterans.
6. Describe recovery-oriented nursing care for veterans with mental health needs.
7. Describe the mental health services available to veterans.

KEY TERMS

- Active duty
- Active duty (regular) service member
- Anxious-arousal
- Betrayal
- Combat-related trauma
- Index trauma
- Microaggression
- Minority stress
- Musculoskeletal pain
- Non-combat-related trauma
- Numbing symptoms
- Operation Enduring Freedom (OEF)
- Operation Iraqi Freedom (OIF)

- Operation New Dawn (OND)
 - Perpetration
 - Post-9/11
 - Re-experiencing
 - Reservist
 - Service-connected disability
 - Sexual assault
 - Sexual harassment
 - Witnessing
-

INTRODUCTION

The defense and protection of the United States (U.S.) depend upon the U.S. military armed forces. Wars and conflicts not only shape the history of the United States but also affect the long-term health and mental health of military service members and veterans. Throughout this chapter specific health and mental health issues of military members and veterans are associated with the wars in which they served. The aim of this chapter is to discuss the mental health needs and recovery-oriented nursing care for veterans.

U.S. MILITARY ORGANIZATIONS

The U.S. military is a complex institution consisting of three departments (Army, Navy, and Air Force) reporting to the Department of Defense (DOD). The Navy and Marines fall under the Department of the Navy and the Air Force and the Space Force under the Department of Air Force. The Coast Guard, which is a military service and a branch of the Armed Forces, is organizationally housed in the Department of Homeland Security (Council on Foreign Relations, 2020).

There are also seven reserve components that provide trained units and qualified persons available for **active duty** in time or war or national emergency. The Army, Navy, Marine Corps, Air Force, and Coast Guard reserves are under federal control and are activated when they are needed. The Army National and Air National Guards are under the authority of their respective states with the exception of the District of Columbia National Guard, which is exclusively a

federal organization. All national guard units can be ordered into federal service if needed (Congressional Research Services, 2021).

The operational names of the conflicts in Iraq and Afghanistan are used frequently to differentiate the time and focus of the military engagement (Box 40.1). The military gives names for different operational phases of a war or conflict. See Table 40.1 for an overview of the military wars and conflicts of the United States (Torreon, 2020).

Active duty (regular) service members are employed full time by the military; the **reservists** and National Guard members are not on full-time active duty but may live on a military base and can be deployed at any time. Enlistment time varies from 2 years to more than 20 years depending on the career goals of the service member. Once service members are discharged from the military, they become veterans and are entitled to varying privileges according to time in service, rank, and situation.

BOX 40.1		
Names of Operational Phases of Conflicts in Iraq and Afghanistan		
Conflict	Operation Name	Period of Conflict*
Afghanistan (Global War on Terror—GWOT)	Operation Enduring Freedom (OEF)	2001–2014
	Operation Freedom’s Sentinel (OFS)	2014–present
Iraq	Operation Iraqi Freedom (OIF)	2003–2011
	Operation New Dawn (OND)	2010–2014
	Islamic State-Operation Inherent Resolve (OIR)	2014–present
Torreon, B. S. (2020). U.S. periods of war and dates of recent conflicts. <i>Congressional Research Service</i> . RS21405 Retrieved on April 28, 2021 from https://crsreports.congress.gov *Dates may vary depending on proclamations, declarations, laws, or treaties.		

In 1973, the United States ended conscription (compulsory enlistment of males) and transitioned to an all-volunteer force. An estimated 1.3 million currently serve as active-duty personnel, or less than one-half of 1% of the U.S. population. The Army is the largest U.S. military service with 35% of the active duty members (Council on Foreign Relations, 2020).

TABLE 40.1 U.S. MILITARY WARS/CONFLICTS

Wars/Conflicts	Periods of War
Revolutionary War	1775–1783
War of 1812	1812–1815
Mexican American War	1846–1848
American Civil War	1861–1865
Spanish American War	1898–1902
World War I	1917–1918
World War II	1939–1945
Korean Conflict	1950–1955
Vietnam War	1959–1975
Gulf War	1990–1991
Conflict in Afghanistan	2001–present
Iraq Conflict	2003–2011

*Dates may vary depending on proclamations, declarations, laws, or treaties.

Military Culture

The military culture is structured to protect and defend the United States. The values, beliefs, and behaviors acquired in the military often last a lifetime. As a hierarchal organization, there is a chain of command with defined authority and responsibility. Leaders protect and maintain the health and well-being of their subordinates. Officers are expected to transmit values of honor, pride, discipline, and loyalty, instill warrior beliefs, and display self-sacrifice behaviors. There is a clear separation of officers and enlisted members with order and discipline being instilled in both groups. Officers and enlisted members are expected to maintain separate social networks. Within the military, there is little room for individuality. Symbols of military order include uniforms and rituals such as saluting officers and military march (Center for Deployment Psychology, 2021).

The Changing Role of Women in the Military Throughout History

Before World War II (WWII), women could only serve in the Women's Army Auxiliary Corps and the Army Nurse Corp., temporary, auxiliary components. They were activated only during times of national need such as during a war. These women were released from duty at the end of each war. Their work was often stigmatized and mocked. Sexual harassment was common (Blakemore, 2019).

The *Women's Armed Services Integration Act* signed into law on June 12, 1948 recognized women as full members of the armed forces. This meant that they could claim the same benefits as their male counterparts and it allowed women to make a career in the armed forces. The law limited the number of women who could serve in the military to 2% of total forces in each branch. As a result of a regulation, mothers with dependent children were ineligible to serve in the military.

During the Vietnam War, 7,000 American military women served in Southeast Asia. When the draft ended in 1973, women represented just 2% of enlisted forces and 8% of the officer corps (primarily nurses). Following the elimination of the draft, the need for service members became apparent and women were actively recruited into the military. Women were finally admitted into America's service academies in 1976. Nearly 40,000 women were deployed for Gulf War. In 2020, women represented 16% of the enlisted forces and 19% of the officers. More than 700,000 women have served since post-9/11, including **Operation Enduring Freedom (OEF)** and **Operation Iraqi Freedom (OIF)** (Gorbulja-Maldonado, 2020).

Inclusion of Underrepresented Groups in the Military

Information related to underrepresented groups in the military is very general because of federal racial and ethnic categorization. Federal agencies categorize race according to five groups—**White, Black or African American, American Indian or Alaska Native, Asian, and Native Hawaiian or other Pacific Islander**. Ethnicity is divided into two groups: (a) Hispanic/Latinx and (b) not Hispanic or Latinx. Based upon federal data, we know that a greater proportion

of underrepresented groups are found primarily in the lower rather than the higher military ranks. The majority of all service members are White with the overwhelming majority of officers in all military departments also White. In all the services, underrepresentation is higher among female recruits than among male recruits (Council on Foreign Relations, 2020).

BOX 40.2

Recommendations to Improve Racial and Ethnic Diversity and Inclusion in the U.S. Military

- **Recruitment and Accessions:** Strengthen both community engagement and the narrative about military service opportunities during recruiting to attract more diverse candidates.
- **Retention:** Retain minorities beyond initial commitment and into leadership ranks.
- **Barriers:** Address barriers confronted by minority members in the workplace.
- **Career Development:** Improve advancement opportunities (e.g., promotion boards, command selection, professional military education, assignments).
- **Organizational Climate:** Address command and organizational climate issues that may negatively impact the retention of minority members.
- **Culture, Worldview, and Identity:** Promote inclusion of minority groups in military culture and strengthen aspects of individual and cultural identity.

Department of Defense (2020). Recommendations to improve racial and ethnic diversity and inclusion in the U.S. military. Retrieved May 21, 2020 from <https://media.defense.gov/2020/Dec/18/2002554852/-1/-1/0/DOD-DIVERSITY-AND-INCLUSION-FINAL-BOARD-REPORT.PDF>

For most of the U.S. military history, persons who identified as lesbian, gay, bisexual, transgender, and queer or questioning (LGBTQ) were excluded from military service. In 1993, a DOD *Directive 1304.26*, known as the “Don’t Ask, Don’t Tell policy,” was issued that prohibited military personnel from asking or requiring recruits and service members to reveal their sexuality. Persons were no longer barred from military service based on sexual orientation. Even though LGBTQ persons could serve in the military service if they concealed their sexual orientation, they could be excluded if they demonstrated “a propensity or intent to engage in homosexual acts, or a homosexual marriage or attempted marriage (DOD Directive, 1993, December 21).” This directive remained in place until 2011 when the policy was repealed following a decision by a federal appeals court that barred further enforcement of the military’s ban on openly gay members. In 2016, President Obama allowed transgender individuals to serve openly in the armed forces, but the policy was later reversed by President

Trump. In 2021, President Biden lifted the ban and now individuals who identify as LGBTQ can serve openly in the military.

The DOD is strengthening policies and procedures that promote diversity and inclusion and equal opportunity missions. In a 2020 report, the DOD recommended six areas of improvement in recruitment and accessions, retention, barriers, career development, organizational climate, and culture, worldview, and identity (see [Box 40.2](#)).

VETERANS OF THE U.S. MILITARY

KEYCONCEPT **Military veteran** refers to persons who served in the armed services.

Every year, about 200,000 service members transition to civilian life (Inhofe et al., 2019). In 2019, there were more than 18 million veterans in the United States or about 7% of the U.S. population. The veteran population has been declining for years and the decline is expected to continue. By 2040, it is projected that there will be about 12.9 million veterans living in the United States (Vespa, 2020).

The veteran population served in several different departments, wars, and conflicts. The largest cohort of veterans served during the Vietnam Era (6.4 million) which lasted from 1964 to 1975. The second largest cohort served during peacetime only (4.0 million). The median age of veterans today is 65. The **post-9/11 group** (military service after September 2001) is the youngest with a median age of about 37, Vietnam Era veterans have a median age of about 71, and WWII veterans are the oldest with a median age of about 93 (Vespa, 2020).

Veteran Identity

The veteran population consists of men and women of varying ages, ethnicities, races, and military experiences. The common element for all veterans is that their experience in the military helped to shape their adult life and form a veteran identity.

KEYCONCEPT **A veteran identity** is the degree to which the veteran role is central or important to how they think about themselves and how they want others to view them (Adams et al., 2019).

In order to measure a veteran identity, researchers surveyed the strength of agreement of three questions on a scale of 0–4. The questions are “Being a veteran is an important reflection of who I am.” “I have come to think of myself as a veteran.” “It is important to me that others know about me as a veteran.” (Adams et al., 2019).

The presence of a strong veteran identity is variable among the cohorts. For example, Vietnam veterans tend to have the strongest veteran identity and the Iraq/Afghan veterans show the lowest identity. Veterans with a prominent veteran identity are generally older, non-college graduates, have limited income, and had their first deployment to Vietnam (Adams et al., 2019).

Female Veterans

Women make up a growing share of veterans. In 2021, about 9% of veterans or 1.7 million are women. By 2040, the number of women veterans is projected to increase to 17% (Adams et al., 2021). In 2017, the median age of women veterans was 51 years compared to 65 years for their male counterparts. The middle age group (45–64 years old) represent the largest group of women veteran Veterans Health Administration (VHA) patients (U.S. Department of Veterans Affairs, 2019).

Females tend to be younger and more likely college graduates than their male counterparts (holding similar positions or functions). Females are more likely to serve during the Afghanistan/Iraq War, be deployed in National Guard/Reserve units, and less likely to experience high combat exposure. The female veteran population is more racially diverse than their male counterpart and is less likely to serve multiple tours. Females are more likely to have low resilience and report poor health. Women veterans are more likely to contemplate suicide and experience depression, but less likely to abuse alcohol than their male counterparts (Adams et al., 2021).

HEALTH CARE FOR VETERANS

Health Issues of Veterans

Veterans have distinctive health issues related to the military service. They are

more likely to suffer from trauma-related injuries, substance use, and mental health disorders than people who have never served in the armed forces. About one-quarter (24.2% of 18,000,000) of all veterans have a **service-connected disability**, an injury, disease, or disability that active duty either caused or aggravated. The Gulf War and the post-9/11 veterans have the highest number of service-connected disabilities with more than 1/3 of whom had a service-connected disability. The post-9/11 veterans have the highest proportion (17%) of disabilities for all groups (Vespa, 2020).

It is thought that the high rate of post-9/11 veterans service-connected disabilities is related to several factors such as extended tours of duty or difficult service conditions that were not experienced by the other cohorts. Medical advances allow veterans to survive injuries that would have been fatal in past wars. Black, Hispanic, and other underrepresented veterans are more likely than White veterans to have a service-connected disability. While the type and severity of most injuries have remained constant across time, this is not true of posttraumatic stress disorder (PTSD). PTSD is more likely to be reported today than during previous periods (Vespa, 2020).

Transition to Civilian Life

Providing access and care immediately upon separation from the military is critical. The transition from the structured military life to civilian life can be difficult and stressful. The first year after discharge from the military is a high-risk period. Many newly separated veterans report chronic physical or mental health conditions and are less satisfied with their health than their work or social relations. Work satisfaction often deteriorates shortly after beginning a civilian job. Enlisted personnel consistently report poorer health, vocational, and social outcomes compared to their officer counterpart. War-zoned deployed service members report more health concerns; women have more mental health concerns when compared to their non-deployed female and male peers (Vogt et al., 2020).

The *Transition Assistance Program* supported by the departments of Defense, Veterans Affairs, and Homeland Security provides seamless access to mental health care and suicide prevention resources, particularly during the first year after separation or retirement (Exec. Order No. 13822, 2018). This program provides information on veteran benefits, mental health resources, training, and other resources to service members as they transition from military to civilian

life. Psychosocial and peer support are also provided. Registration in the Veterans Administration Health Care System is facilitated to assure access to health care. Veterans can choose to seek health care in the private community systems or the VHA ([Figure 40.1](#)).

Veterans Health Administration and U.S. Government Support of Veterans

The U.S. federal government has provided care for veterans since the first Soldier's Home opened after the Civil War in 1866, but it was not until 1946 that the care to the WWII veterans was initiated (U.S. Department of Veterans Affairs, n.d.). In 2021, the VHA is one of the two components of the Department of Veterans Affairs led by the Secretary of Veterans Affairs for Health and operates numerous medical and health care centers. The VA Health Care System has grown from 54 hospitals in 1930 to 1,600 health care facilities including 144 VA Medical Centers and 1,232 outpatient sites of care. The VHA operates one of the largest integrated health care systems in the world (U.S. Department of Veterans Affairs, 2021a).

Nursing attention to the needs of veterans has grown since 2007 when the Department of Veterans Affairs established the VA Nurse Academy which later became the VA Nursing Academic Partnerships. The goal is to enhance the care of the Veterans through developing relationships with nursing schools and providing educational opportunities for students (U.S. Department of Veterans Affairs, n.d.a.). In 2011, Former First Lady, Michelle Obama and Dr. Jill Biden launched *Joining Forces*, a national initiative to support service members, veterans, and their families. The goal was to bring attention to the needs of service members, veterans, and their families including their wellness needs (Joining Forces, n.d.). In 2021, First Lady, Dr. Jill Biden re-launched this initiative to continue to support service members, veterans, and their families.

Figure 40.1 Active service members thanking veterans for their service.

MENTAL HEALTH NEEDS OF VETERANS

Mental health needs are pervasive in the veteran population. Post-deployment depression, PTSD, and substance use disorders are disabling to the veterans and their families. Veterans are also at risk for suicide, traumatic brain injury (TBI), and homelessness.

Protective Factors

A strong veteran identity contributes to a positive self-esteem and self-definition and it can be protective of mental health problems such as suicide ideation (Adams et al., 2019). Protective factors also include serving multiple tours,

having a rank as an officer, and living in a rural area. In a study comparing mental health factors of rural versus non-rural veterans, the veterans living in the rural areas were more likely to be older, more often White, more often married, and less often college graduates. The rural veterans had few stressful events in the previous year, good overall measure of mental health, and used psychiatric services less often than their urban counterparts (Boscarino, Figley, et al., 2020). Other protective factors include employment, being able to meet basic needs, self-care, living stability, social support, spirituality, resilience, and self-determination (Elbogen et al., 2020).

Risks for Mental Health Issues

Veterans who are exposed to stressors and traumatic events during military deployments are at greater risk for mental disorders than the general population (Meyer et al., 2019). Common risk factors for major depressive disorder and PTSD include having high combat exposure, history of concussion, high stressful life events within the past year, and low social support. Other predictors of PTSD include being female, high lifetime trauma, and low social capital (few connections with neighborhood and neighbors). Female veterans have a greater risk than their male counterpart for lifetime PTSD, depression, suicidal thoughts, and for lifetime use of psychological services ([Figure 40.2](#)) (Boscarino, Adams, et al., 2020).

Females veterans living in non-rural areas have an increased risk for PTSD, depression, likelihood of using psychiatric services, and a decreased risk for alcohol problems when compared with the female veterans living in rural locations (Boscarino, Figley, et al., 2020).

National guard and reservists are at risk for post-deployment mental health problems which are more common in the national guard and reserve components than the active duty component. It was initially thought that the national guard and reservists had higher rates of mental disorders because of being less prepared and having less support than the active component. But, research shows that the mental health needs of national guard and reservists were related to combat exposure, lifetime traumatic stress exposures, current life stressors, and current social support (Boscarino, Adams, et al., 2020).

Figure 40.2 Female service members are integrated into military formation.

POSTTRAUMATIC STRESS DISORDER

Trauma and stress during military combat are not new. During the 17th to 19th century, the term *nostalgia* described a condition where a longing to return home was experienced by young people in the military. In nostalgia, service members experienced sadness, insomnia, and anorexia which were sometimes linked to psychic trauma. Nostalgia could lead to death (Battesti, 2016). During the American Civil War (1861–1865), a disorder known as *Soldier's Heart* developed after combat and was expressed as fatigue, shortness of breath, sighing respirations, palpitations, rapid heart rate, and sweating, with no observable cardiological abnormality (Bremner, et al., 2020; Da Costa, 1871). During the First World War (1914–1918), a condition known as “shell shock” or “war neurosis” was identified and shared similar, but not all, characteristics of modern day posttraumatic disorder (Pedroso et al., 2017; Stein & Rothbaum, 2018). In WWII, the terms *Combat Stress Reaction (CSR)* and *battle fatigue*

described a psychological condition that soldiers developed. This syndrome was characterized by anxiety, intense autonomic arousal, reliving, and sensitivity to stimuli (Andreasen, 2010). Up to half of the military discharges during WWII were said to be related to combat exhaustion (Friedman, n.d.).

The Korean and Vietnam wars brought attention to the traumatic experiences of service members. When the *Diagnostic and Statistical Manual III* was published in 1980, a stress disorders category was included (APA, 1980). The PTSD diagnostic criteria have evolved into the current diagnosis published in the *DMS-5* (Andreasen, 2010). See [Chapter 29](#). PTSD is now understood to be a complex interplay of biologic and psychological symptoms that are experienced as a result of other traumatic experiences besides the trauma of war.

Epidemiology

The prevalence of PTSD in veterans is difficult to estimate because of the various diagnostic criteria that have been used over several decades. Reliable data on the prevalence of PTSD in veterans from WWII to Vietnam war are not available. Most experts believe the prevalence is much greater than reported. Estimated prevalence data of PTSD from OEF and OIF veterans vary from 11% to 30% (see [Box 40.1](#)). Experts agree that veterans who served Iraq and Afghanistan report higher rates of PTSD than non-veteran population. Co-occurring disorders, particularly alcohol use disorder (AUD), are common in veterans with PTSD (Pedersen et al., 2020).

Trauma

To meet the criteria for a PTSD diagnosis, there must be exposure “to actual or threatened death serious injury, or sexual violence (APA, 2013, p. 271).” The trauma can be experienced, witnessed, or learned about such as an accidental or violent event of a family or friend (APA, 2013). An **index trauma** is defined as either the worst single event or closely related multiple events (Priebe et al., 2018; Weathers et al., 2018). When there are multiple traumatic events, it may be difficult to identify one single event that precipitated the PTSD symptoms.

Service members deployed to areas of combat are at high risk for trauma, such as Iraq and Afghanistan. In the recent Iraq/Afghanistan wars battlefield lines

were not linear. There was no clearly defined front line or area in the rear where safe operations could be performed. Attacks occurred without warning and battle lines shifted. Witnessing and experiencing combat events in these high-risk locations have provoked traumatic responses and initiated PTSD.

Typical PTSD symptoms related to military trauma include startle reaction with hypervigilance, avoidance of memories with avoidance of external reminders, anhedonia with detachment, being upset when reminded of event (physiological reactivity), and dreams with sleep disturbance (Osório et al., 2018).

Combat Versus Non-Combat-Related Trauma

Military trauma can be categorized as combat- or non-combat-related. **Combat-related trauma** occurs while engaging in warfare activities that involve injuries, loss of comrades on the battlefield, and improvised explosive devices. **Non-combat-related** trauma occurs outside of direct combat and includes trauma such as military sexual trauma (MST), witnessing violence and serious accidents. Both types of traumas can result in PTSD. When combat-related traumas are compared with non-combat-related traumas, differences in PTSD symptom patterns emerge.

In a study of 944 veterans, 63.5% experienced combat-related trauma. They were more likely to be male, White or Hawaiian/Pacific Islander, married or widowed, serve in Vietnam, or OEF/OIF/**Operation New Dawn** (OND). This cohort experienced self-blame, intrusive memories with dreams, detachment, and reckless behavior with lack of positive emotion. The veteran group that experienced non-combat-related trauma were more likely to be female, Black and African American, divorced, separated, or never married and to have either not deployed to a war zone or served in wars other than Vietnam and OEF/OIF/OND. The PTSD symptoms of this group included exaggerated startle, self-blame with distorted beliefs, and concentration problems related to anhedonia (Macia et al., 2020).

Moral Injury

Moral injury is emerging as a significant construct in understanding the consequences of exposure to traumatic events.

KEYCONCEPT Moral injury is “the lasting psychological, biological, spiritual, behavioral, and social impact of perpetrating, failing to prevent, or bearing witness to acts that transgress deeply held moral beliefs and expectations” (Litz et al., 2009, pg. 699).

Moral injurious experiences violate moral beliefs or cause one to question the justness of the world. Three types of moral injury have been identified. **Perpetration** is an act that transgresses or goes beyond personal moral values. **Witnessing** is observing transgression by others. **Betrayal** is being wronged by others’ transgressions. For moral injury to occur, there must be an awareness of the discrepancy between personal morals and the injurious experience which results in dissonance and inner conflict. Consequences of moral injury may include self-harming behaviors and demoralization (Litz et al., 2009).

When gender differences in exposure to potentially morally injurious events were examined in post-9/11 veterans ($N = 48,965$), 27.9% experienced witnessing events, 18.8% reported perpetration by commission or omission, and 41% reported being betrayed by leadership, fellow service members, or others outside the U.S. military. When separating the findings according to gender, women were more likely to experience psychological distress by witnessing and betrayal, whereas men experienced all three—perpetration, witnessing, and betrayal (Maguen et al., 2020).

The consequences of moral injury are apparent in the lives of the veterans. For example, for men who are parents who experienced perpetrating events such as the killing of children in war, they may fear harm to their own children who serve as a reminder of those who were killed. For women, betrayal, such as MST, may be a strong driver of impaired functioning leading to demoralization and self-blame (Maguen et al., 2020).

Violent Combat and Caring for the Wounded

Violent combat is associated with a greater risk of developing **re-experiencing**, a cognitive–sensory experience with an emotional response to current stimuli that resembles the aspects of the index trauma. Violent combat also is associated with **numbing symptoms**, (feeling flat physically and emotionally, unable to

fully participate in life) that are likely a result of intrusive memories, nightmares, distress, and physiological reactivity (Osório et al., 2018).

The proximity to wounding and death is associated with re-experiencing and **anxious-arousal** symptoms (cognitive impairment with autonomic symptoms). For example, military personnel who gave aid to the wounded and seriously wounded or handled bodies of killed service members are more likely to re-experience the trauma and exhibit anxious-arousal symptoms (Osório et al., 2018).

Microaggressions and Stress in Underrepresented Groups

Veterans who identify as lesbian, gay, bisexual, transgender, questioning, or queer LGBTQ are under stress because of social attitudes, stigma, and prevailing policies that may include exclusion from the service or reduction of benefits. They have PTSD from experiencing the trauma of war, plus discrimination, **microaggressions** (brief verbal, behavioral, or environmental indignities, whether intentional or unintentional, that communicate hostile, derogatory, or negative slights and insult), and **minority stress** (high levels of stress experience by stigmatized minority groups). These individuals report experiencing paranoia, hypervigilance, drug use, sexual risk taking, and heightened anxiety and depression (Livingston et al., 2020).

Evidence-Based Nursing Care for Veterans with PTSD

As with any patient, a comprehensive, patient-centered, and culturally informed assessment will guide veteran care. Veterans have unique needs which should be considered during the assessment process. Some veterans have a strong veteran identity, but others do not. It is important to determine the significance of the veteran experience and the relationship of the current PTSD symptoms to the military experience. Safety is always a concern. Is the patient having suicide thoughts or behaviors? For combat-related veterans, evidence of detachment, avoidance of people and places and lack of social support are important

indications that the veteran is experiencing PTSD symptoms.

The nurse should help the veteran identify the PTSD symptoms and refer patient to PTSD services. Encouragement from friends and family will increase the likelihood of engaging in therapy and the need for interpersonal therapy.

MILITARY SEXUAL TRAUMA

KEYCONCEPT **Military sexual trauma (MST)** refers to sexual assault and sexual harassment experienced during a veteran's military service (Title 38 U.S. Code 1720D).

MST includes any sexual activity during military service where a veteran is involved against their will. MST can occur on or off the military base (see [Box 40.3](#)). Perpetrators can be anyone—mentor or women, military personnel or civilians, commanding officers or subordinates, strangers, friends, or intimate partners.

MST is not a new phenomenon but has become more visible because victims are more likely to report the incident. In earlier wars, such as WWII and Vietnam, MST was underreported. If reported, the prevailing attitudes were that the victim was responsible or “asking for it.” **Sexual harassment** (e.g., jokes, images involving sexual innuendos, and comments regarding sexual activity,) is documented by female veterans from before 1973 through 1993. This harassment often occurred in public and work locations. **Sexual assaults** (i.e., intentional sexual touching without the persons consent, groping, rape, and forcing a person to engage in sexual act) occurred more likely when a woman was alone and on duty. Perpetrators were more likely to be ranked higher than the victim (Wolff & Mills, 2016).

BOX 40.3

Military Sexual Trauma (MST)

MST Behaviors

- Pressured into sexual activities—threats of negative consequences for not cooperating
- Unable to consent to sexual activities (i.e., when intoxicated)
- Physically forced into sexual activities
- Unwanted sexual touching or grabbing
- Threatening, offensive remarks about a person's body, or sexual activities

- Threatening and unwelcome sexual advance

Survivor Reactions

- Strong emotions (depressed, intense emotions, angry, and irritable)
- Feelings of numbness
- Trouble sleeping
- Difficulties with attention, concentration, and memory
- Problems with alcohol or other drugs
- Difficulty with reminders of experience
- Difficulties in relationship
- Physical health problems

Adapted from U.S. Department of Veterans Affairs (n.d.b). Military sexual trauma. Mental Health Retrieved April 27, 2021 from <https://www.mentalhealth.va.gov/mentalhealth/msthome/index.asp>

Epidemiology

MST occurs primarily to women, but also to men. One in three women and 1 in 50 men have told their VA health care provider that they experienced sexual trauma in the military (U.S. Department of Veterans Affairs, 2020a). In a study of 60,000 OEF/OIF female and male veterans, approximately 41% of women and 4% of men reported experiencing MST (Barth et al., 2016). LGBTQ individuals are at an increased risk for sexual harassment. There is an increased risk of sexual harassment and assault for those who identify as transgender (Schuyler et al., 2020).

Mental Health Issues Related to MST

MST is a life changing event. MST is highly associated with mental health disorders including PTSD, depression anxiety disorders, eating disorders, suicide, lower satisfaction with interpersonal relationships, and substance use. There is evidence that many victims of MST do not seek mental health care or disclose the trauma. MST represents a morally injurious experience that can profoundly affect their view of the world. There are several barriers that prevent victims from reporting abuse including self-stigma and fear of loss of relationships (Andresen & Blais, 2019). Women victims are often hesitant to seek treatment at the male-dominated VA Medical Centers (Gilmore et al.,

2016).

Depression, PTSD, substance use, suicidal ideation, and severe self-directed violence are associated with MST (Forkus et al., 2020; Gross et al., 2020; Livingston, Fargo, et al., 2020). Self-directed violence such as suicide attempt or non-suicidal self-injury following MST occurs in both male and female victims, but female victims have a greater risk of self-directed violence (Gross et al., 2020).

Evidence-Based Nursing Care for Veterans with MST

Screening for MST should be included in any nursing assessment of veterans. If the veteran screens positive for MST, the impact of the MST should be discussed and considered for a referral to an experienced therapist or service for MST. In caring for persons with MST, nurses should follow similar care strategies as anyone who has had been physically or sexually abused (see [Chapter 23](#)). The VHA has developed programs to address the needs of women and men who have experienced MST.

DEPRESSION

Depression is common in the U.S. population and is associated with high rates of mortality and morbidity (see [Chapter 25](#)). Depression is more common in the veteran population than in the general U.S. population. An increasing number of veterans are reporting depressive symptoms. Depression is highly comorbid with PTSD and suicidal ideation. Trauma exposure is associated with both depression and PTSD, which can ultimately result in suicidal ideation. There is limited research on depression among U.S. veterans (Liu et al., 2019).

Epidemiology

The large study of veterans ($N = 6577$) over the age of 50 in 2006 showed that veteran status was not associated with an increase in anxiety or depression when compared with non-veterans. However, additional analysis showed that Vietnam

veterans were twice as likely to have elevated depression and anxiety than WWII or Korean War veterans (Gould et al., 2015). In a study of OEF/OIF/OND service members and veterans, depression, PTSD, and military TBI were associated with a high risk for substantial disability such as getting around, communicating, and getting along with others (Lippa et al., 2015).

When depression data were analyzed in the *National Survey on Drug Use and Health* (NSDUH) from 2005 to 2016, the prevalence of depression (9.6%) in veterans was higher than that of the 6.7% rate of adults in the United States. The rate of depression peaked in 2011–2013 at 12.3% of veterans experiencing depression. Female veterans have a higher prevalence of depression than male veterans. White veterans consistently have a higher prevalence rate of depression than Black and Hispanic veterans (Liu et al., 2019).

Protective Factors

Involvement in community groups and activities, which fosters a sense of belonging and identity, has been shown to be a protective factor for depression and PTSD in veterans. An optimistic disposition appears to be protective of depression. Veterans who are optimistic are more likely to use adaptive and problem-focused coping strategies such as positive reframing of problems and seeking social support (Nichter, Haller, et al., 2020).

Risk Factors

Veterans of racial or ethnic minorities (Black and Hispanic) are at high risk for depression and PTSD. The number of lifetime traumas increases the risk for PTSD and depression. They experience more psychosocial stressors (minority stress and microaggressions) than White veterans that, in turn, interact with PTSD to increase the risk for depression (Nichter, Haller, et al., 2020).

Evidenced-Based Nursing Care for Veterans with Depression

Nursing care for veterans with depression is similar to care of non-veterans. Cognitive therapy, cognitive processing therapy, medications, and transcranial magnetic stimulation are used. The care should be tailored to the needs of the veteran.

Depression in women veterans has been associated with impaired quality of life (QOL), which leads to functional decline and behavioral problems (Devine et al., 2020) (see [Box 40.4](#)). Accessing treatment for depression in women veterans can be complicated by discrimination and sexual harassment by male veterans when accessing VHA health care facilities. When inappropriate or unwanted comments or behavior from male veterans occur, the women are more likely to report feeling unwelcome and unsafe. Hence, the treatment is delayed or appointments missed (Klap et al., 2019). Depression and poor QOL improve with treatment that is timely, comprehensive, and gender-specific (Devine et al., 2020).

BOX 40.4

Research for Evidence-Based Practice: Quality of Life Among Women Veterans

Devine, D. T., McMillan, S. C., Kip, K., & Powell-Cope, G. (2020). *Quality of life among women veterans*. *Journal of the American Association of Nurse Practitioners*, 32(11), 745–755.
<https://doi.org/10.1097/JXX.0000000000000445>

THE QUESTION: Do women veterans age 40 to 60 years who use VA women’s health specialty clinic have a lower quality of life (QOL) compared with normal reference values of women in North America?

METHODS: Records of 51 females veterans age 40 to 60 attending a women’s health specialty clinic were retrospectively reviewed. Multiple linear regression models were fit to explore QOL and depression levels with socioeconomic status, parity, years of service, and military sexual trauma.

FINDINGS: Female veterans had significantly lower baseline QOL scores than the comparison group. Following treatment, their QOL and depression improved.

IMPLICATIONS FOR NURSING: Care for female veterans should be individualized with a focus on improving QOL, reducing depressive symptoms, and identifying MST.

SUICIDE

Suicide in the Military

Active-duty military personnel dying by suicide is a relatively new phenomena.

For example, WWII (1939–1945) had a reported suicide rate of 5 per 100,000. Between 1945 and 1991, the rate generally stabilized in the low to mid-teens (10–15 per 100,000). Some experts suggest that rates of suicide in earlier wars are likely underreported. They suggest that wars provide other ways to end lives such as rushing from a trench into enemy fire. The military suicide rate began increasing in 2004, peaking 2012 during the Afghanistan and Iraq Wars with 29.7 per 100,000 reported suicides. From 2008 to the present, the annual rate remains within a range of 20.2 to 29.7 per 100,000 (Jones, 2019; Smith et al., 2019). It should be noted that suicide in the general population had increased from 2005 to 2018 (see [Chapter 22](#)).

In 2015, almost half of the service members who died by suicide had a history of at least one behavioral health disorder such as substance use disorder, adjustment disorder, or major depression. Stressors associated with suicide included failed/failing intimate-partner relationships and legal proceedings (Pruitt et al., 2019).

Suicide in the Veteran Community

Suicide rates in the veteran community began increasing in 2001 (U.S. Department of Veterans Affairs, 2016). From 2005 to 2018, the veteran suicide rate gradually increased from 18.5 per 100,000 (16.6 per day) to 27.5 per 100,000 (17.6 per day) (U.S. Department of Veterans Affairs, 2020b).

The most common suicide method is firearms with 68.2% of suicide deaths due to a self-inflicted firearm injury (69.4% of males; 41.9% of females). Poisoning and suffocation are the next most frequent methods (U.S. Department of Veterans Affairs, 2020b). Veterans have higher rates of firearm ownership than the general population and are at substantially increased risk of firearm suicide compared to non-veterans. They use firearms mainly for personal protection and generally favor measures to restrict access to firearms among at-risk individuals. Providers are often hesitant to screen and counsel for firearms because of the lack of familiarity with guns, little confidence in intervention effectiveness, or philosophical reasoning related to constitutional rights (Theis et al., 2020).

Epidemiology

The 2018 rates (latest data) of suicide among veterans were higher and rose faster than those among non-veteran U.S. adults. Suicide rate is 1.5 times the rate for non-veteran adults. The suicide rates were highest among White veterans and lowest among Black or African American veterans. Veterans ages 18–34 had the highest rate in 2018 (45.9 per 100,000). Veterans, age 75 and older, had the lowest suicide rate (27.4 per 100,000). The rate of women veteran suicide was 2.1 times that of non-veteran women. Veterans identifying as LGBTQ are more likely to report suicidal ideation and screen positive for PTSD, depression, and alcohol problems than heterosexual veterans (U.S. Department of Veterans Affairs, 2020b).

Protective Factors

The *National Health and Resilience in Veterans Study* (NHRVS), initiated in 2011, is an ongoing study characterizing the longitudinal trajectories of mental and physical health outcomes in U.S. veterans. This study focuses on genetic and environmental risk and protective factors that contribute to these trajectories. Findings from this study show that perceived social support, curiosity, resilience, and acceptance-based coping are protective of suicide. In veterans who had been diagnosed with PTSD and/or major depressive disorder, greater purpose in life, curiosity, and optimism were inversely related to suicide ideation. For veterans who experience moral injury, having a greater global purpose and meaning in life were important in combating suicidal thoughts (Fogle et al., 2020).

Risk Factors for Veteran Suicide

Several risk factors are associated with veteran suicide including economic disparities, race, ethnicities, LGBT disparities, and homelessness. Difficulties translating military-related skills to civilian jobs contribute to lower income and homelessness. Other risks include greater age, loneliness, disability in instrumental daily living (e.g., shopping, cooking), somatic symptoms, and use of denial-based coping (Fogle et al., 2020).

With the COVID-19 pandemic there has been an increase in unemployment among veterans. In April 2020, there were 833,000 more unemployed veterans than in April 2019. As the veteran unemployment rate increased from 2.3% to 11.7%, suicidal ideation was higher for racial and ethnic minority populations (U.S. Department of Veterans Affairs, 2020b).

Suicide rates are higher in veterans with mental health or substance use disorder diagnoses. The risk of suicide is greater in veterans who have been diagnosed with PTSD and/or major depressive disorder (Fogle et al., 2020). In 2018, the suicide rate for VHA patients with a substance use or mental illness was 57.9 per 100,000 veterans; for patients with depression, the rate was 65.6 per 100,000 (U.S. Department of Veterans Affairs, 2020b).

Childhood abuse is associated with suicide behavior in adulthood. Combat-exposed veterans with a history of childhood sexual abuse are nearly three times more likely to contemplate suicide compared to those without a history of abuse. Childhood sexual abuse is a stronger predictor of suicide attempts than either childhood physical abuse or combat exposure. Childhood sexual abuse leads to long-term psychological consequences such as chronic depression, PTSD, and suicide-related outcomes (Nichter, Hill, et al., 2020).

Experiences during deployment contribute to risks for suicide ideation. There is evidence that morally injurious events are associated with suicidal ideation. Many veterans experienced or witnessed transgressive acts that violated their moral code such as killing an enemy or a non-combatant while serving in the military (Cameron et al., 2020).

Evidence-Based Nursing Care for Veterans with Suicide Ideation

The results of the NHRVS studies indicate that a considerable proportion of U.S. veterans experience suicidal ideation, but that ideation may fluctuate over time (Fogle et al., 2020). That is, there may be long periods where suicidal thoughts are absent. Monitoring suicidal ideation by primary care nurses becomes important in identifying veterans' high risk for suicide.

The nursing care of a veteran with suicide ideation begins with engagement in the therapeutic relationship and treatment. The aim of the care is to keep the veteran safe and to help the person develop a safety plan (see [Chapter 22](#)). The nurse should recognize that veterans often internalize the stigma that seeking

mental health care means weakness and are less likely to engage in care. It is estimated that as many as two-thirds of veterans with suicidal ideation are not engaged in mental health treatment (Nichter, Hill, et al., 2020).

Older male veterans with suicide ideation are less likely to engage in treatment than their younger female counterparts. Concerns about masculinity and gender role expectations are often barriers for male veterans. Veterans are more likely to engage in treatment if they have a diagnosis of depression, a prior suicide attempt, multiple medical problems, or lifetime traumas (Nichter, Hill, et al., 2020).

There are several nursing approaches for the care of veterans. The nurse should always screen for suicide ideation by using a standardized screening tool such as the Columbia Suicide Severity Rating Scale (see [Chapter 11](#)). Every veteran should know about the Veterans Crisis Line ([Figure 40.3](#)). If the veteran screens positive for suicide ideation, the nurse should refer the patient to a mental health professional. If the veteran is currently thinking about hurting or killing self, looking for ways to kill self, talking about death, dying, or suicide or carrying out self-destructive acts such as drug abuse or using weapons, the nurse should not leave the patient alone and seek available mental health help.

The VHA suicide prevention program is an important resource. Suicide prevention is a VHA clinical priority. Each VA Medical Center has a full-time suicide prevention coordinator who provides active preventive interventions and follows-up with at risk veterans. Suicide prevention teams provide community outreach, coordination of resources, and increases awareness of suicide risks. The VA provides medical screening and assessment of patients at risk for suicide. Patients with elevated suicide risk receive an enhanced level of care, including missed appointment follow-up, safety planning, follow-up visits, and care plans that directly address their risk factors for suicide (U.S. Department of Veterans Affairs, Office of Suicide Prevention, 2018).

Figure 40.3 Veterans Crisis Line

SUBSTANCE USE

Alcohol and Drug Use in the Military

Alcohol and drugs have long been associated with the military and war. Whiskey was used for wounded soldiers, but supplies would disappear and run consistently low. Drinking alcohol was a part of everyday life in the Civil War. Ulysses S. Grant had a well-documented alcohol problem (Chernow, 2017). Morphine was given as an anesthetic and a diarrhea cure, leaving many soldiers with a morphine addiction or *Soldiers Disease*. During World War I, cocaine became the drug of abuse of the frontlines. Amphetamines were the most popular drugs used in WWII. Dextroamphetamine was a popular drug during the Vietnam war. During this war, antipsychotics were also given to soldiers (Tackett, 2019).

The misuse of alcohol and drugs in the military continues to be a problem in 2021. Deployment is associated with smoking initiation, unhealthy drinking,

drug use, and risky behaviors. Many service members see drinking as part of the military culture. Military members are at higher risk of developing a drug or alcohol problem than civilians. Substance use is associated with combat, trauma, PTSD, sexual and physical abuse (National Institute on Drug Abuse [NIDA], 2019).

Even though illicit drug use among active duty personnel is relatively low, alcohol and rates of binge drinking are high compared to the general population. Cigarette smoking and misuse of prescription drugs have decreased in recent years (NIDA, 2019).

Use of Substances

Substance use often continues long after military service ends. In the military, service members can face dishonorable discharge or criminal prosecution for a positive drug test. These consequences discourage illicit drug use. Once the service member transitions to civilian life, the protection of the service is gone and substance use becomes more likely. More than 1 in 10 veterans is diagnosed with a substance use disorder. (NIDA, 2019).

Alcohol Use

AUD is one of the most prevalent mental disorders in the United States (see [Chapter 31](#)). Veterans are more likely to use alcohol than other substances. They also are more likely to use alcohol than their non-veteran counterparts. Within 1 year of deployment, 39.2% of OEF/OIF veterans screened positive for AUD. In the U.S. veteran population, 42.2% met criteria for lifetime AUD (Fuehrlein et al., 2018).

Data from the NHRVS identified four veteran trajectories of alcohol consumption over 4 years ($N = 3,157$). *Rare drinkers* (65.3%) were abstinent or rarely drank alcohol; moderate drinkers (30.2%) consistently drank at a moderate level; *excessive drinkers* (2.6%) drank at elevated levels and *recovering drinkers* (1.9%) were excessively drinking and decreased consumption over time. The researchers posited that the low percentage of excessive drinkers was related to the older age of the sample (Fuehrlein et al., 2018).

AUD is highly comorbid with PTSD, major depressive disorder, and suicide (Bohnert et al., 2017; McHugh & Weis, 2019; Straus et al., 2019). Research shows that comorbidity varies among White, Black, and Hispanic veterans. Black and Hispanic veterans with AUD have greater psychiatric comorbidity relative to White veterans. Hispanic veterans with lifetime AUD have worse physical health, cognitive function and QOL. Black and Hispanic veterans with lifetime AUD are more likely to screen positive for depressive disorder (Carr et al., 2021). These results suggest that racial and ethnic minorities with AUD may have higher rates of mental disorders and poorer outcomes. There is a need for race/ethnicity-sensitive approaches to the care and treatment AUD in veterans.

Risks and Protective Factors

Alcohol consumption and use of drugs are risks for the development of lifetime AUD. Other risk factors of AUD include trauma, exposure to military stress and adjustment to civilian life. Due to the stigmatization of mental illness in the military culture, many veterans self-medicate with alcohol rather than access mental health services (Fuehrlein et al., 2018; Straus et al., 2020).

Resilience, purpose in life, dispositional gratitude (believing that there is much in life to be thankful for), and religiosity/spirituality are protective factors for developing AUD. Social support, and secure attachment style (feeling that it is easy to get close to others; feeling comfortable with others) are also protective.

Opioid Use

Opioid addictions are discussed in [Chapter 31](#). The following discussion is specific to the unique challenges the veteran experiences who uses opioids.

Opioid Use in the Military

ODUs often begin with a prescription following an injury. Service members are high risk for trauma and injury requiring the treatment of pain. Injured and sick military personnel are often prescribed pain medication. Because opioids can quickly become addictive, regular use of opioids can lead to addiction. The

amount of pain medication prescribed to service members peaked in 2009 but began decreasing in 2011 in response to the prevention and appropriate prescribing initiatives of the DOD (NIDA, 2019).

Opioid Use by Veterans

The lifetime prevalence of OUD in veteran men is estimated at 418,000 and is not proportionately different than the 2.5 million non-veteran men with OUD. Risk factors for lifetime OUD include a younger age, lower income, and fewer years of education. Racial minority status is associated with a risk of OUD because the general veteran population includes an older generation of adults with OUD who started using heroin when the problem was more prevalent among African American than Caucasians. In recent years, opioid users are more likely to be Caucasians starting with prescription drugs rather than heroin (Rhee & Rosenheck, 2019).

About one-half of veterans using the VHA are diagnosed with chronic pain that is treated with opioids, putting them at higher risk of dependency and overdose (Ahonle et al., 2020). From 2001 to 2009, the percentage of veterans in the VHA system receiving opioid prescription increased from 17% to 24% (Teeters et al., 2017). The VHA launched a system-wide *Opioid Safety Initiative* to address the opioid epidemic. Since 2012, the number of veterans prescribed opioids decreased 56% and co-prescribed opioid/benzodiazepine decreased 83% (Sandbrink et al., 2020).

Polysubstance Use, Comorbidity, and Overdose

The majority of veterans in the VHA diagnosed with OUD appear to have at least one comorbid substance use disorder and many have multiple substance use disorders (Lin et al., 2021). OUD is strongly associated with psychiatric and substance use disorders. In a study comparing veterans with OUD ($N = 61$), veterans without OUD ($N = 2,679$), and non-veterans with OUD ($N = 329$), 63.4% of veterans with OUD and 60.9% of the non-veterans had a comorbid lifetime psychiatric disorder compared with 22% of veterans without OUD ($N = 2,679$) (Rhee & Rosenheck, 2019).

Opioid use is associated with suicide and unintentional overdose (Bohnert & Ilgen, 2019). Some veterans qualify to enroll in both the VA and Medicare Part D where they can receive prescription opioids from both systems. Dual-users are at significantly higher odds of death from opioid overdose than those who receive opioids from the VA only (Moyo et al., 2019). Veterans with an OUD have among the highest rates of suicide when compared to veterans with psychiatric disorders (U.S. Department of Veterans Affairs, Office of Mental Health and Suicide Prevention, 2020b). Comorbid OUD and depression and comorbid OUD and AUD are significantly associated with additive risk of suicide attempts (Ashrafioun et al., 2020).

Tobacco Use

Tobacco use of cigarette and non-cigarette products is prevalent in the U.S. veteran population, especially younger veterans. Nearly half of the veterans who served during September 2001 or later report using tobacco products. These veterans are more likely to have comorbid conditions including poor physical health, poor mental health, other substance use and problematic alcohol use than their non-veteran counterparts. In nearly all age groups, veterans have a higher prevalence of tobacco use than non-veterans (Cooper et al., 2019).

Many veterans were introduced to tobacco use while in the military. Another explanation for such high use of tobacco is that the use is related to the stress associated with re-integrating into civilian life (Cooper et al., 2019).

Evidence-Based Nursing Care for Veterans with Substance Use Disorder

Nursing care for any veteran should include an assessment of substance use. Based on the research, veterans are high risk for multiple substance use which significantly impacts their health and well-being. The U.S. veteran population has complex health needs that that can be complicated by substance use.

The VHA health care system is prepared for treatment of substance use disorders, but not every veteran seeks care in the VHA system. Recognizing the relationship between the substance use and other health and mental health issues

will guide the nurse in planning for the appropriate care. The approach to patients should always be non-judgmental and foster a therapeutic partnership and help patient move toward recovery. The nurse should always conduct a medication assessment and determine where the prescriptions are filled. A medication assessment is especially important when the veteran is receiving care at the VA and non-VA facility to prevent over prescribing of medication, particularly opioids.

OTHER ISSUES IMPACTING VETERAN MENTAL HEALTH

The wellness and mental health of veterans are impacted by other conditions. These conditions are related to the mental health needs and recovery and interrelated with other disorders. It is important for nurses to stay informed about the issues and challenges that are unique to military veterans.

Pain

The prevalence of chronic pain (pain lasting longer than 3–6 months) occurs more frequently in veterans than non-veterans (Nahin, 2017). See [Chapter 43](#) for an in-depth a discussion of pain and its treatment. General chronic pain prevalence estimate ranges from 25% to 72% of veterans. Pain type includes most parts of the body from head to neck, chest, and back (Reyes et al., 2020). Individuals with chronic pain experience high rates of disability, decreased QOL, and emotional distress (Brintz et al., 2020).

Chronic back pain in veterans is the most frequently reported type of pain followed by jaw pain, severe headaches or migraine, and neck pain (Nahin, 2017). **Musculoskeletal pain** (MSP) is caused by injuries or disorders of the joints, muscles, tendons, or ligaments to the bones, muscles, nerves, and/or connective tissue. Combat injuries (polytrauma, blast injuries) and non-combat injuries (muscle strain, overuse) lead to which can lead to chronic MSP. In an integrative review of the incidence, prevalence, and risk factors for MSP and headaches in active duty, inflammation and pain from overuse comprised the largest proportion of injury (82% of all non-deployed military personnel). The

risk of MSP was highest among active duty, female, Army, enlisted personnel and those with greater time in mother vehicle. For veterans who sustained a TBI, 92% reported headaches (Bader, et al., 2018).

Considering the number of active duty service members who transition each year to veteran status, chronic MSP is a major focus of treatment for this population (Grinberg et al., 2020; O’Neil et al., 2020). Pain is associated with an increased in allostatic load leading to physical manifestations of chronic stress including changes in endocrine dysfunction, sleep disturbance, orthopedic problems substance use, depression, and suicide (Figure 40.4) (Frueh et al., 2020). Multifocal pain (i.e., multiple pain sites such as back, knees, hips, knees) is common and leads to poorer outcomes (Bushey et al., 2021). Prolonged opioid use for pain can result in an OUD (Riva et al., 2020).

Figure 40.4 Veteran being assessed for health problems.

Traumatic Brain Injury

TBI is often referred to as a “signature injury” of the post-9/11 conflict (OEF/OIF/OND) (Hoge et al., 2008). Pain medication estimates from 49.5 to 78% of veterans with chronic pain use pain medication. It is estimated that general chronic pain among veterans with a history of TBI is 59% (O’Neil et al., 2020). The estimates of the number of veterans with TBI from 2000 to 2019 was 423,858. Hearing disturbance and headaches are the most frequently reported adverse outcomes of blast-related injuries. Frequent comorbidities associated with the blast-related injuries include PTSD, depression, anxiety, sleep disorders, attention disorders, and cognitive disorders (Phipps et al., 2020).

Homelessness

U.S. veterans who are homeless have served in wars from WWII to the recent war in Afghanistan and Iraq. Nearly half of the veterans who are homeless served during the Vietnam era and two-thirds served the United States for at least 3 years and one-third were stationed in a war zone. It is estimated that there are over 37,000 veterans homeless on any given night (see [Chapter 41](#)). The majority are predominantly male with about 9% being female. Roughly 45% are African American or Hispanic, despite only accounting for 10.4% and 3.4% of the U.S. veteran population. About 1.4 million other veterans are at risk of homelessness due to poverty, lack of support networks, and poor living conditions (National Coalition for Homeless Veterans, n.d.).

The VHA has multiple programs to support veterans who are homeless or at risk of being homeless. The VA conducts coordinated outreach to seek out veterans in need of assistance. Veterans who are homeless or at risk of being homeless are connected with housing, health care, community employment services, and other required supports (U.S. Department of Veterans Affairs, 2021b).

There are multiple factors that contribute to homelessness in the veteran’s population. In one study, one-third of the veterans screened positive for lifetime PTSD. Compared with veterans who are not homeless, veterans who were homeless, especially underrepresented groups (Black and Hispanic) were likely to screen positive for PTSD (Tsai et al., 2020). A higher proportion of veterans who are homeless received high-dose opioid therapy compared with non-veterans associated with increased rates of fatal opioid overdoses (Jasuja et al., 2021).

Veterans who are experiencing homelessness have multiple health and mental health issues. While there are available services for veterans who are homeless, there are multiple barriers as well. Social stigma and perceived lack of support contribute to hesitancy to access services (Bounthavong et al., 2020). Veterans with children make up a considerable component of the female veterans who are homeless. Veterans with families have additional stressors when compared to non-veteran homeless families such as military-related experienced, deployment, reintegration stress, and PTSD or MST (Ijadi-Maghsoodi et al., 2021).

SUMMARY OF KEY POINTS

- The U.S. military consists of three departments (Army, Navy and Air Force). The Department of the Navy is responsible for the Navy and Marines and the Air Force is responsible for the Air Force and Space Force. There are seven reserve components that can be activated in time of war or national emergency. The Army is the largest U.S. military service with 35% of the active duty members.
- The values, beliefs, and behaviors acquired in the military often last a lifetime.
- Historically, women in the military was very limited until the elimination of the draft when the need for service members became apparent. Women were admitted into the service academies in 1976.
- Individuals who openly identified as LGBTQ were excluded from military service until 2016 and reaffirmed in 2021. The majority of all service members are White with the greater proportion of minorities found primarily in lower ranks.

- Every year about 200,000 service members transition to civilian life. The transition year is a high-risk period for physical and mental health issues. The Transition Assistance Program provides support, resources, and training.
- A veteran identity is the degree to which the veteran role is essential or important to how they think about themselves.
- The VHA operates one of the largest integrated health care systems in the world. Nursing plays an important role in the care of the veterans through developing relationships with nursing schools and providing educational opportunities for students.
- Joining Forces is a national initiative to support service members, veterans, and their families.
- Mental health needs are pervasive in the veteran population. Post-deployment depression, PTSD, and substance use disorders are disabling to the veterans and their families.
- Veterans are at risk for suicide, TBI and homelessness. A strong veteran identity can support positive self-esteem and be protective of mental health problems.
- High combat exposure, history of concussions, stressful life events, and low social support are risk factors for depression and PTSD.
- PTSD is associated with both combat and non-combat trauma. PTSD symptoms from combat trauma include self-blame, intrusive memories with dreams detachment, and reckless behavior. PTSD symptoms from non-combat trauma include exaggerated startle, self-blame with distorted beliefs, and concentration problems.
- Moral injury can be a consequence of exposure to traumatic events.

Moral injury can be caused by perpetration, witnessing, and betrayal.

- Veterans who identify as LGBTQ experience the trauma of war plus microaggressions and minority stress.
- MST refers to sexual assault and sexual harassment. MST occurs primarily to women, but also to men. MST is a life changing event and is highly associated with mental health disorders.
- Nursing care of veterans should always include a comprehensive assessment that screens for PTSD and MST. Veterans with these disorders should be referred to mental health specialists.
- Depression is more common in the veteran population than in the general U.S. population. Depression is highly comorbid with PTSD and suicidal ideation.
- Suicide is a major mental health problem in the veteran community. The most common method of suicide is firearms followed by poisoning and suffocation. Childhood sexual abuse of veterans is a strong predictor of suicide. Experiences during deployment contribute to risks for suicide ideation especially morally injurious events.
- Veterans are more likely to use alcohol than other substances. Alcohol use often begins in the military service and continues after discharge. AUD is highly comorbid with PTSD, major depressive disorder, and suicide.
- Opioid use by veterans often begins with prescription pain medication putting them at risk of dependency and overdose. Veterans who have opioid use disorder are likely to have at least

one comorbid substance use disorder. Opioid use is associated with suicide and unintentional overdose.

- Tobacco use is more prevalent by veterans than in the general population.
- Chronic pain, TBI, and homelessness contribute to health and mental health issues of veterans.

CRITICAL THINKING CHALLENGES

1. Describe how the military culture influences the values, beliefs, and behaviors of a veteran.
2. Compare the mental health problems of World War I and II service members with those serving in Iraq and Afghanistan.
3. Trace the role of women in the military from the Revolutionary War through the wars in Iraq and Afghanistan.
4. Discuss the difficulties the LGBTQ community has experienced in the military. Include a discussion about microaggression and minority stress.
5. M.J. was recently discharged from the U.S. Army. M.J. experienced combat in Afghanistan and was treated for PTSD but is reluctant to seek out care in the community. M.J. visits a clinic for an influenza injection and the nurse notices the ARMY insignia on the patient's wallet. What approach should the nurse take in giving the influenza injection? Should the nurse ask about serving in the military?
6. Differentiate combat-related trauma from non-combat-related trauma. Explain the different PTSD symptom patterns.
7. Define the components of a "moral injury" and explain their relationship to PTSD.
8. Discuss the nursing responsibility of screening for MST in veterans.
9. P.S., a Vietnam veteran is attending a health screening at a local community clinic. The veteran is expressing worthlessness and sadness following the

death of a life-long partner. Should the nurse conduct a suicide screening on the patient. Explain your answer.

- 1. During a health assessment, a 32-year-old veteran talks about consuming a six-pack of beer each night before going to bed to sleep. What additional assessment data are needed to determine the likelihood of an alcohol use disorder?
- 2. Discuss the use of opioids and the treatment of pain in veterans. How should a nurse approach a veteran who is suspected of using excessive opioids for the treatment of pain?

Movie Viewing Guides

Thank You for Your Service (2017) Adam Schumann (Miles Teller) returns home to Kansas after a 15 month combat tour in Iraq. He returns to his wife, Saskia (Haley Bennett) and two young children, a daughter and an infant son born while Adam was still overseas. Adam suffers from PTSD as manifested by nightmares and frequent flashbacks for which his wife convinces him to seek help from the Department of Veterans Affairs. The movie depicts the struggles of Adam and two service buddies as they transition to civilian life.

VIEWING POINTS: Identify the inherent difficulties in making the transition from military to civilian life. How did the military culture influence Adam's willingness to seek help for PTSD? Identify the PTSD symptoms that are characteristic of combat-related trauma. Describe the TBI symptoms that Solo Aeti (Beulah Koale) manifested. Did you increase your understanding of the difficulties veterans can have when transitioning to civilian life?

Unfolding Patient Stories: Andrew Davis

Part 2 (56 years)

Recall from [Chapter 31](#) Andrew Davis who admitted himself to an alcohol rehabilitation facility. His alcohol abuse began in early adolescence. What factors can increase the risk for alcohol abuse and addiction as an adolescent? What are the psychosocial influences and consequences of alcohol abuse? What assessments can help the nurse identify the signs of alcohol abuse?

Care of Persons Who Are Experiencing Homelessness and Mental Illness

Mary Ann Boyd

KEYCONCEPTS

- homelessness

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Define sheltered and unsheltered homelessness.
2. Describe risk factors for becoming homeless.
3. Describe challenges of persons who are experiencing homelessness and have a mental disorder.
4. Discuss personal and societal attitudes and beliefs about homelessness.
5. Describe nursing care of people who are experiencing homelessness and have a mental disorder.
6. Discuss the importance of advocacy for those who are experiencing homelessness with a mental illness.

KEY TERMS

- Assertive Community Treatment (ACT)
- Continuum of Care
- Day treatment
- Housing First
- Safe Havens
- Section 8 housing
- Sheltered homeless individuals
- Shelter Plus Care Program
- Supportive housing
- Transitional housing
- Unsheltered homeless individuals

INTRODUCTION

Homelessness is a word that evokes images and feelings in everyone. Without a stable dwelling place, meeting basic needs is difficult. Homelessness means carrying all of one's possessions in a car, suitcase, bag, or shopping cart or storing necessities in a bus station locker or under the bed of a night shelter. It means no chest for treasured objects, no closet for next season's clothing, no

pantry with food to eat, no place to entertain friends or have solitude, and no place for a child to play.

People who are experiencing homelessness tend to be ignored or not seen by the general population, who hurry on their own way. The homeless community is treated poorly by society and often suffers from acts of violence. Many attacks go unreported. Hate crimes against the homeless community are a vital issue in the United States. Perpetrators of these acts are generally males under age 30 (National Coalition for the Homeless, 2018).

This chapter explores issues relevant to individuals who are experiencing homelessness and who are also experiencing mental health problems. It presents nursing care measures and suggests ways to improve services for the homeless population.

HOMELESSNESS AND MENTAL ILLNESS

Children, adults, and families can become homeless from encountering a natural disaster, home fire, some situational crisis or unexpected overwhelming life situation, or economic hardship. Others find themselves homeless because of problems related to substance use or mental illness. [Box 41.1](#) lists characteristics of people who are experiencing homelessness and are mentally ill.

BOX 41.1

Characteristics of People Who Are Mentally Ill and Homeless

- People with mental disorders are at greater risk for homelessness than the general population.
- Mental health problems increase with the duration of time the person is homeless.
- They have at least one psychiatric service encounter annually, usually in an ED rather than inpatient or outpatient units.
- They are homeless for longer periods, often years, than are those who are homeless and not mentally ill or substance abusing.
- They are more likely to be in poor physical health compared to other homeless people.
- They have more contacts with the legal system than other homeless or housed people.
- They are more likely to encounter employment barriers and less likely to benefit from societal economic growth.
- They are less likely to have contact with family or friends, especially if they come from higher-income households.
- Most are eligible for, but have difficulty obtaining, income maintenance such as Social Security

Disability Insurance, Veterans Affairs disability benefits, or other benefits.

- Most are willing to accept treatment after basic survival needs are met and a therapeutic relationship has been established.

Substance Abuse and Mental Health Services Administration. (2013). *Behavioral health services for people who are homeless. Treatment Improvement Protocol (TIP) Series 55. HHS Publication No. (SMA) 13-4734*. Rockville, MD: Substance Abuse and Mental Health Services Administration.

KEYCONCEPT Homelessness is a lack of a fixed, regular, and adequate nighttime residence, which includes places not designed for or ordinarily used as a regular sleeping accommodation (i.e., car, park, abandoned building, bus/train station), as well as publicly or privately operated shelters or **transitional housing**, including a hotel or motel paid for by government or charitable organization.

The following criteria define homelessness in the United States:

- Individual or family who lacks a fixed, regular, and adequate nighttime residence
- Individual or family who will imminently lose their primary nighttime residence with no subsequent residence identified, and they lack resources or support networks to remain in housing
- Unaccompanied youth under 25 years of age, or families with children and youth who do not have permanent housing
- Any individual who is fleeing or attempting to flee domestic violence, dating violence, sexual assault, stalking, or other dangerous or life-threatening situations related to violence and lack resources or support networks to remain in housing (U.S. Department of Housing and Urban Development, 2021a).

Homelessness can be either sheltered or Sheltered homeless individuals obtain temporary or transitional housing operated by public and private agencies for individuals and families who do not have stable housing. **Unsheltered homeless individuals** live in places that are not used for housing, such as cars, parks, abandoned building, tents, or bus/train stations.

As the United States is emerging from the COVID-19 pandemic, homelessness will continue to be a national crisis. Homelessness has been increasing since 2016 as likely consequences of the national recession, economic disparities, and the pandemic (National Alliance to End Homelessness, 2020).

Epidemiology

The homeless population includes people of all ages, economic levels, racial and cultural backgrounds, and geographic areas. In January 2019, more than 560,000 people were homeless on a single night in the United States. Seventy percent of people experiencing homelessness are living on their own or in the company of other adults. The remainder are people in families with children. Sixty percent of all people experiencing homelessness are male. Most underrepresented groups are considerable in the homeless population, with African American individuals making up the largest group. Among individuals experiencing homelessness, one in two are unsheltered (National Alliance to End Homelessness, 2021).

Approximately, one-third of the total homeless population are persons with untreated serious mental illnesses. Many of these individuals suffer from schizophrenia, bipolar disorder, or major depression. Substance use is common, which further impairs these individuals. Many of these individuals were discharged from state and federal facilities with limited opportunities for housing and follow-up treatment. Studies show that persons with psychosis are more likely to be assaulted or threatened while homeless. Stigma and discrimination toward individuals remain pervasive across societies (Mejia-Lancheros et al., 2020).

Homelessness was a major problem for veterans since the early 2000s. Since 2011, the number of veterans experiencing homelessness had dropped by 43.3%, and since 2018, the number dropped another 2.1%. However, in 2019, still more than 37,000 veterans were homeless on a single night (National Alliance to End Homelessness, 2021).

Risk Factors

There are a variety of factors that place individuals and families at risk for homelessness. Adolescents and runaway youths can become homeless because of strained family relationships, family dissolution, foster care struggles, economic instabilities, and instability of residential placements. The consequences of COVID-19-related restrictions, such as remote learning, stay-at-home orders, increase the risk of homelessness for vulnerable youth. Young people experiencing homelessness may resort to drug trafficking and prostitution

to support themselves. They are at risk for physical and mental health problems, including substance abuse, HIV infection or AIDS, pregnancy, and suicidal behaviors (Silliman Cohen & Bosk, 2020).

New immigrants and refugees can lose housing when they experience economic problems or conflicts with the sponsoring family or organization. Language barriers and citizenship/documentation status impede Latinx individuals' success in the rental market, increasing the risk of homelessness (Chinchilla & Gabrielian, 2020). Mental health problems arise because of torture experiences, losses suffered in the country of origin, culture shock, and discrimination experienced in the United States. Posttraumatic stress is common in this group; their physical health problems are often complex (Hasanović et al., 2020).

Migrant workers and their families lack residential stability as they move from one geographic region to another for 6 to 9 months of the growing and harvest season. These laborers and their families may be U.S. citizens or foreign born. They are poor and typically lack adequate living quarters and health care. Physical health problems and depression are common in these families. After farm labor is completed, family members may be homeless until they can return to their place of origin or to a relative's home (Blackmore et al., 2020).

Mental illness is significant risk factor for becoming homeless. Symptoms of mental illnesses often interfere with family relationships and impair judgments. Mental illness increases a person's vulnerability to be victimized (see [Box 41.2](#)).

The Experience of Being Homeless

The person who is experiencing homelessness spends time hunting for shelter, food, and clothing and lacks consistent ways to meet basic needs. They are at higher risk for disease, infection, and exposure to the coronavirus (Shinn & Viron, 2020). This lifestyle, plus grinding poverty and victimization, especially if the person is mentally ill, leaves little energy for change or reentrance into mainstream society. Panhandling, hustling, doing odd jobs, and selling plasma or aluminum cans are common sources of income, although some people who are homeless receive Social Security or veterans' pension benefits. The longer a person is homeless, the more likely the person is to experience mental illness or engage in substance use (Montgomery et al., 2016).

Box 41.2

Risk Factors for Homelessness among People with Serious Mental Illness

INDIVIDUAL RISK FACTORS

- Symptoms of mental illness, including unpredictable behavior; an inability to manage everyday affairs; and an inability to communicate needs, which results in conflicts with family, employers, landlords, and neighbors
- Youth and adults with a concurrent mental disorder and substance use are at high risk for eviction, arrest, and incarceration in jails or repeated admissions and short stays in mental hospitals
- Coexisting HIV or AIDS with mental illness, chemical use, or both
- Coexisting demographic and societal factors of poverty; single-parent family (usually female headed); dependent child; child in foster home; underrepresented groups; veteran status; single men and women; ex-offender released from jail or prison
- Coexisting physical illness or developmental disability
- Exposure to traumatic events repeatedly, resulting in posttraumatic stress disorder and deficits in independent living skills
- Exposure to victimization (physical and sexual abuse), especially if a family member was the perpetrator
- Inability to cope with or manage the requirements of family, community, or group living home
- Lack of high school education or equivalence
- History of war veteran

ENVIRONMENTAL RISK FACTORS

Mental Health System Factors

- Inadequate discharge planning with a lack of appropriate housing, treatment, and support services
- Lack of funding for community-based services
- Lack of integrated community-based treatment and support services for individual and group therapy, medication monitoring, and case management
- Lack of community-based crisis alternatives for housing, health care, and respite care for families with risk for rehospitalization and loss of residence
- Lack of attention to consumer preferences for autonomy, privacy, and integrated regular housing
- Changing environment, such as loss of home caused by natural or human-made disaster

SOCIETAL AND FAMILY FACTORS

- Lack of affordable housing; affluent economic times have caused housing prices to soar out of reach, to reduce construction of low-cost housing, and to create a tight rental market
- Insufficient disability benefits; Social Security income recipients are below the federal poverty level
- Lack of coordination between mental health and substance abuse systems
- Waiting lists to receive a subsidy that requires the person to pay only 30% of income for rent and utilities

- Lack of job opportunities for disabled people
- Stigma and discrimination; resistance to community housing for people with mental illnesses is widespread
- Poor family relationships; willingness to help the ill person is exhausted as relatives cope with frightening or disturbing behavior and receive insufficient help from the community or medical profession

Substance Abuse and Mental Health Services Administration. (2013). *Behavioral health services for people who are homeless. Treatment Improvement Protocol (TIP) Series 55. HHS Publication No. (SMA) 13-4734*. Rockville, MD: Substance Abuse and Mental Health Services Administration.

The healthiest survivors seek support from others, maintain hope for the future, and strive to have valued lives and selves. They believe they are resourceful, can handle uncertainty, and can maintain health. Women with children who are experiencing homelessness have described the need to keep going for the sake of, and to avoid, losing their children. However, women living in temporary or transitional shelters are confronted with insecurity, lack of privacy, isolation, stigma, and disempowerment (Andrade et al., 2020). Some women have preexisting mental health problems that lead to homelessness, while others develop mental illness because of their homelessness. Domestic abuse is often an antecedent to homelessness (Duke & Searby, 2019; see [Chapter 23](#)).

Chronic Homelessness

A person is considered to be experiencing chronic homelessness when they spend more than a year in state of homelessness or have experienced a minimum of four episodes of homelessness over a 3-year period (U.S. Department of Housing and Urban Development, 2016). The experience of being homeless for a long time results in a sense of depersonalization and fragmented identity; a loss of self-worth and self-efficacy and a stigma of being “nothing,” “a bum,” “lazy,” and “stupid” (Singh et al., 2019). They may have lived in poverty for years. People who are homeless are often chronically ill, jobless, or have recently lost all financial resources. Educational level varies greatly, from less than an eighth-grade education to doctoral degrees.

Some people wrongly associate all homelessness with mental illness, violence, and alcohol or drug addiction. A person who is homeless for the first time or for a few months is more likely to have a more positive outlook than a

person who has been experiencing homelessness for a longer period of time because the chances of recovering economic and social status are greater. Biographies and research describe the tragedy and nightmare of being homeless (Mejia-Lancheros et al., 2020).

Homelessness and Hope

Deprivation of needs, the sense of isolation and stigma, and the lack of accessible resources may be of short- or long-term duration. In turn, self-confidence and sense of competence can be eroded. Persons who have been or are homeless and have mental illnesses have typically endured and coped with constraints or problems with extreme stressors or catastrophes and negative life events. Instilling a sense of hope and possibility of recovery from homelessness and mental illness is important. Many people who experience homelessness maintain hope and a positive attitude, which in turn helps them to reach out to help, take advantage of opportunities, and become part of the housed population (Karadzhov et al., 2020).

Federal Assistance

There are several federal programs that provide assistance to people who are homeless. The McKinney–Vento Homeless Assistance Act (Public Law 100–77, first passed in 1987 as the McKinney Act), signed by President Ronald Reagan and confirmed by President Bill Clinton, provides federal money for homeless shelter programs. This law established the U.S. Interagency Council on the Homeless that provided for the use of funds in a coordinated manner, and for programs to assist the homeless, with special emphasis on older adults, persons with disabilities, families with children, Native American individuals, and veterans. This program is funded through grants to the states.

Substance Abuse and Mental Health Services Administration (SAMHSA) recognizes that housing is critical to recovery from mental and substance abuse disorders and promotes safe, affordable, and permanent support housing in the community with access to benefits and services for individuals, families, and communities. SAMHSA has several initiatives to create safe places for people with mental illness and substance abuse. SAMHSA works closely with the U.S.

Interagency Council on Homelessness to support and implement Opening Doors, the federal strategy to prevent and end homelessness. SAMHSA's programs emphasize the importance of employment and education as outcomes and core components of recovery (SAMHSA, 2020).

ETIOLOGY OF HOMELESSNESS

Homelessness has no single cause. People want to have a home and be part of a family or social group. People do not choose or purposefully maintain homelessness and living on the streets. Many factors—unemployment, lack of skills, mental illness, substance abuse, domestic violence—typically combine, with time, to cause the person or family to lose permanent housing. The series of events that results in having no home is the culmination of individual and environmental factors, including factors in the mental health system, society, and family or community ([Box 41.3](#)).

The reduction of psychiatric beds has had a huge impact on the increase in the number of persons with mental illness who are homeless. In 1955, there were 337 beds per 100,000 persons. The deinstitutionalization movement decreased the number of state hospital beds to 11.7 per 100,000 by 2016. Even though there has been an increase in community and private hospital expansions to provide mental health services, their beds are primarily occupied by insured patients who have voluntarily sought care (Fuller et al., 2017).

Box 41.3

Causes of Homelessness

- Poverty; history of childhood family instability
- Lack of affordable housing; doubling up with relatives or friends until the situation is intolerable
- Mental illness or substance abuse and lack of needed services
- Low-paying jobs; unemployment
- Domestic violence; flight from a violent home or abandonment; youth aging out of services
- Eviction for not paying rent; multiple movers
- Limited life coping skills; disturbing behavior
- Changes or reductions in public assistance programs
- Veteran status
- Prison release; having no money, job, or place to go

State hospitals that do exist dedicate most of their beds to those who have committed crimes and have court-ordered treatment. Even under these circumstances, there is often a 30-day to 6-month wait for a bed. Many “nonforensic” individuals are detained in emergency departments (EDs) until beds are available (Fuller et al., 2017).

Gentrification, upgrading of inner-city property so that it is affordable only to people who have the resources of upper-middle or upper economic levels, is increasingly a factor in creating homelessness among urban residents. Middle-class and upper-middle-class professionals, mostly White individuals, are relocating to the inner city. Thus, abandoned or substandard buildings are demolished to build modern condominiums or “lofts.” People who reside in poverty-stricken urban areas cannot afford the new housing in their regenerated neighborhood. They are often displaced and are at risk of becoming homeless (Tran et al., 2020).

Family Response to Homelessness

Family homelessness, whatever its cause, has an especially adverse effect on children. Underprivileged children move two or three times within 1 year before becoming homeless and moving into a shelter. Children experiencing homelessness are generally school-aged or younger. These children have high rates of both acute and chronic health problems and are more likely than children who are not homeless to be hospitalized, have delayed immunizations, and have elevated lead blood levels. In addition, they are at risk for developmental delays and emotional and behavioral difficulties. School attendance is disrupted frequently, and they are vulnerable to violence, either as victims or witnesses. Children who experience family homelessness, even for brief periods of time, are significantly more likely to be a victim aggressor or aggressor compared with those who have never experienced homelessness (Andrade et al., 2020).

Living in shelters is stressful for families for several reasons. Many shelters exclude men and adolescent boys older than 12 years; thus, family members are separated. Overcrowding prevents privacy and promotes loss of personal control. Stressors of poverty and reduced social support compound the trauma of these experiences.

A history of abuse and assault is common among homeless. Women have greater mental health concerns, higher rates of diagnosed mental health issues,

suicidal thoughts and attempts, and adverse childhood trauma. Mothers who are experiencing homelessness have often left abusive relationships and have difficulty accessing shelter and health care (Milaney et al., 2020).

RECOVERY-ORIENTED CARE FOR PERSONS WITH MENTAL ILLNESS WHO ARE HOMELESS

It is beyond the scope of most mental health services to meet many of the urgent needs for individuals with mental illness who are homeless. The mental health system is often the first contact for the person who is homeless or facing homelessness. The mental health team should have a working knowledge and relationships with community resources that provide housing, physical health care, financial support, and legal support.

Teamwork and Collaboration: Working Toward Recovery

SAMHSA recommends a five-stage process in homeless rehabilitation for persons who are homeless with a mental illness. *Outreach and engagement* is the first step in the process and involves facilitation of the individual into behavior changes. Outreach and engagement involves recognizing the needs of people who are homeless for preventive and basic service and developing a trusting and supportive relationship with these individuals. *Transition to intensive care* occurs when individuals agree to accept health and/or financial benefits, substance abuse/mental health treatment. During this phase, the clinician maintains a relationship with the individual and works with any resistance or concerns the person has. *Intensive care* phase emphasizes the person's participation in defining and managing their own goals. The primary focus of this phase is mental health treatment, accessing benefits, attending to medical problems, accessing housing, and seeking preventive services, such as skills training. *Transition from intensive care to ongoing rehabilitation* is preparation for sustaining the process of recovery. Depending on the individual, some may move quickly into affordable housing and maintain an independent lifestyle. Others may need 1 or 2 more years of supportive recovery and housing. *Ongoing*

rehabilitation is an open-ended phase in which people gradually establish an identity as no longer homeless. This stage includes an active and continuing supportive counseling relationship, participation in mental health treatment as needed, and continued participation in prevention programs as appropriate (SAMHSA, 2013).

Safety Issues

Safety needs are always a priority. If an individual is threat to others or self, safety interventions should be implemented. The person may be involuntarily hospitalized for stabilization of symptoms. Overdose of opioids or alcohol intoxication is also a priority care issue. Persons should be referred to emergency services. The nurse may be required to take immediate action to reverse the drug effects by administering naloxone. Other priority issues involve basic needs, including housing and food. Many persons who are homeless are fearful of being incarcerated and resist any attempts to provide shelter.

Screening, Brief Interventions, and Referral to Treatment

Screening, brief interventions, and referral to treatment (SBIRT) integrates initial screening with brief interventions or referral to treatment for people who may have substance use disorders and co-occurring mental disorders (see [Chapter 42](#)). SBIRT is particularly useful for individuals who are homeless. The screening requires little time—5 minutes to screen and 10 minutes to provide the interventions (SAMHSA, 2013).

Homelessness and COVID-19

People experiencing homelessness are at high risk for contracting coronavirus. Many people who are homeless live in congregate living settings and might not have access to basic hygiene supplies or shower facilities. Their exposure may negatively affect their ability to find safe housing and the mental health.

COVID-19 infection increases the mortality disparity between those who are homeless and those who are not (Tsai & Wilson, 2020).

EVIDENCE-BASED NURSING CARE FOR PERSON WITH A MENTAL ILLNESS WHO IS EXPERIENCING HOMELESSNESS

A holistic perspective is essential for assessing any person or family unit who is experiencing homelessness. Assessing a person who has a mental disorder and does not have a home requires patience and skill. Generally, these individuals have not been following a recommended treatment regimen and are symptomatic.

Mental Health Nursing Assessment

The assessment begins at the point of the person's need; often, it is a physical need or health problem (Box 41.4). The person may be malnourished and most concerned about food and shelter. Because of negative past experiences with the health care system or providers or because of mental illness or substance use, the person may not allow a thorough physical examination or may refuse to answer questions about history at the first visit.

Box 41.4

Assessment Tips for the Physical Assessment

- Use unobtrusive observation as a part of physical assessment. Some conditions will be immediately obvious. Other conditions may become apparent during the interview.
- Examine—look, touch, palpate, auscultate—the person to the extent that they allow. The person may resist anything more than a superficial conversation and observation. The nurse may need to perform initial palpation of the abdomen or auscultation of the lung through several layers of clothes. If the patient perceives the health care provider as too intrusive, the patient may leave the setting even though they are desperate for care.
- Listen carefully to what the patient does *not* say and pay attention to nonverbal as well as verbal expressions. Avoid unnecessary directness and probing. Give the person time to answer questions. The blood test or urine screen may have to wait; a patient, nonintrusive manner may ensure that the person

returns for needed tests or screening.

- Determine whether the person has been prescribed medications in the past. Often, the person who is homeless is not taking medications, even if they are prescribed and essential. The person may have difficulty keeping pills dry and easily retrievable or paying for medications. A daily insulin injection, for example, may not seem practical. Or the person may have been mugged by another homeless person seeking to quiet addictive urges or to sell drugs for cash.

Physical Health Assessment

Provide privacy for any assessment. Be gentle. Avoid hurry. Explain the need for any physical examination. The person may feel very embarrassed about their physical appearance or body odor if there has been no opportunity for physical hygiene or clothing change. Observation of mucous membrane and skin integrity, including the face, torso, limbs, and feet, is essential. Explain your concern about the person's health status and the need to remove clothing, including shoes and socks, and to pull down underwear.

Realize that many people who are experiencing homelessness consider themselves well as long as they can get where they need to go. The individual may believe that refusing to admit illness is adaptive behavior. Be aware of the many health problems that may be present ([Box 41.5](#)). Children and adolescents who are experiencing homeless may experience any of those listed, plus diseases that are specific to their age group. If a woman is pregnant and experiencing homelessness, assess indications that she is at high risk for maternal or fetal complications.

Box 41.5

Common Physical Health Problems Experienced by Homeless People

- Injuries, fractures, epistaxis, or edema from trauma, falls, burns, assault, gunshot wounds
- Influenza, colds, bronchitis, asthma, shortness of breath
- Hypothermia, hyperthermia
- Arthritis, musculoskeletal disorders, headaches, fatigue
- Diabetes mellitus
- Hypertension
- Cardiovascular and peripheral vascular diseases
- Malnutrition

- Pulmonary tuberculosis
- Infestations, such as lice or scabies
- Dermatitis, sunburn or frostbite, bruises
- Foot injury, blisters, calluses
- Sexually transmitted diseases
- Hypothyroidism or hyperthyroidism
- Kidney or liver disease
- Cancer
- Epilepsy
- Impaired vision, glaucoma, cataracts
- Impaired hearing
- Dental caries, periodontal disease

Psychosocial Assessment

Mental Status and Appearance

The mental status examination may have to be done over several sessions (see [Box 41.6](#)). Symptoms of schizophrenia may be difficult to differentiate from emotional responses to the stressors of experiencing a homeless lifestyle. Required hypervigilance may augment suspicion or paranoid beliefs. The need for constant awareness of possibilities for meeting basic needs can augment self-preoccupation. Blunted affect, lack of communication, loose associations, ambivalence, isolation, and uncertainty may be the result of life on the streets and living in various places. Such symptoms or behaviors may be part of the homelessness experience and reflect healthy coping mechanisms and creative survival techniques rather than pathology.

Box 41.6

Assessment Tips for the Psychological Assessment

- Observe for behavior that indicates hallucination and try to validate.
- Listen for delusions or denial over time; try to sense what purpose these serve.
- Observe and listen to what the person defines as a problem and potential solution and what they consider to be a strength or coping strategy; validate and reinforce when applicable.
- View the person and their situation from the individual's perspective; be a patient, nonthreatening listener. Such an approach encourages the person to return regularly; the nurse can then observe the

patterns of behavior.

- Determine the extent of stability or integration of the person's sense of self, cognitive appraisals, and overt behavior. Lack of integration or stability indicates the need for continued monitoring and therapy.

Substance abuse should be considered because it is common among people who are homeless, including people with mental illnesses. Because people who are experiencing homelessness, especially those with psychiatric disorders, are often victims of crime and violence, the incidence of posttraumatic stress disorder among them may be higher than in the general population. Homeless women are especially in danger of being assaulted, abused, and raped.

When a child or adolescent is homeless, ask about the educational history, if the youth is enrolled in school, and about perceived progress. Homeless children often have difficulty with school; the school district may change every time the parent changes shelters or moves from a temporary residence. Determine whether the child has behavioral or emotional problems and whether they need special education services.

Behavioral Responses

The behavioral assessment should follow the one presented in [Chapter 11](#). The nurse should recognize that the person who is homeless has their own way of being in the world. They may not have insight into their illness and deny that they have a mental health problem. Much of the behavioral assessment will be conducted through observation and listening to the person's explanation of events.

Stress and Coping Skills

Homelessness is stressful. It is important that the nurse understands how the person who is experiencing homelessness copes on a day-to-day basis. The nurse should ask the person how basic needs are met: How the client eats and sleeps? How does the person cope with experiencing homelessness?

Cultural Assessment

Cultural value differences exist between people who are experiencing homelessness and people in the dominant American culture, to which most providers of health care subscribe. Thus, providers and the person who is homeless and needs health care may experience cultural conflict in their norms of health and illness, basic value systems and priorities, and perceptions about health care. Health care providers expect patients, including those who are homeless and mentally ill or chemically dependent, to problem solve, become more independent, and be future oriented. These values affect assessment, treatment, and interactions with the person and can interfere with the nursing process and patient response to the health care system. Consider how the person perceives their everyday life and vary the assessment and therapy approach accordingly.

Support Network and Support System Assessment

Homelessness is an expression of and response to certain family, societal, or environmental conditions, as well as to individual factors. See [Box 41.7](#) for factors included in the social and family assessment. It is also important to consider that childhood abuse and prior trauma may be continuing to affect the person as a stressor or contribute to interpersonal crises.

Box 41.7

Assessment Tips for the Social Assessment

- Ask about support systems, people who could be helpful, and what services have been or could be used.
- Determine whether the person is isolated from the family, and if so, if it is by personal choice rather than by family choice.
- Respect that the person who feels isolated may avoid talking about their biologic family.
- Explore if the patient views a homeless peer, local pastor, counselor, or another health care provider as “family” or as a support system.
- Convey genuine interest in the person and convey that others may also care. Questions may be the catalyst to reestablishing family ties.

Spiritual Assessment

Listen for expressions that convey a spiritual faith, a connection to a transcendent being, or a belief system that helps the person endure. Questions about the spiritual dimension may convey an invitation to talk about an aspect of life that is often ignored but that may be very important to the beliefs, and preferred practices will help determine relevant therapy approaches.

CLINICAL JUDGMENT

A person who is experiencing homelessness has several immediate needs. The first priority is safety from immediate harm to self or others. The next priority will depend upon the current housing situation—do they have safe shelter at night. The nurse should consider whether the gender, mental status, and history of mental disorders. Physical health needs should be a priority before addressing mental health needs.

THERAPEUTIC RELATIONSHIP

Self-awareness on the part of the nurse is important. Often people do not know how to respond to a person who is homeless and who asks for food, money, or interpersonal communication because they hold common stereotypical beliefs about homelessness. Nurses and teachers, for example, who are accustomed to caring for others and giving attention to people who ask for it may find themselves considering various myths when approached by a person who is homeless ([Box 41.8](#)). To respond appropriately, one must first examine these myths and one's own feelings about people who are homeless and mentally ill. Relating to people who are homeless requires a gentle and compassionate approach.

MENTAL HEALTH NURSING INTERVENTIONS

Interventions are to be directed at the social system, as well as at the individual or family level. Interventions should take advantage of community resources and the inner resources and support systems of the individual or family. [Box 41.9](#) describes interventions that focus on the individual and social system.

Box 41.8

Myths and Facts about People Experiencing Homelessness with Psychiatric Disorders

Myth #1. People choose to be homeless.

Fact: Most people who are homeless want what most people want: to support themselves, have jobs, have attractive and safe housing, be healthy, and help their children do well in school.

Myth #2. Housing is a reward for abstinence and medication compliance, and society shouldn't house people who have active substance use or mental disorders.

Fact: Housing may be the first step to becoming abstinent and/or entering treatment to address a variety of problems. From a public health perspective, adequate housing reduces victimization, hypothermia or hyperthermia, infectious diseases, and other risks to the population as a whole.

Myth #3. People who are homeless are unemployed.

Fact: Many people who are homeless are employed full or part time.

Myth #4. There are few homeless families.

Fact: Families become homeless for a variety of reasons.

Myth #5. People who are homeless aren't smart enough to make it.

Fact: Keeping things together while homeless takes ingenuity and experience. People who are homeless often have well-developed street skills, resourcefulness, and knowledge of the service system.

Myth #6. Those with substance use or mental disorders need to "bottom out," so homelessness is okay and provides a motivator to make behavioral changes.

Fact: People who have substance use and mental disorders are more responsive to interventions before they become homeless or when placed in housing.

Myth #7. Everyone stands an equal risk of homelessness.

Fact: Although any of us could find ourselves homeless in our lifetime, some people are at higher risk than others. If we can identify people at special risk of homelessness, we may be able to intervene earlier and prevent the devastating effects experienced by people who are homeless and have accompanying mental and/or substance use disorders.

Myth #8. All clients with substance use and mental disorders who are homeless require extensive, long-term care.

Fact: The process of recovery from substance abuse and mental illness is an ongoing and sometimes lifelong process, yet healing often begins with short-term, strategic interventions. Screening, brief intervention, and referral to treatment is a proven method for early intervention with substance use and mental disorders, and it can significantly reduce the impact and progression of illness.

Substance Abuse and Mental Health Services Administration. (2013). *Behavioral health services for people who are homeless. Treatment Improvement Protocol (TIP) Series 55. HHS Publication No. (SMA) 13-4734*. Rockville, MD: author.

Establishing Recovery and Wellness Goals

Prioritizing the patient's goals will guide the nursing care. The individual may only want to get a warm coat and a bus pass. The nurse should encourage the patient to identify meaningful goals, but it is important that their primary needs are met. Hospitalization may be needed to treat illness symptoms and providing immediate shelter. The nurse should advocate for finding permanent housing, which is associated with mental health recovery (see [Box 41.10](#)).

Box 41.9

Interventions for People Who Are Experiencing Homelessness

- Stabilize physical health status.
- Provide a list with addresses and telephone numbers of shelters and luncheon sites that provide food; discourage rooting through dumpsters and panhandling.
- Provide a list of facilities that are safe, including shelters that provide clothing, a safe place to sleep, and opportunity for basic hygiene and laundry.
- Give information on city ordinances that forbid sleeping on park benches, in building doorways, on sidewalk grates, at bus or train stations, in vacant buildings, or in viaducts.
- Explore sources of income, such as gathering and selling aluminum cans or engaging in temporary day labor. Discourage selling blood or plasma.
- Assist the person directly or by referral to pursue entitlements, such as Social Security, veterans, or other benefits.
- Explore how to stay safe. Even in a night shelter, the person who is homeless may not be safe from assault. It is difficult for the person who is homeless to know who is trustworthy; carrying a bag or case is usually considered a marker for being robbed on the streets.
- Explore how to secure privacy, which is difficult to achieve, and how to cope with loneliness, which can be overwhelming.
- Give a list of names, addresses, and telephone numbers of agencies that offer services and socialization, such as the local mental health agency, the local chapter of NAMI, or the local Emotions Anonymous group.
- Give information about meetings of Alcoholics Anonymous, Narcotics Anonymous, or Cocaine Anonymous if the person is using substances.

Overcoming Barriers to Care

Cost and lack of insurance are the biggest barriers to health and hospital care for people who are homeless. Another barrier is the inability of this population to carry out treatment recommendations; survival is their first priority. Compliance with medication and treatment regimens is difficult because successful treatment requires collaboration, monitoring, time for medication and other measures to be effective, and a secure place to keep medication. People with mental disorders who are experiencing homelessness often cannot routinely get prescriptions filled. Medicine may be stolen. It is necessary for the person or family unit to have a place to keep medications that can be reached at the necessary times and to have access to primary care services for regular check-ups, assessment for adverse drug responses, and necessary blood monitoring.

BOX 41.10

Recovery, Homelessness, and Mental Illness

Kerman, N., Sylvestre, J., Aubry, T., Distasio, J., & Schütz, C. G. (2019). Predictors of mental health recovery in homeless adults with mental illness. *Community Mental Health Journal*, 55(4), 631–640. <https://doi-org.libproxy.siu.edu/10.1007/s10597-018-0356-3>

THE QUESTION: What are the strongest predictors of mental health recovery among homeless people with mental illness at baseline?

METHODS: Data from 2,187 participants who had a mental illness, were currently homeless, and 18 years of age were assessed for recovery, mental health symptoms, substance use, community integration, use of social services for 24 months.

FINDINGS: Having fewer chronic medical conditions, fewer mental health symptoms, having a diagnosis of a psychotic disorder, having a close confidante with whom to share personal information, being more involved in community activities, and feeling a greater sense of belonging in the community were most consistently associated with more positive recovery ratings.

IMPLICATIONS FOR NURSING: Many of the predictors for recovery occur within the context of permanent housing. Finding housing facilitates mental health recovery.

NCLEXNOTE The priority for people who are experiencing homelessness is meeting the basic needs—food, shelter, and so on. Care for the response to the mental illness is secondary. Use Maslow hierarchy of needs as the guiding framework when you are planning interventions.

Improving Quality of Life

Interventions that improve quality of life include providing food, clothing, and

assistance with housing; addressing physical health problems; promoting safety and self-esteem; and educating the person to decrease the risk of victimization. A trusting relationship with the care provider and ongoing follow-up care is also necessary.

People who have been homeless for several years have greater difficulty readjusting to stability and need more time for healing, depending on illness severity, comorbidity, and available support system. People who are experiencing homelessness, including those with psychiatric disorders, become creative at surviving on the streets. Explore resources with the individual or family (see [Box 41.9](#) for appropriate interventions).

Meeting Spiritual Needs

Depending on the person's beliefs, the nurse may explore ways to meet spiritual needs. In one study, respondents listed the following as ways to meet spiritual needs: pray and put trust in God, hope that things will get better, obtain strength from religious beliefs and say these beliefs to self daily, seek a religious worker and attend religious services, talk about the meaning of the life situation with someone who is understanding and caring, and read devotional material (e.g., the Bible or the Koran).

NCLEXNOTE Providing physical resources, social services, and social and legislative advocacy counter the negative social and emotional effects of homelessness for the person and family.

Evaluation and Treatment Outcomes

There are two outcomes for people who are homeless with a mental illness. Recovery from a mental disorder and living in a housing of choice are primary. In some instances, after the mental disorder is treated and in remission, housing, a job, and positive interpersonal relationships follow. In other instances, finding housing sets the stage for strengthening coping skills to address the mental disorder.

COMMUNITY SERVICES

Diverse services and integrated systems are essential to address all aspects of the life situations of people who are without a home and experiencing psychiatric disorders. Essential components include **Safe Havens** or stable shelters or residences, accessible outreach, integrated case management, accessible and affordable housing options, treatment and rehabilitation services, general health care services, vocational training and assistance with employment, income support, and legal protection. The agencies that provide these services must develop a physical and emotional atmosphere that conveys a sense of caring and community. Often, community agencies are located at one site, much like a shopping mall, so that the person or family does not have to travel to numerous separately located agencies to get their needs met.

Emergency Services

Some agencies provide a street or mobile outreach program. As part of this program, a van travels the streets to areas where homeless people are found outdoors. Food, warm coffee, hygiene kits, and blankets are the first steps in building trust between staff and homeless persons. The person who is homeless may accept an offer to be driven to a local shelter for the night. Following up the next day by van or bicycle provides a way to recontact the individual and invite them to the agency programs or take them to other social service or health care services. Luncheon sites for homeless people are a basic step in emergency services. Some agencies have a health clinic on site for treatment of minor problems.

Integration with Primary Care

Integrating crisis intervention with physical and medical care is essential for individuals with psychosis who are seeking service in a hospital ED. The ED is likely to emphasize triage and rapid disposition while administering essential care. The physical orientation supersedes care for the emotional status of the person. Medication should be supplemented by crisis intervention techniques.

The developmental level of the person, regardless of age, should also be considered. Emergency shelters typically provide refuge at night, along with an evening meal and morning coffee. Shelters for homeless women and children usually allow them to remain during daytime hours as well. The child leaves the shelter for school; the mother may attend educational classes, counseling, **day treatment**, rehabilitation, or employment programs.

Housing Resources

Transitional housing may consist of a halfway house, a short-stay residence or group home, or a room at a hotel designated for people who are homeless. Some agencies have a transitional home and stabilization center where the atmosphere and staff are a model for residents, who work on specific goals and a treatment plan. Sharing housekeeping tasks; obtaining psychiatric stabilization; and attending residence group meetings, social skills and budgeting classes, day treatment programs, and vocational training are steps to independent housing and employment. A holistic program reduces readmission to the hospital and reentry to street dwelling.

Housing First is a homeless assistant approach that prioritizes permanent housing to people experiencing homelessness. This approach is adopted by communities in providing services to people who are homeless. It is guided by the belief that people need basic necessities like food and housing before they can attend to other issues such as recovery from a mental illness, secure a job, and develop meaningful relationships. Case management, living skills classes, and other services are provided as “wrap-around” interventions as needed. There is a direct relationship between the safety and security provided by the Housing First program and a decrease in psychiatric symptoms and chronic homelessness, with an increase in a sense of independence, choice, and mastery of living skills.

The HEARTH Act of 2009 consolidated the McKinney–Vento homeless assistance program, **Shelter Plus Care Program**, and Section 8 Moderate Rehabilitation single room occupancy (SRO) Program into one program known as the **Continuum of Care**. Shelter Plus Care provides long-term housing and supportive services for people who are homeless with disabilities, primarily those with serious mental illness, chronic problems with alcohol or drug use, or AIDS or related diseases (USDHUD, 2021b). **Section 8 housing** has been helpful to this population for many years. Section 8 federally subsidized housing

units are supervised or operated by the state or city, for which tenants are responsible for paying one-third of the monthly income (e.g., Supplemental Security Income or Social Security Disability Insurance) toward rent. The difference between the tenant payment and the maximum fair market rental price is calculated as the federal Section 8 housing contribution to the housing provider.

Safe Haven programs are found throughout the United States and provide 24-hour residence for an unspecified duration. Safe Havens serve hard to reach people with severe mental illness who are on the streets and have been unwilling or unable to participate in traditional supportive services, meet the following criteria. A Safe Haven provides private or semiprivate accommodations and limits overnight occupancy to 25 persons (USDHUD, 2014).

Supportive housing, permanently subsidized housing with attendant social services, was previously considered too expensive. Today, communities are realizing that such programs for people who are mentally ill and homeless are a good investment. The person who is safely housed is less likely to use other acute care and publicly funded services, such as shelters, although case management services are needed. Use of acute psychiatric and medical services is reduced, and the person is less likely to be arrested or incarcerated (Fuller et al., 2017).

U.S. Military Veterans Services

The Veterans Administration has a national service dedicated to the care of homeless veterans with mental health problems. The Health Care for Homeless Veterans (HCHV) Program provides community-based residential treatment for homeless veterans. The HCHV serves as a hub for housing and other services that provide the Veterans Health Administration with a way to reach and assist homeless Veterans (Veterans Administration, 2021; see [Chapter 40](#)).

Case Management

Case management is essential in addressing an individual's needs and preventing the person from becoming lost in the complexity of community services (SAMHSA, 2013). Case management involves systematic assessment,

planning, goal setting, counseling and other interventions, coordination of services, referral as necessary, and monitoring of the person's or family's needs and progress. It enhances self-care capability and quality of care, decreases fragmentation, provides for cost containment, and reduces unnecessary duplication of services or hospitalization. The case manager is the gatekeeper and facilitator who may at first network with services on the person's or family's behalf and then encourage them to deal directly with other service providers to obtain bus passes and transportation, children's services and supplies, medical or obstetric care, or housing. The nurse is the ideal team member or case manager because of knowledge about both psychiatric and physical diseases and the ability to develop therapeutic relationships and stay connected with persons or families who are homeless and with the health care system.

Rehabilitation and Education

Day Treatment Programs

Day treatment provides a bridge between institutional and community care for people with mental illness or substance abuse problems. Participation in structured day treatment programs can provide emotional and practical support and strengthen ties to community services and potentially to family and friends. A day treatment program can provide legal assistance, help with finding employment and independent housing, and a mailing address for people who are homeless. It can provide case management, assistance with goal setting and problem-solving, and psychiatric or medical care. The day treatment program may incorporate adult basic education classes to increase literacy and survival skills, and general education development (GED) classes for those who want a high school diploma, and computer skills to improve employment options. A Living Skills Program typically includes content in nutrition, budgeting, parenting, household and family management, tenant responsibilities and rights, and employment readiness. Such classes are especially useful to women who will no longer be receiving welfare benefits. The person can receive assistance applying for government benefits, if qualified, and obtaining identification, such as a birth certificate, if needed. The informal environment of day treatment programs promotes a feeling of camaraderie, self-confidence, trust in staff, and aspirations for independent living.

Alcohol and Substance Use Treatment

The structure of some day treatment programs included alcohol and substance abuse treatment. Sobriety or harm reduction is the goal; the person attends daily meetings, receives necessary psychiatric and medical treatment, and participates in all of the other activities and services available at the day treatment program. No one is terminated for relapse; the person is referred to more intensive services, including hospitalization, if necessary.

Employment Services

Job placement is most likely when an employment program teaches basic job-seeking skills (e.g., resume writing; interview skills; appropriate attire, hygiene, and behavior; and computer skills) and offers job training in settings that prepare the person for the real world and real jobs. Case management during employment training can increase self-confidence, teach budgeting skills and methods of coping with the stresses of regular employment, and link the person with community resources. It can also help to teach various skills for job retention and career development. The employment service should periodically follow up with both the employee and their employer to ensure a successful record and movement to independence.

Integrated Services

Assertive Community Treatment (ACT) programs focus on service delivery to the homeless and mentally ill population by a transdisciplinary team of 10 to 12 specialists with a 1:10 staff–client ratio. A single, integrated, mobile staff team uses outreach, case management, practical assistance and support, and rehabilitation services to maximize the possibility that the most disabled consumers will live independently in the community and have a good quality of life. The team provides counseling and advocacy; monitors the person’s management of housing, income, medication use, and leisure activities; and provides opportunities for employment if appropriate. Substance abuse management and physical health care are provided as needed.

Ongoing social support groups; membership in day treatment programs; attendance at meetings of AA, Narcotics Anonymous, or Cocaine Anonymous; or the local National Alliance on Mental Illness (NAMI) or Mental Health Association can help the person remain in the community and live independently or with family. Support groups foster peer socialization and problem-solving, enhance self-esteem, and offer many activities (e.g., art and recreation therapy, legal assistance).

For a number of years, the SAMHSA and the Center for Substance Abuse Treatment have funded treatment programs for women and young children. Long-term stays have been found to predict positive treatment outcomes, including lower rates of drug use, criminal behavior, and unemployment. Improved parenting and mother–child relationships, less child abuse and neglect, improved developmental outcomes in children, and lowered costs for mother and infant health are other benefits.

Advocacy

Nurses can share experiences and research findings with the local chapter or national headquarters of NAMI and with state legislators and members of Congress who are involved in developing legislation and policies related to people who are homeless, mentally ill, and substance abusing. Continued advocacy is essential to convey the perceptions and needs of this population, to influence allocations for needed programs and services, and to end the social injustice of chronic homelessness.

SUMMARY OF KEY POINTS

- People who are experiencing homelessness are a heterogeneous, diverse group, some of whom have a mental disorder and a substance use disorder.
- There are many risks for being homeless.
- People do not want to be homeless.

- Meeting the needs of people who have a mental illness and are experiencing homelessness requires more than mental health services. Housing services are critical.
- The nursing assessment must be holistic; the nurse must listen to the person's perceptions and observe carefully.
- People who have a mental illness or substance use disorder and are without a home may have various physical health problems.
- Intervention must be oriented to the person's or family's perceived needs, culturally sensitive, and compassionate.
- People who have mental disorders and are experiencing homelessness may avoid traditional health care services.
- Nurses must incorporate new trends in providing and improving services for health care and social integration.

Critical Thinking Challenges

1. How do the effects of mental illness, substance use, and homelessness interact with one another?
2. What factors might interfere with the ability of the person who is mentally ill to participate in treatment? What is the impact of exposure to the coronavirus?
3. What barriers to communication might the nurse experience when relating to the person who is homeless and mentally ill?

Movie Viewing Guides

Home (2013): Jack (Gbenga Akinnagbe) lives in a group home and is suffering from a mental illness. He wants to have his own home and reconnect with his son. When he moves into an apartment, he finds that living alone is more difficult than expected.

VIEWING POINTS: How does Jack illness limit his ability to maintain his independence? What does having his own place represent to Jack?

West 47th Street (2001, 2003): This documentary describes services offered by Fountain House, the original clubhouse for persons who are homeless and mentally ill, through the eyes of four clubhouse members. Fountain House has celebrated 50 years of providing services and is the model for more than 300 clubhouses nationwide. (This video is available for purchase from Lichtenstein Creative Media, 617-682-3700. Information is also available online.)

VIEWING POINTS: Discuss the range of services needed for people who are homeless and mentally ill. Visit a clubhouse program in your community and compare the services with those of Fountain House.

Care of Persons with Co-occurring Mental Disorders

Mary Ann Boyd

KEYCONCEPTS

- co-occurring disorders (CODs)
- relapse cycle

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Define the term *co-occurring disorders* (CODs).
2. Describe the cycle of relapse in COD.
3. Discuss patterns of substance use with other mental disorders.
4. Analyze barriers to the treatment of patients with COD.
5. Discuss the significance of integrated health care for persons with COD.
6. Apply a person-centered, recovery-oriented approach for persons with co-occurring disorders.

KEY TERMS

- Assertive Community Treatment (ACT)
- Engagement
- Integrated treatment
- Motivational interventions
- Quadrants of care
- Relapse prevention
- Recovery
- Self-medicate

KEYCONCEPT The term **co-occurring disorders** (COD) refers to coexistence of a mental and a substance use disorder (SUD) in the same person.

INTRODUCTION

Mental disorders and SUDs are each a primary mental disorder even though they do not necessarily appear at the same time. A diagnosis of COD means that at least one disorder of each type can be established independently. However, the person's experience, symptoms, and outcomes are influenced by the interaction of the two disorders, not just the discrete disorders.

The goal of treatment for patients with COD is a comprehensive recovery plan

for the complex problems presented—one that offers the patient a way out of what can be a downward spiral of debilitation. Effective treatment of COD requires an integrated approach based on both an understanding of mental disorder and addiction. **Integrated treatment**, coordinated substance use, and mental health interventions require modifying traditional approaches to both the mental disorder and addiction (Office of Disease Prevention and Health Promotion, 2021).

This chapter presents the epidemiology and etiologic patterns of COD and discusses specific mental disorders and the adverse effects of concurrent substance use. It highlights methods of assessing COD and offers treatment strategies and nursing interventions to address this complex yet common presentation in psychiatric and substance use treatment settings. A complete discussion of related SUDs is provided in [Chapter 31](#).

CO-OCCURRING DISORDERS OVERVIEW

The problem of COD was inadvertently magnified during the community mental health reform movement when there was a rational movement toward deinstitutionalization of people with mental disorders (see [Chapter 1](#)). Large numbers of persons with mental disorders were left homeless, lost to local and state mental health systems. Their long-standing mental disorders and protected life in a state hospital increased their vulnerability to exploitation by others, particularly the more astute and streetwise addicts. Along with homelessness came the increased use of drugs and alcohol and discrimination (Mejia-Lancheros et al., 2020; see [Chapter 41](#)).

It is impossible to make any meaningful distinction between simple recreational use of a substance and actual substance use with this population because even small amounts of alcohol or other drugs can be damaging to people who have concurrent psychiatric problems. Substances of abuse exert profound effects on mental states, perception, psychomotor function, cognition, and behavior. The specific neurochemical and other biologic mechanisms that evoke these psychological features are discussed in [Chapter 31](#). [Table 42.1](#) lists the psychological effects of substances of abuse.

Clinical Course and Relapse

Although two types of disorders are diagnosed independently, people with COD respond to the interaction of two psychiatric disorders. In many instances, the use of substances serves as a coping strategy for dealing with psychiatric symptoms. Without alternative, effective coping behaviors, the patient will continue to self-medicate (using medication, usually over-the-counter medications, or substances without professional prescription or supervision, to alleviate an illness or condition). Persons with COD have lesser outcomes, such as higher rates of HIV infection, relapse, rehospitalization, depression, and suicide risk (Hides et al., 2019).

A frequent problem of this group is relapse, which leads to repeated hospitalizations or the “revolving-door” phenomenon. When symptoms of the mental disorder are stabilized, the hospitalized patient is discharged. Once in the community, the patient fails to follow the therapeutic regimen and resumes the use of alcohol or drugs. Reappearance of symptoms leads to another episode of hospitalization (Urbanoski et al., 2018). The relapse cycle is characterized by a pattern of decompensation, hospitalization, stabilization, discharge, and then decompensation (Fig. 42.1).

TABLE 42.1 PSYCHOLOGICAL EFFECTS OF SUBSTANCES OF ABUSE

Substance	Psychological Effects
Alcohol	Alcohol amnestic syndrome, dementia Agitation, anxiety disorders, sleep disorders Ataxia, slurred speech Withdrawal symptoms, which may include hallucinations, confusion, illusions, delusions; protracted withdrawal delirium can occur Depression, increased rate of suicide, disinhibition
Cocaine	Anxiety, agitation, hyperactivity, sleep disorders, delusions, paranoia, euphoria, internal sense of interest, and excitement Rebound withdrawal symptoms, such as prolonged depression, somnolence, anhedonia

Amphetamines	Similar to cocaine but more prolonged Hyperactivity, agitation, anxiety, increased energy
Hallucinogens (MDMA, or Ecstasy) and phencyclidine	Hallucinations, delusions, paranoia, confusion Withdrawal can produce severe depression, somnolence Hallucinations, illusions, delusions, perceptual distortions, paranoia, rage, anxiety, agitation, confusion
Marijuana	Acute reactions: panic, anxiety, paranoia, sensory distortions, rare psychotic episodes; patients with schizophrenia use these reactions to distance themselves from painful symptoms and to gain control over symptoms Antimotivational syndrome: apathy, diminished interest in activities and goals, poor job or school performance, memory and cognitive deficits
Opiates	Confusion, somnolence Withdrawal can produce anxiety, irritability, and depression and can trigger suicidal ideation
Sedative–hypnotics	Confusion, slurred speech, ataxia, stupor, sleep disorders, withdrawal delirium, dementia, amnestic disorder, sleep disorders
Volatile solvents	Hallucinations, delusions, hyperactivity, sensory distortions, dementia

MDMA, 3,4-methylenedioxy-methamphetamine.

KEYCONCEPT In the relapse cycle, reemerging psychiatric symptoms lead to ineffective coping strategies, increased anxiety, substance use to avoid painful feelings, adverse consequences, and attempted abstinence until psychiatric symptoms reemerge and the cycle repeats itself.

Figure 42.1 Relapse cycle.

Epidemiology

The pattern of alcohol and illicit drug use by those with a mental disorder varies, but it is estimated that as many as 9.5 million adults have both disorders (depending on definitions and methodologies). The most commonly used drug substance is alcohol, followed by marijuana and cocaine. Prescription drugs such as opioids and sleeping medicines may also be abused (SAMHSA, 2020a).

The risk for substance use varies among mental disorders. Antisocial personality disorders, bipolar depression, and disorders of childhood, including conduct disorders, oppositional-defiant disorders, and attention-deficit disorders,

are strongly associated with SUDs. Having any SUD was associated with at least a threefold increased risk of completed suicide when compared with those having no SUD (Østergaard et al., 2017).

Etiology

There is no one model that explains why mental disorders and substance use occur together so frequently. In one pattern of occurrence, the mental disorder precedes the substance use. As adolescents with emerging mental disorders are exposed to drug use, their disinhibition and impulsivity lead to drug experimentation. Substances are used to self-medicate the underlying mental disorders. In the second pattern, the SUD appears first and leads to the mental disorder. For example, lysergic acid diethylamide (LSD) or cocaine use may change the neurotransmission in the brain that results in panic attacks or psychosis. In the third pattern, there are common causes, either genetic or environmental, that lead to the onset or persistence of both disorders.

Current research is beginning to explain a pattern: The symptoms of the mental disorder generally appear first, followed by the substance use and abuse. Psychiatric symptoms have long been associated with dysregulation of the monoamines and neuropeptides. Drugs of abuse (cocaine, alcohol, marijuana) temporarily potentiate neurotransmission in the brain's reward system, relieving the depression and anxiety for a short period of time. Self-administration of drugs of abuse temporarily masks or suppresses the aversive psychological effects of the dysregulated neuronal systems (see [Chapter 31](#)).

BARRIERS TO TREATMENT

High morbidity rates point to the need for effective treatment of individuals with COD. Although it was recognized that integrated treatment should be the standard of care, these patients often face major barriers in obtaining proper treatment. There are many well-documented barriers such as perceived shortcomings of substance use treatment systems, funding barriers, difficulty in communicating with substance use treatment providers, and difficulty reconciling different treatment approaches, and lack of staff (SAMSA). The following discussion highlights some other barriers.

Nature of Co-occurring Disorders

Patients often deny a problem with substances and do not seek treatment because they do not view themselves as needing it. They do not fully understand their mental disorder or the effect of substance use on their mood or behavior. Even those who recognize their disorders are often reluctant to seek mental health treatment. It is confusing to be expected to abstain from alcohol and illicit drugs yet be prescribed medication that also affects their thoughts and feelings. If they take the substance of choice, they experience fleeting moments of joy and escape even though doing so will prompt a decline in overall function and worsen psychiatric symptoms. If they accept prescribed treatments, including medications, they will have higher levels of functioning and better treatment outcomes, but they lose their moments of joy and escape.

Staff Attitudes

Mental health professionals in psychiatric treatment programs are often frustrated in their efforts to assist patients with SUDs. Behavior often associated with addiction, such as denial of substance use, manipulative behavior, and nonadherence with health-related protocols, is often regarded as a sign of treatment failure. This type of behavior can provoke hostility from the staff and can make planning for mental health recovery difficult.

Mental health professionals may have difficulty understanding the compelling nature of drug or alcohol cravings, may not understand differences in drug use patterns and behaviors associated with particular drugs of abuse, and may overdiagnose personality disorders in those who take drugs and commit crimes. In addition, patients or their therapists may excuse substance use because of the patients' psychiatric symptoms.

Stigma

Drug-dependent patients may have the additional stigma of being regarded as criminals because they commit illegal acts every time they purchase, use, or distribute illicit drugs. Strong public feelings about alcohol-related motor vehicle

accidents, negative experiences with family members or friends with drinking problems, and cultural biases against public intoxication can prejudice interactions with patients who are alcohol dependent (Miler et al., 2020).

Health Issues

Numerous health hazards are associated with alcohol and drug use (see [Chapter 31](#)). The use of alcohol and illicit substances in addition to medications prescribed for mental disorders can lead to drug interactions and may exacerbate side effects of these medications. Homelessness can increase these patients' medical problems with inadequate nutrition, poor hygiene, and the adverse effects of exposure to the elements adding to their difficulties. Health care providers often become frustrated with patients' nonadherence and with what they see as behaviors that are difficult to manage. Their frustration may negatively affect the way they treat patients with COD. Because of the confusion about what is the primary and most immediate problem to treat, these patients are often underserved and only partially treated.

RECOVERY-ORIENTED CARE FOR PERSONS WITH CO-OCCURRING DISORDERS

Treatment programs designed for people whose problems are primarily substance use are generally not recommended for people who also have a mental disorder. The **quadrants of care** model is a conceptual framework that classifies patients according to symptom severity, not diagnosis ([Fig. 42.2](#)). Developed in 2014, the quadrants of care model continues to be used today. The quadrant can guide an individual's treatment and site of delivery of care. In an integrated treatment model, treatment for both disorders is combined in a single session or interaction or series of interactions.

Patients with COD enter treatment at various stages of recovery. Flexible treatment programs that can meet each patient's needs are the most effective. **Recovery** is sought through commonly recognized stages of treatment, including engagement, persuasion or motivation, active treatment, and relapse prevention. This recovery involves much more than avoiding alcohol and drugs. Individuals

must believe that life can be better without drinking, but typically, they test the alternatives before they adopt lengthy remissions (Bradizza et al., 2018). An integrated interdisciplinary team is needed in order to move patients to recovery.

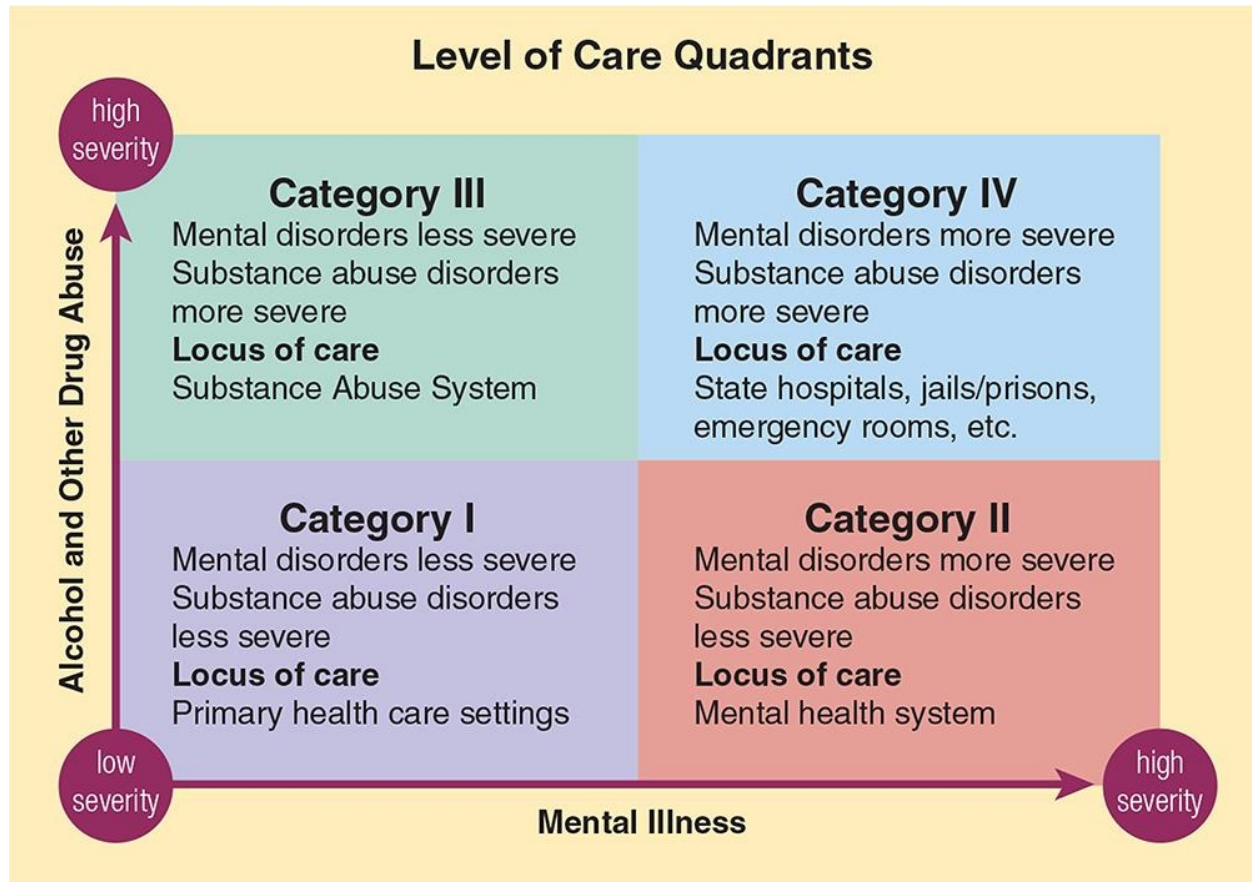

Figure 42.2 Level of care quadrants. (From Center for Substance Abuse Treatment. [2013]. Definitions, terms, and classification systems for co-occurring disorders. SAMHSA/CSAT Treatment Improvement Protocols. Rockville, MD: Substance Abuse and Mental Health Services Administration. Retrieved February 16, 2021 from <http://www.ncbi.nlm.nih.gov/books/NBK25692>.)

Screening, Brief Intervention, and Referral to Treatment

Substance Abuse and Mental Health Services Administration (SAMHSA) initiated and implemented the comprehensive, integrated public health model

called screening, brief intervention, and referral to treatment (SBIRT), which provides for services on a full continuum of care, not only the substance use specialty. This intervention model targets people who do not yet meet criteria for SUD and provides strategies for early intervention before the need develops for specialized treatment. This model consists of universal screening, secondary prevention (detecting risky or hazardous substance use or dependence), timely referral, and treatment for people with SUD. This model has been implemented widely in the United States and other countries throughout the world (SAMHSA, 2020b; see [Fig. 42.3](#)).

Screening

The screening process identifies individuals who might be misusing or abusing substances but does not identify the exact kind of problem or its seriousness. Screening determines whether a problem exists or whether further screening is needed. Screening should be conducted using a validated instrument to classify the person's pattern of alcohol or drug use. Screening should take 5 to 10 minutes and can be repeated at various intervals over time. The Alcohol Use Disorders Identification Test (AUDIT) (Babor et al., 2001) and the National Institute on Drug Abuse (NIDA) Drug Use Screening Tool (NIDA, 2012) are examples of instruments that can be used. Screening can identify people across the whole spectrum of use—from risky to dependence.

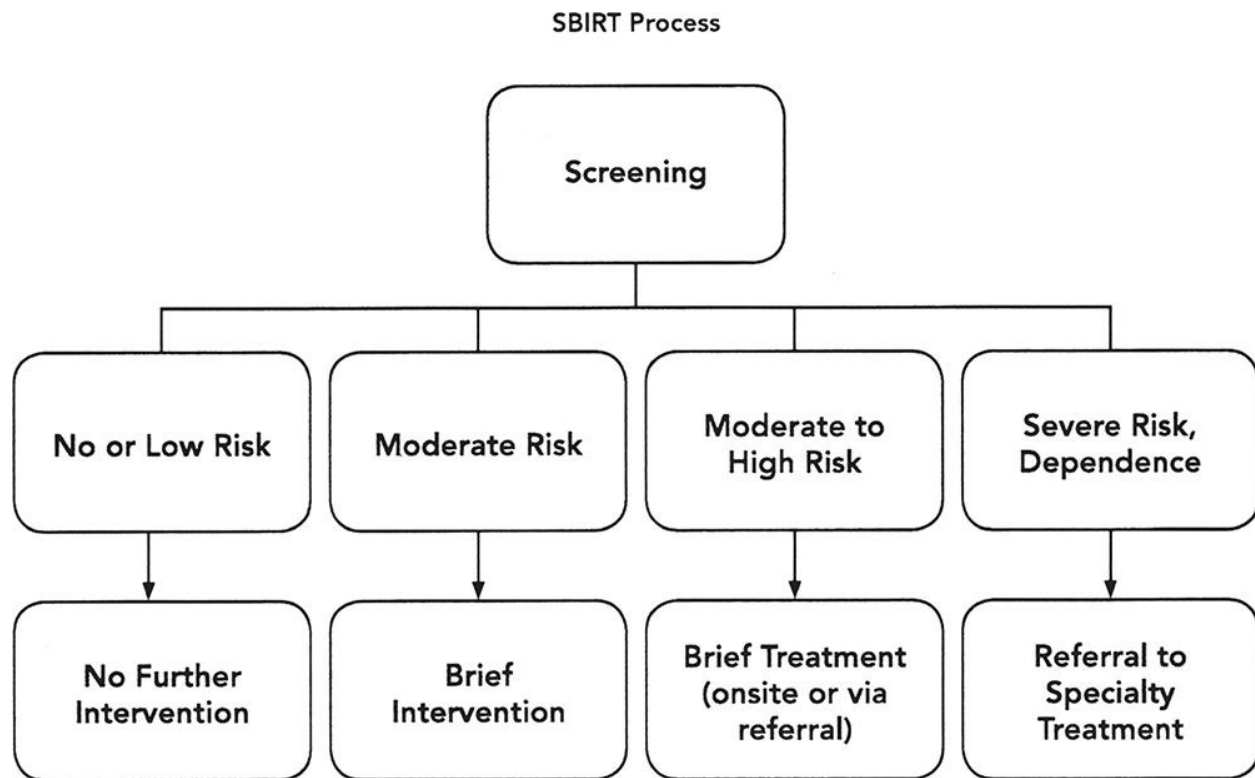

Figure 42.3 SBIRT Process. (From Substance Abuse and Mental Health Services Administration. [2013]. Systemslevel implementation of screening, brief intervention, and referral to treatment. Technical Assistance Publication [TAP] Series 33. HHS Publication No. [SMA] 13– 4741. Rockville, MD: Substance Abuse and Mental Health Services Administration.)

Brief Intervention

A brief intervention is appropriate for persons who are at moderate risk for substance use problems. This is a **motivational intervention** that typically consists of one to several sessions during which the patient becomes interested in seeking treatment. This intervention focuses on increasing a person's insight into and awareness about substance use and behavior change. The primary goal of this stage is to educate the patient and increase their motivation to reduce risky behavior.

Brief Treatment: Brief Intensive Intervention

Brief treatment is a specialty outpatient treatment modality. It is a systematic, focused process that relies on patient engagement and implementation of change strategies. The treatment consists of 6 to 20 sessions of evidence-based, highly focused, and structured clinical sessions (e.g., solution-focused therapy, cognitive-behavior therapy, motivation enhancement). The goals of brief treatment are to change the immediate behaviors or thoughts about a risky behavior, to address long-standing problems with harmful drinking and drug misuse, and to help patients with higher levels of disorder obtain more intensive care. One goal of this intervention is to increase engagement in treatment and help the patient identify their own goals (DiClemente et al., 2017).

Engagement

Engagement entails establishing a treatment relationship and enhancing motivation to make behavior changes and a commitment to treatment. Research has shown that engaged patients are more likely to stay in treatment and have positive outcomes (Thompson et al., 2020). Patients who are abusing substances may experience repeated cycles of detoxification and relapse. They may have prolonged cycles of “revolving-door” admissions and persistent medication nonadherence before acknowledging the need to engage in continuous treatment (Urbanoski et al., 2018). Each admission is a “window of opportunity.” Relapse does not mean that a treatment intervention, the health care provider, or the patient has failed. Readmission and clear, realistic goals can further the patient’s engagement in the treatment process. Effective programs emphasize a combination of empathic, long-term relationship building, and the use of leverage and possible confrontation by family, other caregivers, or the legal system.

Engagement in treatment is a process that may take many contacts with a patient and requires patience. Patients who struggle with authority and control issues must be convinced that the treatment team members have something to offer and are worth listening to before patients will begin to trust them. The engagement process is enhanced if staff can deal with presenting crises concretely (e.g., provide help in avoiding legal penalties and obtaining food, housing, entitlements, relief from psychiatric symptoms, vocational

opportunities, recreation, and socialization). Harm reduction may be a first step toward a goal of abstinence.

The process of engagement is often characterized by approach–avoidance behavior by the patient. Lengthy intake and assessment procedures may discourage the patient from engagement or be intolerable if they are protracted and begin with asking the patient numerous pointed personal questions. These procedures may have to be adjusted to tailor treatment and accommodate the needs or reactions of the patient with COD.

Referral To Treatment

Some individuals will need more intensive treatment than brief treatment. These individuals will be referred to substance use specialty treatment programs.

Assertive Community Treatment

In **Assertive Community Treatment (ACT)**, the delivery of services is in the community (rather than a clinic), with shared caseloads, 24-hour responsibilities for patients, and direct provision of most services. This model was developed for patients with severe mental disorders who do not use outpatient services, are prone to frequent relapses and rehospitalization, and have severe psychosocial impairment (Ponka et al, 2020).

Relapse Prevention

Persons with COD are highly prone to relapse even after they have achieved full remission. Although many relapse factors are the same for those with mental disorders as with the general population, such as interpersonal problems, negative emotions, social stresses, lack of involvement in more satisfying activities, and attempts to escape from painful experiences, there are additional factors that affect this population. Symptoms of the mental disorders recur, and there are inadequate treatment resources in many settings. Many people with mental disorders live in extreme poverty, which forces them into high-crime,

drug-infested neighborhoods, which makes them easy targets for crimes. Employment rates are low for this population even though many want to work. Finally, the same neurobiologic dysfunctions may underlie both addiction and mental disorders (Kolodner & Koliatsos, 2020).

Because persons with mental disorders face more challenges, emerging evidence suggests that **relapse prevention** for this population should be different than for the general population. Relapse prevention needs to account for the pervasive cognitive and social dysfunctions that are inherent in many people with COD. Patients usually need assistance in finding and maintaining housing and employment. Learning new skills may be difficult because of cognitive impairments that reduce the effectiveness of learning new skills. Social deficits can lead to isolation and victimization. Relapse prevention for COD involves the following:

- A stable and safe place to live
- A specific, individualized plan for managing stressful times
- Making informed, healthy choices that support physical and emotional well-being
- Purposeful and meaningful daily activities such as a job, school, volunteering, family caretaking, or creative endeavors
- Relationships and social networks that provide support, friendship, love, and hope
- Support for meeting spiritual needs and finding a sense of meaning in life
- Independence, income, and resources to participate in society (SAMHSA, 2021).

EVIDENCED-BASED NURSING CARE FOR PERSONS WITH CO-OCCURRING DISORDERS

It is crucial for patients with COD to be thoroughly assessed for responses to both psychiatric and SUDs. In some cultural groups, recognition of psychiatric and SUDs is difficult because of the lack of access and stigma associated with COD. Nurses in nonpsychiatric, community settings may be the only health care professional contact that some groups have. Assessment should include

determination of the patient's willingness to change or level of motivation for treatment.

It is important to delineate the relative contribution of each diagnosis to the severity of the current responses presented and to establish priorities accordingly. Because patients with COD often make unreliable historians or distort the reality of their mental health problems and the severity of their substance use, obtaining objective data is especially important. Ideally, one should obtain an objective history of the patient from family, significant others, board and care operators, other health care providers, or anyone familiar enough with the patient to provide an accurate history. [Box 42.1](#) lists basic assessment tools and methods used for patients with COD. The following concepts are paramount when assessing persons with COD:

Box 42.1

Assessment of Co-occurring Disorders

Obtain a history and physical examination and laboratory tests (e.g., liver function tests, complete blood count) to confirm medical indicators related to substance use and also to rule out medical disorders with psychiatric presentations.

- Obtain substance use history and severity of consequences and physical symptoms.
- Identify core cultural values; explore meaning of the symptoms.
- Assess mental status examination and severity of symptoms (e.g., suicidal, homicidal, florid psychosis).
- Explore social context—socioeconomic, environment, literacy, and support system.

Interview with and assess family members to verify or determine (1) the accuracy of the patient's self-reported substance use or mental health history; (2) the patient's history of past mental health problems during periods of abstinence; and, if possible, (3) the sequence of the diagnoses (i.e., what symptoms appeared first).

- Conduct interviews with the patient's partner, friends, social worker, and other significant people in the patient's life.
- Review court records, medical records, and previous psychiatric and substance use treatment.
- Perform urine and blood toxicity screens; use a breath analyzer to test the patient's blood-alcohol level.

Revise initial assessment by observation of the patient in the clinical setting; full assessment of the underlying psychiatric problem may not be possible until there is a long (up to 6 months) period of total abstinence.

- Observe the patient for reappearance of psychiatric symptoms after a period of sobriety.
- Assess the patient's motivation to seek treatment, desire to change behavior, and understanding of diagnoses.

- Psychiatric and SUDs can coexist.
- Responses (psychosis, agitation) to both disorders can be similar.
- Substance use can mask other symptoms and syndromes.
- Psychiatric behaviors can mimic alcohol and other drug use problems.

NCLEXNOTE Patients with both mental and SUDs have responses to both disorders. Prioritizing nursing care depends on the immediate issue, but responses to both disorders should be assessed.

Mental Health Nursing Assessment and Clinical Judgment

Psychotic Disorders And Substance Use

Research shows that a high percentage estimated 50% of persons with schizophrenia will have an SUD during their lifetime. There are a number of possible explanations for the high rate of substance use in individuals with this disorder. Individuals with COD (substance use and schizophrenia) score higher on measures of sensation seeking and impulsivity than those without the COD. Stress reduction, symptom reduction, and relaxation are also offered as explanations. A neurobiologic model suggests that a dysregulated dopamine-mediated mesocorticolimbic network in patients with schizophrenia may also underlie substance use. Whereas all people are vulnerable to experiencing psychotic episodes from the use of various drugs, one psychotic episode increases susceptibility to subsequent episodes (Li et al., 2020).

Assessing the needs of people with schizophrenia, who are also chemically dependent, is complicated by the changing interaction among psychotic symptoms, the antipsychotic effects of medications, and the side effects of medications. A patient with a psychotic disorder may have an altered thought process or delusional thinking and may experience auditory hallucinations. They may also be cognitively impaired and have poor memory. These patients can have negative symptoms, such as poor motivation and poor hygiene. They often have low self-esteem and poor social skills and may have a general sense of not belonging to a community. Their sense of self in relation to the world may be altered.

As with all of the CODs, a multifaceted, integrated treatment approach is

needed. Atypical antipsychotics continue to be the primary pharmacologic agent for the treatment of patients with comorbid schizophrenia with substance use. Not only do these agents treat the symptoms of schizophrenia, but they also appear to reduce cue-trigger cravings of the substances and prevent relapse (Li et al., 2020). While monitoring side effects of antipsychotics, the nurse's attention needs to focus on liver functioning because drugs and alcohol are also metabolized by the liver. Relapse is frequently secondary to medication nonadherence, especially if patients experience side effects associated with the use of antipsychotics. Nursing interventions that focus on medication compliance may reduce the chances of relapse.

A confrontational interactive approach does not benefit this population and could even alienate patients. A more supportive approach is appropriate in which relapses are treated as an expected part of the recovery process. Addressing relapse risk is part of treatment planning. Focus on examining behavior, feelings, and the thinking process that led to the relapse. The nurse must avoid blame and guilt-inducing statements.

Social skills training is needed to help the patient learn ways of avoiding peer pressure and social situations that could lead to substance use. The goal is to successfully interact in a sober living situation, develop problem-solving skills, and refine behaviors.

Mood Disorders And Substance Use

Substance use in patients with depression contributes to treatment nonadherence and less positive outcomes (Hunt et al., 2020). Mood disorders may be more prevalent among patients using opiates than among other drug users. Many who use substances self-medicate an underlying mood disorder. Because many of the symptoms of substance use are the same as those of mood disorders, it is difficult to differentiate between them. This is especially true in the case of stimulant use and bipolar disorder. It is often impossible to determine the presence of an underlying mood disorder until there has been a period of abstinence.

Screening for suicide ideation is a priority during the assessment of these individuals. Both mood disorders and substance use are related to suicide (see Chapters 22, 25, and 31). Depression during withdrawal from alcohol, cocaine, opiates, and amphetamines also puts patients at severe risk for suicide. A

person's presenting behaviors may not have included depression, but depression may develop as the withdrawal syndrome unfolds. Hyperactivity often appears with stimulant use and at times with alcohol use. Patients may be treated for hypomania or bipolar disorder when they are actually hyperactive. Symptoms usually improve as the person maintains abstinence.

Determining whether mood disorders are the cause or the effect of protracted substance use is difficult. An important nursing assessment is to determine how drug use relates to mood states. Patients may be attempting to alleviate uncomfortable symptoms, such as depression or agitation, or to enhance a mood state (e.g., hypomania). Symptoms that persist during periods of abstinence are a clue to the degree that the mood disorder contributes to the presenting symptoms.

There is little research regarding pharmacologic interventions for comorbid mood disorders and substance use. Consequently, treatment is similar to that of mood disorders without substance use or abuse. When a pharmacologic agent is selected, attention is paid to its interaction with drugs and alcohol and its potential for dependence. The selective serotonin reuptake inhibitors (SSRIs) are frequently used for co-occurring depression. Higher doses may be required because of the possibility that alcohol use may induce hepatic microsomal activity. In the bipolar disorders, mood stabilizers are used.

Treatment for bipolar disorders and chemical dependency should be individualized to accommodate the specific needs, personal goals, and cultural perspectives of these individuals in different stages of change. Using interventions centered on examining cognitive distortions (e.g., "I'll never get better; no one likes me; alcohol is my only friend") and cognitive therapy techniques can help improve mood. Use of positive self-talk can be helpful for both the depression and the SUDs.

Anxiety Disorders And Substance Use

Research is scant regarding the relationship of anxiety disorders to substance use. Because there are a variety of anxiety disorders with differing clinical symptoms and numerous substances of abuse, it is difficult to develop studies addressing all of the anxiety disorders. Posttraumatic stress disorder (PTSD) is of particular concern because it has been shown to increase the risk of substance use relapse and is associated with poor treatment outcomes (Vujanovic et al.,

2020).

The symptoms of anxiety may result from an anxiety disorder, such as panic attack, or may be secondary to drug or alcohol use as part of a withdrawal syndrome. Symptoms are so subjectively disturbing that they can lead to drug or alcohol use as self-medication for the emotional pain; therefore, they require prompt evaluation and treatment. There are many unanswered questions regarding the relationship of the anxiety symptoms, stress, and changes in the hypothalamic–pituitary–adrenal axis response to substance use. More research is sorely needed in this area.

Pharmacologic treatment of patients with anxiety is difficult because the traditional medications used, the benzodiazepines, are themselves addicting. Long-term treatment of the anxiety disorders, particularly PTSD, with the SSRIs maintains and improves quality of life. For PTSD, other medications such as the atypical antipsychotics, non-SSRI antidepressants, and mood stabilizers also appear to result in improvements (see [Chapter 29](#)).

Comorbid anxiety disorders and substance use require psychosocial interventions along with pharmacologic treatment. Patients with anxiety disorders should also pay particular attention to their physical health. Regular, balanced meals; exercise; and sleep are ways to decrease and manage stress levels. Patients should avoid excessive consumption of caffeine and sugars. If the patient has a fear of crowds, they may benefit from gradual desensitization techniques.

Personality Disorders And Substance Use

Personality disorders are frequently present in those who use alcohol and other substances. Antisocial personality and borderline disorders carry a high risk of having a comorbid substance use problem (Kaltenegger et al., 2020; Khalifa et al., 2020). The assessment of persons with comorbid personality disorders and substance use focuses on the problems related to the particular personality disorder, as well as the substance use. Individuals with antisocial personality disorder are likely to have a family history of other psychiatric disorders and problems with hostility. Interventions should be individualized according to the disorder and are discussed in the next section.

Substance Use, Mental Disorders, And Coronavirus Disease 2019

The coronavirus disease 2019 (COVID-19) pandemic has profound psychological and social effects, particularly on the most vulnerable populations. Uncertainty, social isolation, and economic problems impact individuals with psychiatric disorders and can exacerbate symptoms and substance use. Most suicide victims have a psychiatric disorder, usually depression. Individuals with CODs are at a greater risk of suicide than before COVID-19. The mental health consequences of the pandemic will be present for a long time. Suicide prevention efforts should be targeted at persons who are at high risk for suicide (Sher, 2020).

Mental Health Nursing Interventions

The nurse who provides care to patients with COD faces numerous challenges. Nurses implement interventions according to their level of practice and knowledge (see [Box 42.2](#)). Comprehensive planning within a multidisciplinary team approach is highly successful in the care of such patients. The entire system is organized to care for persons with COD (SAMHSA, 2020b). Community organizations are valuable sources of support as well. Many of the interventions that are indicated for persons with COD are discussed in previous chapters. The following discussion highlights interventions that are modified because of the special needs of this population.

Medication Management

One essential feature of COD treatment is medication management. Medication for a known mental disorder should never be discontinued on the grounds that the patient is using substances. Nonadherence with prescribed medications is associated with increased behavior problems after discharge and is a direct cause of relapse and rehospitalization. Impulsive behavior in response to transient exacerbations of psychotic symptoms, depressed mood, or anxiety symptoms may lead to relapse.

BOX 42.2

Autism Spectrum Disorder and Substance Use

Helverschou, S. B., Brunvold, A. R., & Arnevik, E. A. (2019). *Treating patients with co-occurring autism spectrum disorder and substance use disorder: A clinical explorative study*. *Substance Abuse: Research and Treatment*, 13, 1178221819843291. <https://doi.org/10.1177/1178221819843291>

THE QUESTION: What are explanations for drug and alcohol use by individuals with SUD and autism spectrum disorder?

METHODS: Four men aged 22 to 44 years with autism spectrum disorder whose drug use included amphetamines, cocaine, alcohol, and benzodiazepines engaged in CBT for their substance use. Therapists were provided with autism spectrum disorder education in order to participate in the study. Three of the four participants improved in functioning and symptoms.

FINDINGS: The individuals identified the reasons they use drugs or alcohol, including to reduce anxiety, improve social skills and concentration, and to be able to socialize, find peace, and forget problems and conflicts. They also used drugs and alcohol to feel normal, to stop worrying, and to think clearer. They wanted to stop using drugs and alcohol because they lost their family and job, felt socially excluded, were placed under arrest, and regretted events that happen while intoxicated.

IMPLICATIONS FOR NURSING: Individuals with autism spectrum disorder are susceptible to using drugs and alcohol and may need specially trained therapists to help them stop using.

Treating a patient with COD can be as complex as the presenting symptoms. Errors in treatment can include treating temporary psychiatric symptoms resulting from withdrawal as if they were a permanent feature of the individual, withholding needed medication for a psychiatric disorder, or setting arbitrary limits on medication based on a belief that medication for all psychiatric symptoms should be suspended until the COD is treated. Overall, patients need ongoing help with adhering to a prescribed medication regimen.

Collaboration between the patient's prescriber and other treatment providers is important to minimize the possible misuse or abuse of prescription drugs such as forging prescriptions, acquiring drugs from nonmedical sources, frequent visits to EDs, or seeking multiple prescribers. In addition, caution is essential in prescribing medications that can increase the patient's potential for relapse into abusing the drug of choice. The patient in recovery is often reluctant to use potentially mind-altering drugs, and the nurse should explore any concerns.

Substance Abuse Counseling

With the COD patient, substance abuse counseling is slower and less confrontational than in many traditional substance abuse programs. Content needs to be repeated frequently and motivation for treatment continually assessed.

Cognitive–Behavioral Interventions

Cognitive–behavioral interventions help patients to (1) analyze which situations are most likely to trigger relapses; (2) examine cognitive, emotional, and behavioral components of high-risk situations; and (3) develop cognitive, behavioral, and effective coping strategies and environmental supports. Role-playing ways out of high-risk situations is a technique that these groups often use. Homework assignments help patients create relapse-prevention plans that address new coping strategies for these high-risk situations.

Patient Education

Patient education is an essential element in treating COD. Patients need to learn about their specific mental disorder, substance use and abuse, and their effects. Relapse prevention and recovery should be highlighted. Education can be conducted in individual sessions, but group sessions encourage interaction among patients. Sharing their experiences with their peers, patients can enhance these presentations.

Topics should be clear; relevant to the group members; and illustrated with charts, handouts, or appropriate films. Each session should be relatively short and not contain too many new or difficult concepts. Reinforcing and reviewing previous discussions can be helpful to remind patients of particularly relevant concepts. [Box 42.3](#) lists some suitable topics for nurse-led discussion groups. Individual patient education can focus on areas of knowledge deficits and reinforce topics discussed in group settings. Group sessions can also assist patients in learning interpersonal skills (e.g., assertiveness) and problem-solving skills and in relapse prevention planning.

Topics for Education Groups for Patients with Co-occurring Disorders

- The effects of alcohol and drugs on the body
- Alcohol, drugs, and medication—what can go wrong?
- What is a healthy lifestyle?
- Triggers for relapse
- What is Alcoholics (or Narcotics) Anonymous?
- What is a sponsor in Alcoholics (or Narcotics) Anonymous?
- What is recovery from mental illness and substance use?
- What are the tools of recovery?
- The disease of addiction
- The relapse cycle
- How to cope with feelings without using alcohol or other drugs?
- Relapse prevention: what works?
- What are cognitive distortions?
- HIV prevention and education
- Leisure time management
- How to manage stress?
- Relaxation training
- Assertiveness and recovery
- Common slogans to live by
- Pitfalls in treatment
- The process of recovery
- Creating a relapse-prevention plan
- What are my goals? How does the use of alcohol and drugs affect them?
- Coping with thoughts about alcohol and drugs
- Problem-solving basics
- Coping with anger
- Negative thinking and how to manage it
- Enhancing social support networks

Mutual Self-Help Groups

Several mutual self-help groups are appropriate for many patients with COD. Peer-led self-help approaches specifically for persons with COD are being tried with some success. The most common groups are 12-step programs, such as Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) (see [Chapter 31](#)). The advisability of a patient enrolling in a 12-step program needs to be evaluated

on an individual basis. A health care provider familiar with 12-step concepts can often facilitate patients' attempts to use these programs. The numerous advantages of self-help groups make them a potentially powerful support for continued recovery. Alternative mutual self-help programs similar to 12-step programs are available in some geographic areas. Rational Recovery and Secular Organization for Sobriety are groups that downplay the concept of powerlessness and the spiritual aspects associated with 12-step programs.

Family Support And Education

The families of patients with COD need education and support. Family psychoeducation interventions address mental disorders, substance use, and their interactions. The focus of family support groups, such as those under the auspices of the National Alliance on Mental Illness, has been both to educate and to help the family cope with a mentally ill relative. AA and NA take a similar approach to providing peer support to families of substance users. These self-help groups aid family members in balancing confrontation of the problem, detachment from forcing a solution to it, and support of the treatment process.

Evaluation and Treatment Outcomes

Evaluation of the patient's ability to deal with both the substance use and mental disorder is an ongoing process. Because the goal of recovery is to have quality of life in the community of choice, treatment outcomes should be evaluated for quality of life as well as management of two disorders.

MENTAL HEALTH NURSING INTERVENTIONS CONTINUUM OF CARE

An integrated approach that combines mental health and substance use interventions at the clinical site has been shown to be the most effective. In an integrated system, the same team provides coordinated mental health and substance use interventions and guides the patient toward learning to manage

these intertwined disorders. When the mental health and substance use systems are truly integrated, patient outcomes are positive (Carlo et al., 2020).

When Hospitalization Is Necessary

Often, patients with COD can be treated effectively in community mental health settings if their symptoms are stable, they are following their treatment plan, they are compliant with the use of psychiatric medications, and they remain alcohol and drug free. Patients are hospitalized when they have a need for detoxification, exacerbation of comorbid psychiatric or medical disorders, suicide or homicidal ideation, or a disorder that prevents abstinence or outpatient treatment.

Crisis Stabilization

Setting priorities is essential for hospitalized patients with COD. The first priorities are gathering data from a physical examination and nursing assessments, stabilizing psychiatric symptoms, and treating withdrawal symptoms (see [Chapter 31](#)). After these issues are addressed, the patient enters the rehabilitation phase of treatment for both diagnoses. Rehabilitative therapy is appropriate if the patient (1) can participate in a group process, (2) can focus attention on groups or reading material, (3) does not engage in behavior that is detrimental to the group process, (4) can listen to and receive feedback from others, and (5) can benefit from the group process.

Early Stages of Recovery from Substance Use

Many patients seeking alcohol or drug use treatment experience transitory cognitive impairment, which usually resolves within the first month of abstinence. Patients often experience difficulties with disorientation, clouding of consciousness, incoherent thoughts, memory loss, and delirium, which may hinder their ability to learn new concepts. These problems are a result of the neurobiologic insult on the brain by these substances and psychosocial factors such as fear of legal or relationship difficulties, depression, grief, and feelings of

guilt and shame. However, if Wernicke syndrome, a reversible alcohol-induced amnesic disorder caused by a thiamine-deficient diet, or Korsakoff psychosis, characterized by a loss of recent memory and confabulation (or filling in the blanks in memory by making up facts to cover this deficit) is present, cognitive problems may last longer. Patients with this condition are highly suggestible, have poor judgment, and cannot reason critically. Korsakoff psychosis often follows Wernicke encephalopathy and is also associated with prior peripheral neuropathy (see [Chapter 31](#)).

Psychological testing and other methods of assessment determine the patient's level of cognitive functioning in order to select the appropriate treatment. It is also important to determine the extent of the mental disorder and the substance use. The nurse assesses the patient's abilities for self-care, independent living, impulse control, control of assaultive behavior, direction taking, and development of new responses to new situations and ideas. The nurse must also evaluate changes in mental status during the past 6 months and examine previous treatment outcomes.

Clear, direct, simple interventions that avoid extraneous issues and theoretical discussion may be useful for patients with cognitive or memory impairment such as the following:

- Reading material that is relevant to recovery and that can be referred to in short study sessions
- First-person accounts of addiction and recovery found in AA and NA literature
- Basic concepts of recovery, such as those in AA slogans and on patients' need for continuing care after discharge
- Films with scenes illustrating relevant family problems or other problems related to substance use; movies can be more effective than lectures

Social interaction skills and coping skills learned in treatment need to be reinforced in community settings to create or enhance a stable living situation and possible vocational opportunities. Active planning and intervention are needed for housing and employment, or deterioration may occur despite gains made during hospitalization.

Recovery

To move toward recovery, establishing a positive social network is critical. Isolation and alienation from prior sources of support is a problem that most people with comorbid mental disorders and substance use share. Some patients relate poorly to their families, others are overly dependent on their families, and others have difficulty establishing and maintaining social relationships. Some patients' only "families" are peers within the drug subculture who reinforce substance-abusing behavior.

Compliance with an agreed-on treatment plan is integral to recovery. [Box 42.4](#) presents features of a COD outpatient program. Opportunities to socialize, access to positive recreational activities, and a supportive peer group are stabilizing influences on patients who may otherwise drop out of treatment altogether. Part of a comprehensive relapse prevention plan is to establish or reinforce the patient's social support network so that they can obtain (1) opportunities for substance-free socializing, (2) crisis counseling to prevent readmission to a hospital, and (3) support for sobriety.

Supportive housing is also essential for patients with COD. Supportive housing is especially crucial for patients who are being discharged from the hospital because the risk for relapse is greatest during the first few months after discharge. Halfway houses for substance users may deemphasize medication compliance, and housing designed for chronically mentally ill individuals may not emphasize abstinence enough. Thus, an important part of the multidisciplinary team approach to discharge planning for patients with COD is to help them find the best possible living situation.

BOX 42.4

Features of a Co-occurring Disorders Outpatient Program

- *Community meeting and goal setting:* Patients set small, realistic goals for themselves for the day, which aid them in their ultimate goal of better living in recovery.
- *Anger management and social communication:* Patients learn appropriate ways to express anger and how to socialize with others.
- *Group therapy:* Patients discuss interpersonal issues, get feedback from their peers, and learn problem-solving skills.
- *Dual recovery anonymous meetings:* Patient-run meetings (a modified AA meeting) address the specific needs of patients with COD.

- *Leisure planning:* Patients learn skills to enjoy leisure involving clean and sober fun.
- *Gardening, art therapy, music therapy, swimming:* These methods provide alternatives to the use of alcohol and other drugs.
- *Health education:* Patients learn about the effects of drugs and alcohol on the body and about other relevant medical topics.
- *Medication education:* Patients learn about psychiatric medications, their uses, their side effects, and interactions with drugs or alcohol.
- *Relapse-prevention planning:* Patients talk about their last relapse; triggers, feelings, and stresses that contributed to the relapse; and the consequences, and formulate relapse-prevention plans.
- *Individual counseling:* Patients receive individual counseling to develop goals and work on problem-solving techniques.
- *Psychiatric consultation:* Patients are evaluated and followed up for medication and other psychiatric interventions.

Note: Patients are *not* discharged from the program if they are intoxicated. They are asked not to come to the program intoxicated but to return when they are sober to continue work on their recovery.

Younger patients with a mental disorder may want and expect to find appropriate employment, but some of these patients may be unrealistic about potential professions. However, this desire can be a significant motivator and a useful tool in a treatment program. Referring patients to halfway houses or residential substance use treatment programs that stress vocational skill training can be beneficial. Use of community vocational rehabilitation services and of educational opportunities can be an important part of a discharge plan.

SUMMARY OF KEY POINTS

- In co-occurring mental disorder and SUD, each disorder is considered a primary disorder. Patients should be treated concurrently with an integrated approach.
- People with COD are at high risk for relapse. The relapse cycle repeats itself without treatment.
- There is not one model that explains why mental disorders and substance use occur together so frequently. The most common

pattern is the onset of the mental disorder, followed by the problems with substance use leading to use. It appears that the substance use is an attempt to self-medicate the psychiatric symptoms.

- Barriers for treatment include homelessness, unemployment, and lack of social support. Other barriers include the complexity of the COD, staff attitudes, stigma, and health issues that interfere with treatment.
- Interdisciplinary treatment is through an integrated approach. Patients are moved toward recovery through engagement, motivation, assertive outreach and treatment, and relapse prevention.
- Recovery through commonly recognized stages of treatment—engagement, persuasion or motivation, active treatment, and relapse prevention—involves much more than avoiding alcohol and drugs.
- Nursing assessment of COD often depends on objective data obtained from interviews with family members, reviews of court records, laboratory test results, and physical examination findings. Assessment should include a determination of the willingness to change and motivation for treatment.
- Treatment and nursing care need to be individualized within the context of the specific mental disorder and substances used.
- Interventions that are tailored to the special needs of the patient with a COD are medication management, substance abuse counseling, cognitive–behavioral interventions, patient education,

and family support and education. Participation in peer-led self-help groups has had some success.

- An ideal continuum of care is an integrated approach with one team coordinating the mental health and substance use interventions. Patients should not have to negotiate treatment with two separate systems. Hospitalization may be required during periods of crises. Most treatment occurs in the community, where recovery is the goal.

CRITICAL THINKING CHALLENGES

1. An 18-year-old patient, newly diagnosed with schizophrenia, is relatively compliant with their medication and treatment. This patient was recently at a social event where they were experimenting with alcohol and marijuana. Develop a teaching plan for them that includes the risks of developing a SUD.
2. A nurse in an emergency department recommends AA for every patient who is admitted for detoxification. Is that an appropriate referral for a person with comorbid mental disorder and substance use?
3. A community health nurse wants to refer a young person who lives in a poor rural area to an integrated treatment program several miles away. Discuss the likelihood of the patient's actually being able to access services. What barriers would she face, and how could they have access to the care they need?
4. How would you respond to a patient with COD who states, "Once my medication is stable, I will be able to drink again"?
5. Compare traditional substance use approaches to an integrated treatment program.
6. A patient with a COD tells the nurse, "All chemicals are bad for you. I do not want to take my medication." Develop a response to this statement that reflects the use of engagement.

7. Discuss the differences in behavior of a person with schizophrenia who uses cocaine and a person with a mood disorder who uses marijuana.
8. Which COD concepts should be included in patient education?

Movie Viewing Guides

***Love & Mercy (2014)*:** This film is a biographical drama film about Brian Wilson, the musician-songwriter, cofounder of the Beach Boys. There are two periods of time depicted. Paul Dano stars Wilson in the 1960s and John Cusack plays Wilson in the 1980s. Brian's psychiatric symptoms and use of drugs occurred in his early years. He is misdiagnosed and abused by his therapist. This story is about Brian's struggle to regain independence and quality of life.

VIEWING POINTS: How does Brian's mental disorder interact with his substance use? How are you feeling throughout this movie? Do your feelings about the character change? How could a nurse advocate for Brian's recovery?

Care of Persons Who Are Medically Compromised

Dorothy M. Corrigan

KEYCONCEPTS

- chronic pain

LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify medically ill populations at risk for psychosocial problems.
2. Discuss the impact that both a mental disorder and a medical problem have on patients and their families.
3. Discuss the multimodal approach of treatment of pain, especially for those experiencing chronic pain.
4. Describe assessment and nursing care for patients who are experiencing mental health problems associated with trauma or central nervous system (CNS) disorders.
5. Discuss the importance of integrating the medical aspects of care into psychiatric care for patients with mental health problems.

KEY TERMS

- Allodynia
- Beta-endorphins
- Bidirectional illnesses
- Gate-control theory
- Hyperalgia
- Hyperesthesia
- Ischemic cascade
- Nociceptors
- Pain mosaic
- Pain vulnerability
- Plasticity
- Postconcussive syndrome
- Prostaglandins
- Self-efficacy
- Substance P
- Traumatic brain injury (TBI)

INTRODUCTION

Persons with chronic mental disorders often have one **comorbid condition** which is defined as the presence of a physical illness, injury, or disability that exists simultaneously with another disorder. In some cases, there are several **multimorbid conditions**, the presence of two or more chronic conditions, which overlap each other and influence medical and psychiatric disease complexity. An estimated 68% of adults who have been diagnosed with a mental disorders have at least one medical comorbidity (Avery et al., 2020) and are more likely to describe their own overall health as poor (Walker & Druss, 2017). Though medical and psychiatric disorders are often intertwined, mental health providers may not recognize medical illness, and medical providers may not screen for mental health problems.

This chapter will discuss some common comorbid and multimorbid medical disorders that are experienced by people who have mental disorders. It will also explore some mental health disorders which are linked to primary medical illnesses. Three special populations will be also be presented: those with comorbid pain, those who have experienced physiologic trauma, and those with mental health issues related to CNS disorders. Psychosocial implications will be explored throughout this chapter.

OVERVIEW OF CONNECTIONS BETWEEN MENTAL AND MEDICAL DISORDERS

The increased presence of comorbid conditions among people with serious mental disorders has long been recognized. As early as 1937, the presence of common comorbidities such as hypertension and diabetes among those with mental disorders had been studied and the connection between comorbid disorders and recurrent hospitalizations within the same population was also observed (Phillips, 1937). We are now aware that mental health problems may diminish the motivation for self-care, impair symptom reporting, and delay treatment. As a result, hospitalization for medical problems may be prolonged, at increased emotional and financial cost to the patient and their family (Šprah et al., 2017).

Although the principal causes of death (cancer and cardiovascular disease [CVD]) among the general population are the same as that of persons with serious mental illness, those with serious mental illness die prematurely of these disorders (Davies, et al., 2021). On average, in the United States, people with chronic mental illness die about 25 years earlier than those in the general population (Olker et al., 2016). For those with psychotic disorders such as schizophrenia, life expectancy is estimated to be about 14.5 years earlier (Hjorthoj et al., 2017). Overall, people with serious mental illness have mortality rates 2 to 3 times higher than the general population and this is likely attributable to cardiovascular risk factors such as obesity, hypertension, and diabetes mellitus (McGinty et al., 2016). However, additional social risk factors such as poverty, lack of safe recreation space for exercise, limited access to full-service grocery stores, unemployment, undereducation, and homelessness also contribute to the presence of medical comorbidities and to the overall experience of decreased health and wellness among those with chronic mental illness. People with mental disorders may be more likely to refuse medical care, may be less likely to maintain their treatment regimen (Swartz, 2018), and may be less able to communicate new health problems or symptoms than those who do not have mental disorders (Carliner et al., 2014; Phan, 2016). Some may simply not have adequate access to health care. To complicate matters further, some health care providers may have the mistaken belief that people with mental disorders are incapable of advocating for and achieving physical health and wellness (Bradford et al., 2016).

The end result of all of this is that care can become fragmented, undermining the possibility of a consistent, holistic, recovery-oriented approach to care. Such fragmentation of care is also expensive. Health care expenditures for individuals with serious mental disorders are approximately 3.3 times higher than for individuals without mental disorders (Lee et al., 2016). Care for persons who are medically compromised requires culturally competent engagement of patients and their families, thorough screening and assessment, systematic monitoring, and comprehensive treatment planning among interdisciplinary team members. This includes lifestyle advice, connection to community services including transportation, and **self-efficacy** (self-care effectiveness) coaching. This is especially critical in the presence of other challenging psychosocial issues, including aging, complex family dynamics, economic hardship, no or inadequate housing, and other issues.

COMMON COMORBID PHYSICAL ILLNESSES AMONG PERSONS WITH MENTAL DISORDERS

It is estimated that at least 68% of those diagnosed with mental disorders have at least one comorbid medical condition (Avery et al., 2020), including obesity (50%), hyperlipidemia (45%), hypertension (44%), asthma (28%), diabetes mellitus (21%), and arthritis (22%) (Razzano et al., 2015). Heart failure, CVD, chronic obstructive pulmonary disease (COPD), kidney disease, cancer, hepatitis B, hepatitis C; and HIV (human immunodeficiency virus) are also diagnosed with frequency and are more prevalent for persons with serious mental disorders than for the rest of the population (Davies, et al., 2021). CVD among persons with mental disorders, for example, is estimated to be 2 to 3 times higher than the general population (Robson & Gray, 2007). This is linked to an increased prevalence of modifiable risk factors, such as obesity, hypertension, and hyperlipidemia among people with mental disorders (Zomer et al., 2017). Subsequently, metabolic syndrome, the clustering of obesity, hypertension, hyperlipidemia, and insulin resistance/glucose dysregulation has been reported at 1.58 times higher among people with mental disorders than among the general population (Vancampfort et al., 2015). With respect to cancers, especially digestive and breast cancer, higher rates of these illnesses have been reported among people with schizophrenia than in the larger population (Bradford et al., 2016). An estimated 88% of the people with schizophrenia have untreated hyperlipidemia and 66% have untreated hypertension (Zomer et al., 2017). Another common comorbidity is poor dental health that can be related to xerostomia from medications as well as limited access to dental care. To complicate this picture, many of these conditions remain untreated. Even more concerning, nurses who care for patients with mental disorders and comorbid or multimorbid health conditions are often unprepared to do so (Avery et al., 2020).

COMMON SECONDARY MENTAL DISORDERS IN PEOPLE WITH CHRONIC MEDICAL ILLNESS

Conversely, persons with chronic physical health issues are at risk for developing comorbid anxiety disorders, substance abuse disorders, depressive

episodes, and other mood disorders, and approximately 50% of patients in primary care settings will endorse mental health issues related to their physical health (Hirsch et al., 2016). This is sometimes referred to as “secondary mental disorders” (mental health disorders linked to a medical problem). Chronic illness itself is a stressful event that alters the person’s perception of the physical, social, and emotional self (Klein-Gitelman & Curran, 2015). Chronic illness in adults is a risk factor for depression and suicidal ideation (Gurhan et al., 2019). In children with chronic physical illness, the occurrence of secondary mental health disorders is four times that of their peers in the general population (Bennett et al., 2015). Among high school students with asthma, atopic dermatitis, obesity, heart disease, and diabetes, female students were more likely to suffer depression (Kim et al., 2020). For adolescents with chronic physical illness and who are transitioning to adulthood at a critical time of emotional growth, individuation, and unique social pressures, the risks of developing mood disorders, especially depression, are increased (Klein-Gitelman & Curran, 2015). All patients with chronic health conditions should be considered as at risk for developing mental health problems, especially children and adolescents as well as older adults.

Depression has been found to be the most common affective prodrome of many medical disorders (Cosci et al., 2015). Depressive symptoms are often an intrinsic part of the primary pathophysiology of endocrine disorders, metabolic disturbances, malignancies, viral infections, inflammatory disorders, and cardiopulmonary conditions. [Table 43.1](#) lists medical conditions associated with depression. Depression and anxiety often complicate the clinical picture in patients with hyperthyroidism and hypothyroidism, Cushing disease (hyperadrenalism), and Addison disease (hypoadrenalism). Depression has been shown to be an independent risk factor for type 2 diabetes and metabolic syndrome (Kim, et al., 2015). The early onset of vascular disease, multiple infections, and subsequent disability are also associated with increased depressive symptoms. Malignancies have also been associated with anxiety and depression. Depressive syndromes have been associated with cancer in up to 50% of cancer cases and biologic relationships between the two disorders may herald undetected carcinoma. Depression with cancer is associated with poor prognosis and increased morbidity (Wu et al., 2016). Depression can also present as a consequence of antineoplastic therapy and is a risk factor for cancer recurrence (Wen et al., 2018). In people with inflammatory bowel disease (IBS), the odds of developing generalized anxiety disorder have been shown to be twice

the rate of the general population (Fuller-Thomson et al., 2015). IBS is also a risk factor for the development of mood disorders, anxiety, and panic disorder (Simpson, et al., 2020).

TABLE 43.1 MEDICAL ILLNESSES ASSOCIATED WITH SYMPTOMS OF DEPRESSION

Medical Illness	Symptoms of Depression
Endocrinopathies	Hypothyroidism and hyperthyroidism Hypoparathyroidism and hyperparathyroidism Cushing syndrome (steroid excess) Adrenal insufficiency (Addison disease) Hyperaldosteronism
Malignancies	Abdominal carcinomas, especially pancreatic Brain tumors (temporal lobe) Breast cancer Gastrointestinal cancer Lung cancer Prostate cancer Metastases
Neurologic disorders	Ischemic stroke Subarachnoid hemorrhage Parkinson disease Normal-pressure hydrocephalus Multiple sclerosis Closed head injury Epilepsy
Metabolic imbalance	Serum sodium and potassium reductions Vitamin B ₁₂ , niacin, vitamin C deficiencies; iron deficiency (anemias) Metal intoxication (thallium and mercury) Uremia
Viral or bacterial infection	Infectious hepatitis Encephalitis Tuberculosis AIDS
Hormonal	Premenstrual, premenopausal, postpartum periods

imbalance

Cardiopulmonary	Acute myocardial infarction Postcardiac arrest Postcoronary artery bypass graft Post-heart transplantation Cardiomyopathy
Inflammatory disorders	Rheumatoid arthritis

CVD deserves special attention because evidence over the years has supported the idea that depression is an independent risk factor in the development and progression of CVD and that this evidence appears to be **bidirectional** (Macchi, et al., 2020). **Bidirectional** refers to a biologic relationship between two separate disease processes, each of which is a risk factor for the other (e.g., heart disease influences the development of depression and depression influences the development of heart disease). Bidirectional markers involving an emerging relationship between depression and CVD include alteration in platelet activity related to thrombus formation, increase in inflammatory cytokines, and heart rate variability. The incidence of CVD is estimated to be around 20% to 50% in patients with depression (Macchi, et al., 2020). In patients who have had a myocardial infarction (MI) risk of cardiac death in the 6 months after an acute MI is approximately four times greater. Despite these risks, depression and anxiety are often underrecognized and undertreated in cardiac patients (Bruyninx, et al., 2020).

Depression is also prominent in neurologic illness. Parkinson disease has a 40% to 50% lifetime prevalence of depression (Lima et al., 2019). Depression commonly co-occurs in both children (Florea et al., 2020) and adults (Silva & Cavalcanti, 2019) with multiple sclerosis. Depression is also a common feature in people who have experienced a cerebral vascular accident (CVA) (Kawasaki & Hoshiyama, 2020).

In addition, some medications used to treat medical disorders are known to be associated with agitation, anxiety, and depressed mood as side effects ([Table 43.2](#)). When a drug is suspected of causing mood or mental status changes, it should be withdrawn and an adequate alternative should be tried. When this is not possible, the dosage should be decreased to an effective level at which mood symptoms resolve.

Psychological Aspects of Medical Illness

It is normal for patients to respond to the loss of health with anxiety or depressed mood, particularly when the illness is debilitating, life threatening, and without a clear prognosis. People who have chronic illness are frequently distressed by loss of function and limitations imposed on their daily activities. The person's usual social support systems may also be impacted as the person withdraws from usual activities outside of the home as a consequence of functional loss or pain. Sometimes, relationships are also changed that can further affect healthy coping. Undiagnosed and untreated mental disorders in medically ill people are potentially life threatening because stable moods and cognitive functioning are essential to compliance with the interdisciplinary treatment plan and recovery. In addition, the underuse or overuse of analgesics and reluctance to perform self-care and rehabilitative activities hinder recovery and expose the person to other potential complications. Subsequently, the diagnosis, treatment, and follow-up of a comorbid mental disorders in patients with medical illnesses is crucial.

TABLE 43.2: MEDICATIONS ASSOCIATED WITH MENTAL DISORDERS SYMPTOMS IN MEDICALLY ILL PATIENTS

Drug Class	Medication
Analgesics and NSAIDs	Ibuprofen
	Indomethacin
	Opiates
	Pentazocine
	Phenacetin
	Phenylbutazone
Antihypertensives	Clonidine
	Hydralazine
	Methyldopa
	Propranolol
	Reserpine
Antimicrobials	Ampicillin (gram-negative agents)
	Clotrimazole

	Cycloserine
	Griseofulvin
	Metronidazole
	Nitrofurantoin
	Streptomycin
	Sulfamethoxazole (sulfonamides)
Neurologic agents	L-Dopa
	Levodopa
Antiparkinsonism drugs	Amantadine
Anticonvulsants	Carbamazepine
	Phenytoin
Antispasmodics	Baclofen
	Bromocriptine
Cardiac drugs	Digitalis
	Guanethidine
	Lidocaine
	Oxprenolol
	Procainamide
Psychotropic drugs	Benzodiazepines
Stimulants and sedatives	Amphetamines
	Barbiturates
	Chloral hydrate
	Chlorazepate
	Diethylpropion
	Ethanol
	Fenfluramine
	Haloperidol
Steroids and hormones	Adrenocorticotrophic hormone
	Corticosteroids
	Estrogen
	Oral contraceptives
	Prednisone
	Progesterone
	Triamcinolone
Antineoplastic drugs	Bleomycin

	C-Asparaginase
	Trimethoprim
	Vincristine
Other miscellaneous drugs	Anticholinesterases
	Cimetidine
	Diuretics
	Metoclopramide

Clinical Features of Special Significance

Two problems of special significance, psychotic states and suicidal thoughts, are related in that patients with delusions and hallucinations tend to be at greater risk for suicide attempts and are more likely to have compliance issues with respect to their treatment (e.g., to refuse to eat or take medication). It is important to discern the difference between a patient's capacity to exercise the right to refuse lifesaving treatment and a chronically ill and a depressed patient who expresses hopelessness and a desire to die. A clinical evaluation of the effect of depression on the patient's capacity to make competent decisions regarding their care is imperative. Ethics consults are often utilized at this point to clarify the ethical issues at hand and to provide a forum for discussion of possible patient care interventions, including hospice. Patients with primary mental disorders and comorbid chronic medical illness may pose similar problems when their medical condition deteriorates while admitted to a hospital. The use of advance directives helps to address these complex and sensitive issues.

Assessment of Patients with Medical Illness and Secondary Mental Disorders

Mental health assessment should be part of every patient visit regardless of current health status. The Mini-Mental Status examination or a Saint Louis University Mental Status (SLUMS) examination (see [Chapter 39](#)) can be helpful to determine baseline cognitive function. Documenting mental health status and cognitive status at each appointment helps establish a baseline and provides for early intervention when there are changes. For patients who have risk factors

such as family history of mental health disorders, new psychosocial stressors, current primary mental disorders, or who have chronic medical illnesses, especially CVD, thorough assessment at each visit should always be a priority so that problems can be identified and treated as early as possible. If possible, family and/or caregivers should be engaged as well so that clinical staff can monitor for changes in family dynamics or other new psychosocial issues that could impact the patient's progress and recovery.

The main challenge for clinicians is to determine which signs and symptoms are part of a medical illness and its treatment and which may symptoms signify the presence of a new or worsening mental health disorder. Factors to be considered in assessing mental health problems in medical patients are outlined in [Box 43.1](#). Sometimes, it is difficult to determine whether the presenting symptoms are actually a mix of a psychiatric disorder(s) and chronic medical illness. Some chronic medical illnesses present with decreased appetite, sleep disturbances, and loss of energy as part of the disease process. However, when coupled to feelings of failure, low self-esteem, difficulty concentrating, feelings of hopelessness, and feelings of being punished, a psychiatric liaison referral is needed to determine if depression or anxiety is also present. Side effects of medications for chronic medical illness should also be evaluated. Finally, it is important to recall that changes in mood may signal the beginning of another medical illness for the patient.

BOX 43.1

Factors to Consider in Assessing Mental Health Problems in Medical Patients

- One or more specific medical illnesses
- Past psychiatric history of the patient (before the medical illness)
- Family history of mental health problems
- Current mood, sense of hopelessness, suicidal ideation excessive worry, anxiety
- Current mental health problems, treatment, response to treatment
- Change in sleep or eating (not related to medical illness)
- Sex of the patient

Nursing Interventions for Patients with Medical Illness and Secondary Mental Disorders

Ideally, an interdisciplinary team of care providers that includes a psychiatric liaison nurse should work closely together to deliver optimal treatment of complex medical and mental disorders. Current psychosocial stressors and patient coping mechanisms should be monitored and taken into consideration in developing all plans of care. Most reports suggest that clinicians should be more aggressive in the pharmacologic treatment of mental disorders in medically ill patients. The basic rules for medicating patients include using the minimal dose initially, advancing the dose slowly, and performing frequent blood-level monitoring if appropriate. The person's weight should be carefully monitored at each appointment. Because of pathophysiologic changes associated with the medical illness and likely subsequent changes in pharmacokinetics of medications, doses required to achieve therapeutic blood levels may be less than the usual therapeutic dose and may take longer to titrate. SSRIs (selective serotonin reuptake inhibitors) and SNRIs (serotonin–norepinephrine reuptake inhibitors) are frequently used in the treatment of depression in the medically ill patient population. Both potential interactions and side effects of all medications should be monitored.

Cognitive and behavioral strategies including individual therapy, group therapy, and family therapy are helpful. Assisting the patient and family to understand the nature and relationship of the medical and psychiatric diagnoses may strengthen the support system, alter the perception of caregiver burden, and identify appropriate coping strategies. Mutually agreed-upon goals and therapy actively involve the patient in progress toward recovery and ideally should also include input of caregivers and family members whenever possible. Cognitive intervention should address the areas of the patient's life that can be controlled, despite major lifestyle changes, so that feelings of competence and self-efficacy can be reinforced. At some point, psychodynamic conflicts and maladaptive coping strategies may need to be explored. A referral to clergy or other spiritual support person may also be of value for some patients and their family. In sum, secondary mental disorders can be approached using many of the same strategies that are effective for primary mental health disorders.

MENTAL HEALTH ISSUES RELATED TO PAIN

Pain is one of the most powerful and complex of human experiences and can affect all levels of a person's biopsychosocial and spiritual functioning. It is one

of the most common reasons adults seek medical care (Dahlhamer et al., 2018). In the United States, 50 million adults, 15 million of whom are older adults between the ages of 65 and 85, experience chronic pain and an estimated 19.6 million adults experience high-impact pain that interferes with daily life or work activities (Dahlhamer et al., 2018). For children in the United States, chronic pain has been reported to be as high as 15% of the population between 8 and 18 years old (Grout et al., 2018.). Pain is also experienced by neonates who are receiving intensive care. For example, frequently needed eye exams for retinopathy of prematurity (ROP) can produce significant discomfort and distress for premature infants (Corrigan et al., 2020).

Pain can negatively impact the mental health and well-being of anyone and can exacerbate other existing medical conditions. Pain is a frequent comorbidity in persons diagnosed with depressive disorders, anxiety disorders, alcohol use disorder, opioid use disorder, bipolar disorder, and sleep disorders (Borsook et al., 2018). Pain can initiate new or exacerbate existing manic episodes (Stubbs et al., 2015). The presence of pain is considered to be a prominent risk factor for suicide (Kirtley et al., 2020). Pain can stress interpersonal relationships and complicate family systems. In the United States, pain is a serious public health issue that contributes to high health care costs, lower worker productivity, and increased disability (Dowell et al., 2016).

The continuing opioid epidemic in the United States and elsewhere has initiated a long overdue scrutiny of the ways in which we conceptualize, assess, and manage pain. In this new era of pain management, the use of opioids alone, for example, is no longer considered a first-line therapy for pain management (Dowell et al., 2016). Innovative, person-centered approaches to pain have now become clinical necessities. A comprehensive review of pain neuroscience and pain management is beyond the scope of this chapter. However, this section will briefly explore important areas of pain etiology, classification, assessment, and management that are essential for effective nursing of persons with mental health disorders.

Pain Vulnerability and Pain Resilience

Physiological pain is personal. It involves a series of complex, neuropsychological events that culminate in a highly subjective and deeply individualized experience of discomfort and distress. The experience of pain

occurs within each person's biopsychosocial and spiritual ecology where a unique, personal meaning to pain is created by the person who is suffering. **The BioPsychoSocial Spiritual (BPSS) Model for Pain Management and Delivery** (Matteliano, et al., 2014) is one nursing model that takes into consideration the multidimensional complexity of pain and its management. **The Loeser Model of Pain** acknowledges the biopsychosocial experience of pain but importantly identifies **pain behavior** as the end outcome of the pain experience (Loeser & Ford, 1983). Pain behavior may be thought of as the actions and reactions a person has in response to pain. Given the Loeser Model, it is easy to see how comorbid pain complicates care of all patients and especially those with mental health diagnoses. Behaviors such as anger, agitation, isolation, insomnia, change in appetite, lack of focus, and/or depressed mood may represent pain, a change in mental health status, or a combination of both and always require careful nursing assessment.

Recent advances in neuroscience have attempted to partially decode why each person's experience of pain is so individualized. One explanation has suggested that early pain exposure in some neonates may alter and then "prime" pain pathways in the brain. It is theorized that these changes later produce hypersensitivity to nociceptive trauma and greater **pain vulnerability** for some people (Denk et al., 2014). On the other hand, genetics may play a significant role in the mediation of the experience of pain. For example, some people may produce more or different **beta-endorphins**. These are neurotransmitters that exhibit opioid-like behavior. When activated, they diminish pain perception in some people (Choi & Lee, 2019). In doing so they may also improve **pain resilience**, which can be thought of as a diminished susceptibility to suffering from pain over time (Ankawi et al., 2017). There are many other genetic possibilities for pain vulnerability that are being explored.

Age, race, ethnicity, marital status, military veteran status, sex, immune responsiveness, socioeconomic status, comorbid medical and mental diagnoses, past psychological or physical trauma, and stress are also factors that contribute to each person's pain vulnerability and pain resilience (Borsook et al., 2018). According to the BPSS pain model, a person's spiritual beliefs and practices are also part of the pain complex. This biopsychosocial complex of risk factors for pain is defined as the "**pain mosaic**." For example, non-Hispanic White women and non-Hispanic Black women in the United States are more likely to report persistent and bothersome pain than U.S. men of any ethnicity. Military veterans who have been diagnosed with posttraumatic stress disorder (PTSD) and

comorbid pain experience worse pain than veterans who have chronic pain but not PTSD (Bair et al., 2020). Older adults who have experienced the biologic changes of aging such as systematic inflammation, altered autonomic function, and changes in neuronal structure suffer increased chronic pain, and they are routinely undertreated for this type of pain (Fillingim, 2017). Among homeless persons with comorbid mental disorders, chronic pain can occur in as much as 64% of that population (Vogel et al., 2017). Finally, chronic pain is also associated with a number of comorbid clinical syndromes. Clearly, many factors must be taken into consideration when caring for people in pain. The presence of mental health issues can certainly complicate pain management. Knowledge of the various biopsychosocial and spiritual risk factors and attentiveness to the unique pain mosaic of each person will ensure adequate pain assessment and appropriate pain interventions.

Classification of Pain

Knowledge of pain types is useful to determine prevention, assessment, treatment, and follow-up care. In the past, pain was usually defined by how long the person had been experiencing it. **Acute pain** has been described as pain that lasts between 3 and 6 months, and **chronic pain** has been described as pain that lasts over 6 months. Given these two limited classifications, identification of pain type has been described in relation to time only. The American Nurses Association (ANA) and the American Society for Pain Management Nursing (ASPMN) have encouraged nursing professionals to reconceptualize pain type along four main classifications of pain: (1) **temporal pattern**—acute, chronic, and episodic; (2) **etiology**—cancer, post-operative, etc.; (3) **tissue injury**—nociceptive and neuropathic; and (4) **mixed**—different pain types and/or the simultaneous presence of both acute and chronic pain (ANA & ASPMN, 2016). See [Box 43.2](#) for more details regarding these classifications

The Nociceptive Pain Pathway and Gate Control Theory

Nociceptive pain is a protective response to noxious stimuli that serves as a

warning of tissue injury, inflammation, and pathologic processes that lower the threshold of sensitization. Although current research has further refined the more than half-century-old pain model, gate-control theory continues to offer an adequate general framework for understanding the pain response especially nociceptive pain (Pelaez & Taniguchi, 2016). Gate control theory postulates that there is not a single-pain mechanism but that the processing of pain occurs on at least three levels—peripheral, spinal, and supraspinal. Gate-control theory holds that there are neurologic gates that can either inhibit or allow pain signals to be transmitted to the brain. At the site of the tissue injury, pain receptors (nociceptors) cause the release of prostaglandins (an unsaturated fatty acid that helps control smooth muscle contraction, blood pressure, inflammation, and body temperature) and substance P (a peptide found in body tissues, especially nervous tissue, that is involved in the transmission of pain and in inflammation), as well as potassium, histamine, leukotrienes (short-range chemical messengers that help regulate the state of blood vessels and airways and influence the activities of some white blood cells), and bradykinin (chemical that dilates blood vessels). These function as transmitters of a relay signal sent to the dorsal horn of the spinal cord that in turn increases the flow of impulses relayed to the brain (Box 43.3). The excitability of this pathway can be altered by inhibitory interneurons at the site of the dorsal horn, closing the gate and lesser or no pain may be experienced. If the cytokines or projection neurons are released, they sensitize and stimulate central pain receptors to spread the pain experience and activate areas of the brain responsible for memory, emotion, and personality (Fig. 43.1). As these ascending pathways signal higher centers, descending noradrenergic and serotonergic pathways are activated and inhibit the release of substance P, which closes the gate and thereby reduces the pain (Fig. 43.2) (Mendell, 2014).

BOX 43.2

Classification of Pain

Acute Pain: Lasts 3–6 months and has an identifiable cause, e.g., surgery, injury. Described by patients as sharp, throbbing, aching. Resolves when tissues heal and function returns.

Chronic or Persistent Pain: Occurs longer than 6 months or beyond normal healing time and may not have an identifiable cause. Alteration in the dorsal horn of the spinal cord and neuroplastic changes in the brain are thought to be the possible causes. Often associated with mental health comorbidities,

Nociceptive Pain: Pain that elicits the typical response from the nociceptive pathway and is a normal response to noxious stimuli from tissue injury.

Neuropathic Pain: In contrast to nociceptive pain, neuropathic pain originates in a primary lesion of the

peripheral or CNS. Described by patients as tingling, burning, numbness, and/or shooting. Allodynia may also be described.

Cancer-related Pain: Can be acute, chronic, or recurrent and is caused by tumor or metastases, or cancer therapies such as chemotherapy and/or radiation. Often accompanied by malaise, fever, insomnia, and nausea.

Breakthrough Pain: Pain that occurs over baseline pain in a more intense level.

Procedural Pain: Pain associated with any medical intervention.

Pain Chronification

For some people who have sustained an injury or trauma, the accompanying acute pain will resolve as the injury heals. For other people, acute pain does not resolve when the injury heals and instead acute pain transitions into chronic pain. This transition process is known as **pain chronification** and represents potentially permanent changes and modifications throughout the pain pathway and within the brain itself (neuroplasticity). These neurobiological alterations in

dendrites, opioidergic and dopaminergic receptors, and cytokine production, to name a few examples, do not occur with acute pain (Borsook, et al., 2018). People suffering from chronic pain report **hyperalgia** (increased sensation of pain), **allodynia** (pain unrelated to noxious stimuli, lowered pain threshold), and/or **hyperesthesia** (increased nociceptor sensitivity). As with pain in general, vulnerability to the transition from acute pain to chronic pain is driven by a variety biopsychosocial and spiritual risk factors that are unique to the person. Environmental factors such as geolocation, atmosphere, and air quality may also play a role (Borsook, et al., 2018). Pain medication itself, including opioids, NSAIDs, and triptans, has also been linked to the transition from acute pain to chronic pain in some people (Borsook, et al., 2018).

Figure 43.1 Pain stimuli activate regions of the brain that influence memory, emotion, and personality.

Psychosocial Aspects of Chronic Pain

The impact of chronic pain on quality of life can be devastating. When pain persists for an extended period, mood, coping skills, interpersonal relations, and financial and social resources are affected. Pain becomes a preoccupying daily burden. Demoralization, sadness, isolation, loss of interest in life, feelings of worthlessness, self-reproach, excessive guilt, indecisiveness, and suicidal ideation are often associated with chronic pain (Tagliaferri et al., 2020).

Multimodal Pain Management

The treatment of pain, especially chronic pain, is complex and is always interdisciplinary. It requires careful assessment of the patient's pain mosaic and the systematic analysis of the likely mechanisms that are responsible for the experience of pain. In the shadow of the opioid crisis, new models of pain management have been developed. One promising approach is **mechanism-based pain management**, which attempts to target the many unique pain producing mechanisms along the subcellular and molecular pain pathways (Vardeh et al., 2016). Mechanism-based pain management uses simultaneous, **multimodal interventions** to elicit pain mitigation and relief. Once the mechanisms of pain are identified or suspected within the pain pathway, lower-dose traditional analgesia may be used with lower-dose non-traditional analgesia along with non-pharmacological/complementary interventions ([Figure 43.3](#)). For example, combinations of traditional analgesics such as local anesthetic agents to block nerve conduction, acetaminophen to inhibit prostaglandin synthesis, NSAIDS to block peripheral and central cyclooxygenase, and/or opioids that can address multiple sites of pain action may be used in combination with choices of nontraditional analgesics including anticonvulsants to inhibit neuronal firing, NMDA-receptor antagonists like ketamine to inhibit glutamate activation, anti-depressants to activate ascending pain pathways, and alpha-2 adrenergic agonists like clonidine to inhibit substance P. Combinations of non-pharmacological interventions such as transcutaneous electrical nerve stimulation, cognitive-behavioral therapies, massage therapy, music therapy, and acupuncture, among many complementary options, complete the multimodal approach (Manworren, 2015). It is important to point out that in the mechanism-based model described

earlier, the many types of legitimate complementary treatments are no longer considered “alternative” or “adjunct.” Instead, they are viewed as essential modalities of care to be integrated into the entire pain management plan. There is a growing body of evidence that supports this (Clark et al., 2019). Emerging research has also demonstrated the importance of spiritual interventions for pain relief in patients for whom spirituality can be helpful (Siddall et al., 2015). Ritual, prayer, individual and group spiritual direction, and other interventions can be included as part of a care plan for some patients ([Box 43.4](#)).

Figure 43.2 Ascending sensory pathways: Anterior spinothalamic tract with a schematic diagram of the gate-control theory of pain mechanism.

Barriers to Care

There are many barriers to effective pain management (Box 43.5). Providers may fail to acknowledge or properly assess pain or may be fearful of providing enough pain relief, especially with pain medications. Patients may experience reluctance to acknowledge the pain and to communicate their distress or discomfort. Maladaptive coping by patients with respect to pain can lead to a fear of pain or a catastrophizing about how intense the pain will become or how long it will last. This can generate hopelessness, despair, and suicidal ideation for some. Improper pain management may also contribute to pain chronification. Nonadherence with sequential prescription changes and combined treatments can be problematic as well. Strategies to assess adherence include awareness of the patient's pain mosaic and monitoring for new changes in it such as recent homelessness, loss of employment, family stress, and new medical diagnoses, to name a few areas. Encouragement of regular self-report by the patient, biochemical assays that check for the presence of medications, and regular outcome assessments can also promote adherence to the treatment plan.

Box 43.4

Treatment Approaches to Pain

PRINCIPLES OF PAIN TREATMENT

- Establish the correct diagnosis within the context of the person's pain mosaic.
- Recognize that pain reduction, rather than complete pain control, is a reasonable goal.
- Utilize an interdisciplinary, multimodal approach. Opioids are not first-line or routine therapy for chronic pain alone.
- Control other symptoms besides pain. This includes addressing the symptoms that were present before treatment (e.g., depression and anxiety) and any adverse effects associated with the pain therapy. Monitor for signs and symptoms of opioid use disorder.
- Monitor for new mental health issues, including catastrophizing about pain, fear of pain, suicidal ideation, anxiety, depression, mania, psychosis, delirium.
- Treat physical conditions that may initiate or exacerbate the pain.

- Treat the adverse effects of all the agents used.

Examples of Traditional Analgesia Used in Mechanism-Based Pain Management

Nonsteroidal anti-inflammatory drugs (NSAIDs)

Acetaminophen

Acetylsalicylic acid

Oral local anesthetics

Topical agents

Capsaicin

EMLA (lidocaine and prilocaine mixture)

Lidocaine gel

Trigger point injection (TPI)

Epidural steroid injection (ESI)

Facet joint injection (FJI)

Nerve root blocks

Opioids

Examples of Non-Traditional Analgesia Used in Mechanism-Based Pain Management

Baclofen

Neuroleptics

Pimozide

Corticosteroids

Pulsed Glucocorticoids

Calcitonin

Benzodiazepines

Clonazepam

Valium

Drugs for sympathetically maintained pain

Nifedipine

Phenoxybenzamine

Prazosin

Propranolol

Tricyclic and tetracyclic antidepressants

Amitriptyline

Clomipramine

Desipramine

Doxepin

Imipramine

Maprotiline

Nortriptyline

Mirtazapine

Selective and nonselective serotonin reuptake inhibitors

Bupropion

Citalopram

Escitalopram

Fluoxetine

Fluvoxamine

Nefazodone

Olanzapine

Paroxetine
Sertraline
Trazodone
Venlafaxine
Serotonin–norepinephrine or dopamine reuptake inhibitors
Desvenlafaxine
Duloxetine
Ziprasidone
Anticonvulsants
Carbamazepine
Divalproex
Neurontin
Phenytoin

Examples of Non-Medication Treatments: Restorative Therapies, Interventional Procedures, Behavioral Interventions, and Complementary Health Options

TENS (transcutaneous electrical nerve stimulator)
High Frequency Spinal Cord Stimulation (10 kHz)
Cryotherapy
Heat therapy
Massage therapy
Physical therapy
Recreational therapy
Art therapy
Music therapy
Occupational Therapy
Cognitive–Behavioral Therapy
Acceptance and Commitment Therapy
Self-regulatory or Psychophysiological Therapies: Biofeedback
Pain Support Groups
Individual and Group Psychotherapy
Hypnosis
Tai-Chi
Acupuncture
Healing Touch Therapy
Energy Therapies
Meditation/Mindfulness
Yoga
Prayer
Individual and Group Spiritual direction
Ritual

Note: If the patient has failed to experience response to all standard treatments, psychiatric evaluation for underlying problems should be emphasized.

Box 43.5

Barriers to Pain Management

PROBLEMS OF HEALTH CARE PROFESSIONALS

- Inadequate knowledge and experience with pain management
- Poor assessment of pain
- Concern about regulation of controlled substances
- Fear of patient tolerance and addiction
- Concern about side effects of analgesics

PROBLEMS OF PATIENTS

- Reluctance to report pain
- Concern about primary treatment of underlying disease
- Fear that pain means the disease is worse
- Concern about being a good patient and not a complainer
- Reluctance to take pain medications
- Fear of tolerance and addiction, fear of “addict” label
- Fear of unmanageable side effects

PROBLEMS OF HEALTH CARE SYSTEM

- Cost or inadequate reimbursement
- Restrictive regulation of controlled substances
- Problems with availability of treatment or access to it

Piecing the Mosaic Together: Assessment of Patients with Chronic Pain

Appropriate diagnosis and treatment of pain begin with a comprehensive biopsychosocial and spiritual history as well as a physical examination. A functional assessment that investigates how the patient’s pain affects their daily living should also be completed. Attentiveness to any recent falls due to pain, difficulty completing ADLs (activities of daily living) and IADLs (instrumental activities of daily living), and other diminishments of quality of life is important. When discussing pain, a patient should be asked to describe the pain characteristics, including location and severity, and information about possible factors that may be influencing or producing pain. Patients should also be encouraged to express their feelings, beliefs, and values around pain and suffering. If the patient is a child, parents should also be included in the discussion.

A direct relationship between the severity or extent of detectable disease and the intensity of the patient’s pain may not be evident during the first interaction

between nurse and patient. Pain assessment instruments can aid in evaluation. However, using an instrument designed to measure acute pain, such as asking the patient to rate pain on a scale of 1 to 10, is inadequate for assessing chronic pain because the pain may always be a 3 or 4, but the chronic nature of the pain is the problem (Amir et al., 2019). All pain presents over time, so alertness as to whether pain episodically waxes and wanes, is worse at night, or improves with sleep, to name a few factors, is important. Among patients who are critically ill in an inpatient setting, failure to assess pain expeditiously and correctly can result in a variety of complications, including hyperglycemia and increased risk of infection, which among complications may unnecessarily lengthen a hospital stay (Reardon et al., 2015). Attentiveness to the patient's pain mosaic, pain behaviors, levels of pain vulnerability and pain resilience, and acute and chronic medical and psychiatric comorbidities is crucial. Objective data and the patient's own subjective experience of pain must be carefully analyzed so that comprehensive pain management can occur (Box 43.6).

Nursing Response to Chronic Pain

Pain syndromes, especially chronic pain, are very common in the primary care setting (Box 43.7). The nurse–patient relationship is primary for healing and nurses have an important role in helping the patient manage chronic pain. The nurse's therapeutic use of self can help instill hope and improve the patient's self-efficacy and pain resilience. Listening and acknowledging the pain is important because others may ignore or invalidate the impact of the pain. The nurse can help the patient identify circumstances when the pain was diminished and use this information to adjust existing or develop new strategies. Encouraging the patient to engage in all elements of the pain management plan is key. If the patient is taking medications, the nurse should closely monitor therapeutic and untoward effects. Education with the patient and family about approaches to pain mitigation and the patient's particular pain care helps to build compliance.

Box 43.6

Assessing Patients Who Report Pain

QUESTIONS TO ASSESS PAIN

The following questions can guide the nurse in reflecting on the significance of the chronic pain to the individual and family:

- What is the extent of the patient's disease or injury (physical impairment)?
- What is the magnitude of the illness? That is, to what extent is the patient suffering, disabled, and unable to enjoy usual activities?
- Does the person's behavior seem appropriate to the disease or injury, or is there any evidence of amplification of symptoms for any of a variety of psychological or social reasons or purposes?
- How often and for how long does the patient perform specific behaviors, such as reclining, sitting, standing, and walking?
- How often does the patient seek health care and take analgesic medication (frequency and quantity)?

PAIN BEHAVIOR CHECKLIST

Pain behaviors have been characterized as interpersonal communications of pain, distress, or suffering. Pain behavior may be a more accurate indication of intensity and tolerance than verbal reports. Check the box of each behavior you observe or infer from the patient's comments.

- Facial grimacing, clenched teeth
- Holding or supporting of affected body area
- Questions such as, "Why did this happen to me?"
- Distorted gait, limping
- Frequent shifting of posture or position
- Requests to be excused from tasks or activities, avoidance of physical activity
- Taking of medication as often as possible
- Moving extremely slowly
- Sitting with a rigid posture
- Moving in a guarded or protective fashion
- Moaning or sighing
- Using a cane, cervical collar, or other prosthetic device
- Requesting help in ambulation; frequent stopping while walking
- Lying down during the day
- Irritability

Box 43.7

Pain Syndromes Seen in the Primary Care Setting

- *Migraine headache:* A cerebrovasomotor disorder in which a focal reduction of cerebral blood flow initiates an ischemic headache. It may be preceded by a visual aura and followed by nausea, vomiting, and incapacitating head pain.
- *Low back pain:* Pain arising from the vertebral column or surrounding muscles, tendons, ligaments, or fascia. Causes range from simple muscle strain to arthritis, fracture, or nerve compression from a ruptured disk.

- *Chronic benign orofacial pain:* Temporomandibular joint pain, trigeminal neuralgia
- *Rheumatoid arthritis:* More than 100 different types of joint disease produce inflammation of the joints. Associated with varying degrees of pain and stiffness and eventual loss of use of the affected joints.
- *Reflex sympathetic dystrophy:* A painful burning syndrome that occurs after peripheral nerve injury. Associated with hyperesthesia, vasomotor disturbances, and dystrophic changes caused by sympathetic hyperactivity.
- *Cancer pain:* Pain from malignant tumors that is caused by local infiltration or metastatic spread involving specific organs, bones, peripheral or cranial nerves, or the spinal cord. Pain therapy is aimed at providing sufficient relief to allow maximum possible daily functioning and a relatively pain-free death.
- *Neuropathic pain*
- *Polyneuropathy:* neuropathy involving multiple peripheral nerves
- *Diabetic neuropathy:* neuropathy caused by diabetes mellitus; marked by diminished sensation secondary to vascular changes
- *Inflammatory neuropathy:* neuropathy related to the presence of chemical or micro-organic pathogens
- *Traumatic neuropathy:* neuropathy caused by avulsion or compression
- *Plexopathy:* neuropathy involving a peripheral nerve plexus
- *Peripheral or central neuralgia:* abrupt, intense, paroxysmal pain caused by intrinsic nerve injury or extrinsic nerve compression
- *Herpetic neuralgia:* pain associated with the dermatomal rash of acute herpes zoster
- *Radiculopathy:* pain radiating along a peripheral nerve tract, such as sciatica
- *Vaso-occlusive pain:* Thrombotic crisis of sickle cell anemia in joints and peripheral muscles that is caused by ischemia
- *Myofascial pain:* Pain in palpable bands (trigger points) of muscle; associated with stiffness, limitation of motion, and weakness

Pain Management and Nursing Ethics

Patients diagnosed with acute or chronic pain and who have comorbid alcohol or substance abuse or a history of these diseases can present more complex treatment issues. Social stigma associated with various substance use disorders may prevent such patients from receiving timely and adequate pain management. However, having a current or past substance use disorder does not preclude patients from receiving adequate pain relief including the use of opioids, if necessary, as part of a mechanism-based, multimodal pain management plan. Nurses are morally obligated to advocate for these patients so that adequate pain relief can occur. However, nurses must also be alert to the legitimate concerns of those same patients who may fear an exacerbation or relapse of substance abuse

problems. Patient preference regarding pain management options must always be taken into consideration. Multimodal pain management strategies are especially indispensable for these patients. On the other hand, nurses are also ethically responsible for addressing behaviors with the patient that are not part of the pain management plan. Such behaviors may include lost prescriptions, asking for early refills of pain medications, and/or taking more medications than what was prescribed to name a few such behaviors (ANA & ASPMN, 2016). When this occurs involvement of the interdisciplinary care team by the nurse is crucial to assure proper pain management as well as potential referrals for substance abuse.

MENTAL HEALTH DISORDERS RELATED TO PHYSIOLOGICAL TRAUMA

Physiological trauma can be thought of as sudden onset, severe injury caused by blunt, penetrating, and/or burn mechanisms. Physiologic trauma activates the overall stress response of the autonomic nervous system. Massive catecholamine release causes certain cardiovascular, muscular, gastrointestinal, and respiratory symptoms that release energy stores and support survival. Tissue destruction, musculoskeletal pain, physical disability, and body image changes all contribute to the physiologic and psychological stress response, which continues long after the traumatic physical insult. Common behavioral responses are hypervigilance, fear, anxiety, and a sense of being overwhelmed. Psychological sequelae may include social isolation, agitation, PTSD, depression, and, in extreme cases, dissociative identity disorders. It may be difficult to distinguish trauma response from existing mental health issues in some people (Lutton & Swank, 2018).

Biologic Basis of the Trauma Response

The neurotransmitters responsible for behavioral responses to fear and anxiety are usually held in balance to maintain a level of arousal appropriate for environmental threat. Information from the sensory processing areas in the thalamus and cortex alerts the amygdala (the lateral and central nucleus). Events that are appraised as threatening activate HPA (hypothalamic-pituitary adrenal axis), which releases adrenal steroids initiating the generalized stress response

(see [Chapter 19](#)). When the perceived threat is sustained, complex neurochemical processes involving norepinephrine, gamma-aminobutyric acid (GABA), dopamine, and serotonin are overwhelmed, leading to a general dysregulation of the HPA axis. Inappropriate and prolonged secretion of high levels of catecholamines results (Seo et al., 2019).

Adaptation to trauma is related to such factors as the severity of the trauma, the person's maturity and age when the trauma occurs, available social support, and the person's ability to mobilize coping strategies. During adaptation to prolonged stress, the patient's cognitive thought processes and coping behaviors cause dopamine and serotonin to be released in the prefrontal cortex of the brain. These noradrenergic systems are presumed to play a major role in physiologic and emotional coping responses, storage of the trauma experience into memory, and possibly the development of PTSD (Chia-Ying et al., 2015). See Chapters 19 and 29.

Psychological Response to Trauma

An individual's psychological response to trauma depends on the extent of endocrine and autonomic activity that occurs during stress coupled with prior experience, developmental history, physical status, and existing social support. Psychological manifestation of sustained stress and trauma may be manifested as flashbacks, intrusive recurring thoughts, panic or anxiety attacks, paranoia, inappropriate startle reactions, social isolation, and nightmares (see [Chapter 29](#)). The patient may become so withdrawn and depressed that they stop participating in activities of daily living. Toward the other extreme, the patient may become agitated and combative, perceiving any treatment as a continued threat.

Assessment of Patients Experiencing Trauma

Complete physical assessment after physical traumatic injury is imperative in life-threatening circumstances. Multiple trauma and head injuries are the major causes of death and disability in young adults in society. Highly trained emergency and intensive care providers look for signs and symptoms of physiologic injury and intervene to stabilize primary and secondary trauma in the general medical setting.

After physical stabilization, the patient should be examined for psychological injury through observation and interview to determine prevalent signs and symptoms of accompanying psychological disorders. This process includes evaluating the patient's adjustment and coping skills, their personal way of dealing with the trauma, as well as current social circumstances, and environmental and life stressors. The majority of people who present for trauma treatment, however, will be older adults who may have significant cognitive and functional deficits (Fisher et al., 2017). Especially with the older adults, assessment must be ongoing to help the patient deal with disfigurement, sudden disability or increased disability, and changes in self-care. The evaluation should include assessment of the patient's perception of experienced stress, feelings related to the stress, dominant mood, cognitive functioning, defense and coping mechanisms, and available support systems. In addition, assessment of the risk for self-inflicted injury or suicide is essential.

Nursing Interventions for Responses to Trauma

Psychiatric clinicians provide an important aspect of emergency care. Interventions that establish trust, reduce anxiety, promote positive adaptive coping, and cultivate a sense of control help the patient to begin recovery and maintain emotional health. Physical trauma involving children has been connected to serious, long-term psychological complications, making early intervention and support critical (Lantz, 2020). Crisis intervention methods, stress management, cognitive-behavioral therapies, psychotherapy, and psychotropic medications, alone or in combination, may be useful in achieving the best possible outcome.

Traumatic death is often sudden and unexpected, and the victim is often young. When trauma causes the patient's death, the family must be informed of the death and allowed to grieve to prevent the development of a pathologic or prolonged grief response. Surviving family members may have a severe emotional reaction to the death. Unhealthy family dynamics, especially maladaptive coping, may become evident during this period. Ideally, the psychiatric-mental health liaison nurse can use family intervention strategies to enhance or improve relationships while the family's motivation to do all that is possible is high.

MENTAL HEALTH ISSUES RELATED TO CENTRAL NERVOUS SYSTEM DISORDERS

Neurologic impairment is most often related to brain cell (neuron) destruction. The primary causes of neuronal damage are traumatic injury, ischemia, infarction (cerebrovascular accident—CVA), abnormal neuron growth (brain tumor), and metabolic poisoning associated with systemic disease. Brain cell loss may also be the result of degenerative processes, such as those that occur in Alzheimer or Parkinson disease. Psychiatric disorders are often complications of these neurologic diseases and may be difficult to distinguish from the neuropathology itself. Therefore, appropriate intervention depends on skilled assessment to discriminate and detect mental status changes related to organic brain injury as well as disorders of mood and thought.

An injury to the brain can destroy brain cells directly or initiate a cascade of cell breakdown from ischemia. This **ischemic cascade** begins with hypoxia and is followed by paralysis of the ion exchange across the cell membrane, edema, calcium influx, free radical production, and lipid peroxidation (oxidative degradation of lipids). The severity of brain injury is related to the degree and duration of ischemia. Complete ischemia results in brain cell death or infarction, commonly known as stroke. The resulting neurologic impairment is related to the size and location of the affected brain area. Some areas of the brain, such as the internal capsule, are extremely sensitive to ischemia. They are typically injured first and contribute to more generalized impairment, such as memory loss, altered judgment, and post-stroke spasticity (Songjin et al., 2020).

Traumatic Brain Injury

Traumatic brain injury (TBI) is an intracranial injury that occurs when an outside force injures the brain. TBI can result in temporary, mild symptoms or symptoms can be permanent and severe, depending on the scope of brain tissue damage. TBI is a major cause of disability for wounded U.S. soldiers and, among those who served in Iraq and Afghanistan, the prevalence of TBI is estimated to be between 9% and 28% (Lindquist et al., 2017). Mild TBI accounts for an estimated 75% to 95% of all TBI cases (Bryson et al., 2017). **Persistent postconcussive symptoms** (PCS), which include fatigue, sleep problems,

difficulty concentrating, sensitivity to light and noise, problems with memory, and other mood-related symptoms, can exist a year or longer in those with even mild TBI (Agtarap et al., 2019). PCS, depressive disorders, and PTSD often coexist as distinct, but related, phenomena among military veterans with TBI (Agtarap et al., 2019). Depression is estimated to occur in up to 53% of those with TBI, and PTSD has been found to occur in 44% of veterans with TBI (Agtarap et al., 2019). Patients with TBI are considered to be at risk for suicide (Bryson et al., 2017). The triad of PCS, PTSD, and depressive disorders may become evident in the acute recovery phase or during rehabilitation and often negatively affects survival and recovery. Early evaluation assists in the detection of these and other mental health complications after brain injury.

Ischemic Stroke

Depressive disorder and anxiety are frequent complications of ischemic stroke. Up to one fifth of people who suffer a stroke experience both depression and anxiety within 12 months (Arba et al., 2016). These mood changes are not only a result of the changes in the autonomic and endocrine systems but also a result of the breakdown of biogenic amines after ischemia and brain cell death. Recent studies show that in some parts of the brain (Fig. 43.4), there is actually atrophy and post-stroke high cortisol levels especially at bedtime have been linked to this (Tene et al., 2018). Other symptoms, such as sleep disturbances, cognitive dysfunction, poor concentration, difficulty making decisions, somatic discomfort, poor appetite, social withdrawal, and fatigue or agitation, often accompany the mood disturbance.

Minor and moderate depression may go unrecognized and undiagnosed when patients with stroke describe somatic symptoms and demonstrate lack of motivation in ADLs. There is no one-risk factor for the development of depression and other mood disorders. Among people recovering from strokes, mild depression occurs in about 46%, moderate depression in 38%, and severe depression in 16% (Zhang & Qui, 2020). Men with lower income, metabolic syndrome, higher neurological deficit, and lower social support are more likely to experience severe depression following a stroke (Zhang & Qui, 2020).

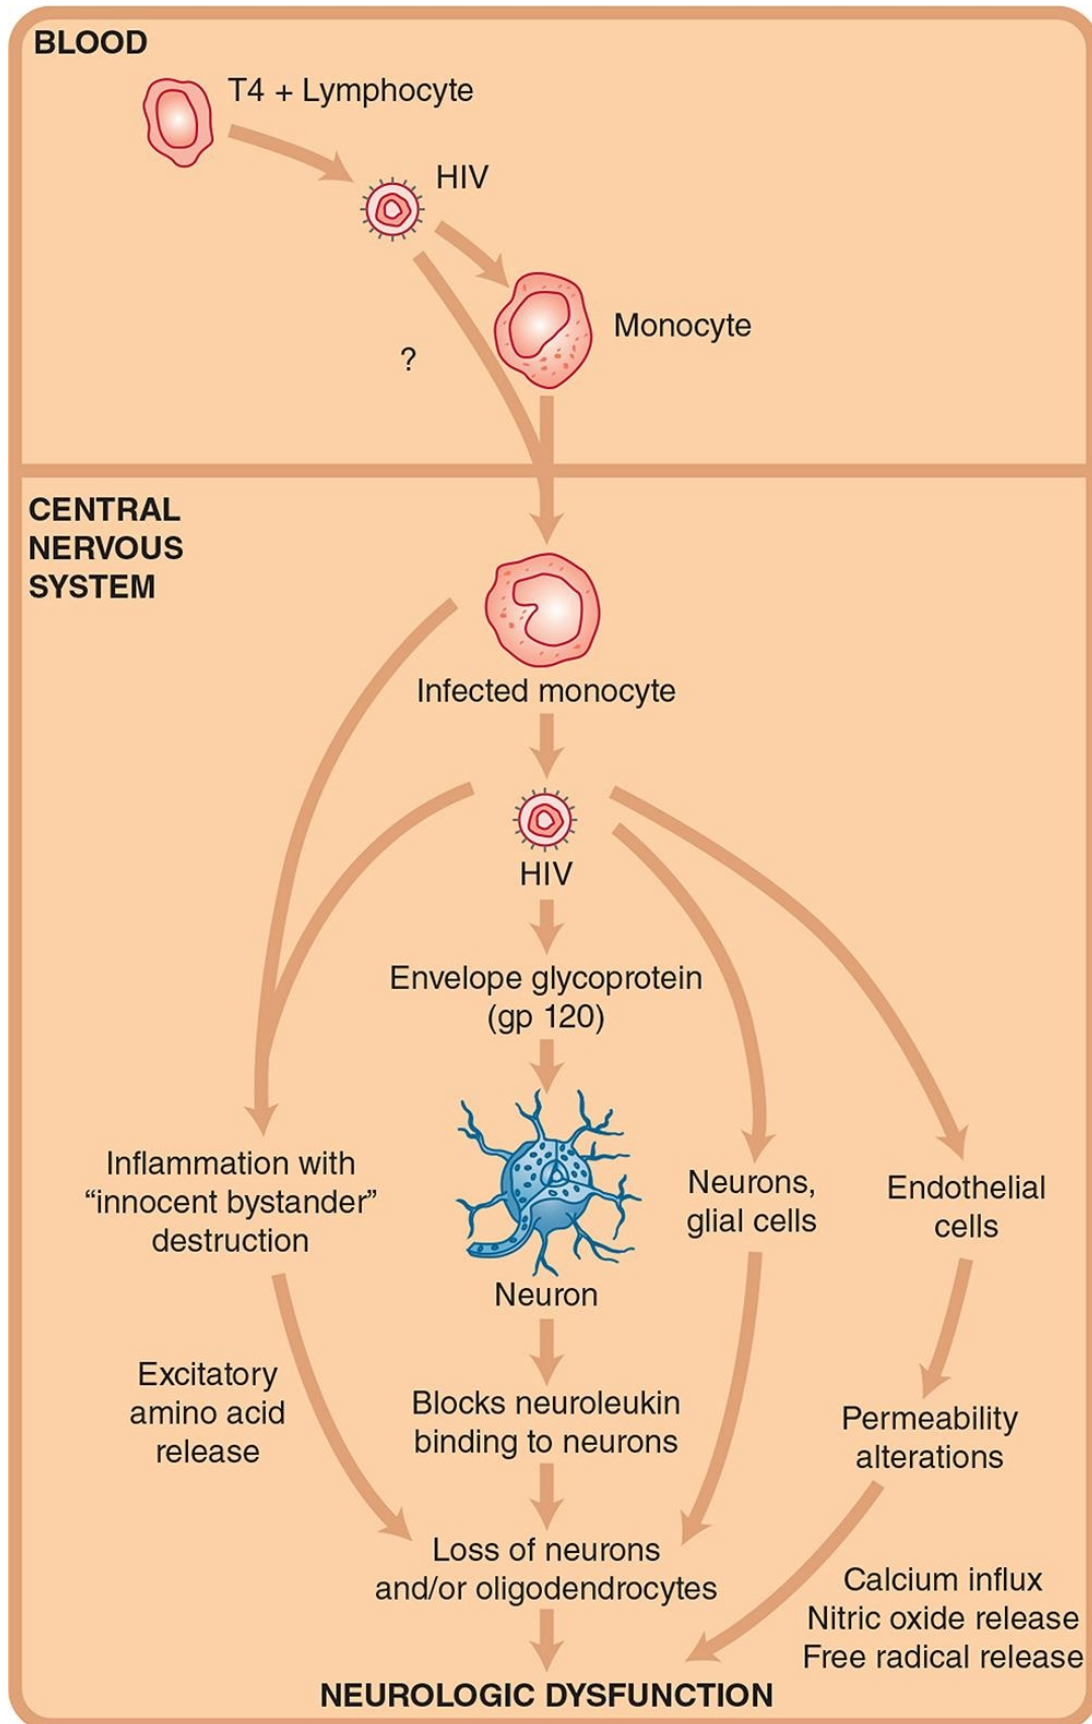

Figure 43.4 Functional cerebral anatomy and stroke.

Parkinson Disease

In Parkinson disease and other neuromuscular diseases, there is degeneration in the motor pathways with a loss of dopamine secretion. This dysregulation affects other neurotransmitters. About 35% of patients with Parkinson disease experience depression that contributes to impairment in daily functioning possibly as much as the underlying disease (Yang et al., 2012). However, only about 20% of these patients receive treatment (Frisina et al., 2008). Evidence suggests that altered serotonergic function may be responsible, at least in part, for the depressive symptoms in Parkinson disease and that altered noradrenergic function may underlie some of the associated anxiety symptoms (Kano et al., 2011). Treatment of depression in patients with Parkinson's is critical because it has been linked to cardiovascular dysautonomia in these patients, which can result in sudden death (Vetrano et al., 2015).

Assessment of Psychological Responses to Central Nervous System Disorders

A thorough neurologic examination is important in determining the location and degree of disability, but is even more critical in establishing the locus of retained function. Cognitive functioning, mood, and functionality are key assessment areas. Many scales exist that accurately assess these areas, are easy to administer, and are generally accepted as reliable tools to detect the degree and limitations of disability. Cognition can be measured using the SLUMS examination (see [Chapter 39](#)), and function ability for self-care can be measured using the Barthel index (Mahoney & Barthel, 1965). Evaluation of mood using the Center for Epidemiological Studies Depression Scale (CES-D) or the Beck Depression Inventory (Beck et al., 1961) provides important information for designing intervention strategies for the at-risk neurologic patient. Findings of depressive symptoms indicate the need for a more definitive neuropsychological referral.

Nursing Interventions for Responses to Central Nervous System Disorders

Isolation, lack of companionship, bereavement, and poverty are associated with depressive symptoms in the general population and compound the relative risk of depression developing after brain damage. Prevention strategies should be used as early and include (1) the assessment and provision of social support resources while the patient is hospitalized and as an important component of discharge planning to rehabilitation services; (2) early identification of potential mental health problems with a referral for complete evaluation; (3) education of patient and family about the mental health complications of CNS disorders so they will know when to seek medical attention and treatment to avert major problems; (4) encouragement to seek treatment for mental health problems, including pharmacologic strategies; and (5) enhancement of competence in performing ADLs, with a focus on the use of retained function rather than on adaptation to disabilities only.

SUMMARY OF KEY POINTS

- Mental disorders are more common in people with systemic or chronic medical illnesses than in the healthy population. Comorbid depression is common in several medical diseases, including endocrine and metabolic disturbances, cancer, viral infections, inflammatory disorders, metabolic syndrome, and cardiopulmonary diseases.
- Mental disorders that accompanies medical illness is often not recognized and treated. Psychiatric symptoms may precede the onset of disease symptoms, and it may be difficult to distinguish between the symptoms of the two conditions.
- Mental disorders in medically ill people is potentially lethal

because normal affective–cognitive function may be critical to recovery and compliance with the medical treatment plan. Therefore, it is imperative that mental health is included in the standard health assessment of all medically ill persons and that appropriate referrals be made.

CRITICAL THINKING CHALLENGE

1. You are caring for a patient who is recovering from a stroke who refuses breakfast and a morning bath. Applying what you know about the neurologic damage caused by stroke and the frequency of depression in stroke patients, develop a care plan addressing the patient's biopsychosocial needs.
2. Discuss the pain syndromes you may see in the primary care setting.
3. A patient is being seen for chronic pain. Discuss how you would go about assessing barriers to pain management with this patient.
4. You are a psychiatric–mental health liaison nurse and have been asked to prepare a program for the medical–surgical nursing staff on psychiatric aspects of medical illnesses. What topics would you include, and what would be your rationale for including each?

Appendix B

Abnormal Involuntary Movement Scale (AIMS)

		None	Minimal	Mild	Moderate	Severe
Facial and Oral Movements	1: Muscles of facial expression: e.g., movements of forehead, eyebrows, periorbital area, cheeks; include frowning, blinking, smiling, grimacing	0	1	2	3	4
	2: Lips and perioral area: e.g., puckering, pouting, smacking	0	1	2	3	4
	3: Jaw: e.g., biting, clenching, chewing, mouth opening, lateral movement	0	1	2	3	4
	4: Tongue: Rate only increase in movement both in and out of mouth, <i>not</i> the inability to sustain movement	0	1	2	3	4
Extremity Movements	5: Upper (arms, wrists, hands, fingers): Include choreic movements (i.e., rapid, objectively purposeless, irregular, spontaneous), athetoid movements (i.e., slow, irregular, complex, serpentine); <i>do not</i> include tremor (i.e., repetitive, regular, rhythmic)	0	1	2	3	4
	6: Lower (legs, knees, ankles, toes): e.g., lateral knee movement, foot tapping, heel dropping, foot squirming, inversion and eversion of foot	0	1	2	3	4
Trunk Movements	7: Neck, shoulders, hips: e.g., rocking, twisting, squirming, pelvic gyrations	0	1	2	3	4
Global	8: Severity of abnormal movements overall	0	1	2	3	4
Judgment	9: Incapacitation caused by abnormal movements	0	1	2	3	4
	10: Patient's awareness of abnormal movements: Rate only patient's report					

		No awareness	0
		Aware, no distress	1
		Aware, mild distress	2
		Aware, moderate distress	3
		Aware, severe distress	4
Dental Status	11: Current problems with teeth or dentures	No	0
		Yes	1
	12: Does patient usually wear dentures?	No	0
		Yes	1

Examination Either before or after completing the examination procedure, observe the patient unobtrusively, at rest (e.g., in the waiting room). The chair to be used in this examination should be a hard, firm one without arms.

AIMS

- 1: Ask the patient whether there is anything in his or her mouth (e.g., gum, candy) and if there is, to remove it.
- 2: Ask the patient about the current condition of his or her teeth. Ask the patient if he or she wears dentures. Do teeth or dentures bother the patient now?
- 3: Ask the patient whether he or she notices any movements in the mouth, face, hands, or feet. If yes, ask to describe and to what extent they currently bother patient or interfere with his or her activities.
- 4: Have the patient sit in the chair with his or her hands on knees, legs slightly apart, and feet flat on floor. (Look at the entire body for movements while in this position.)
- 5: Ask the patient to sit with his or her hands hanging unsupported. If male, between legs, if female and wearing a dress, hanging over knees. (Observe hands and other body areas.)
- 6: Ask the patient to open his or her mouth. (Observe the tongue at rest within the mouth.) Do this twice.
- 7: Ask the patient to protrude his or her tongue. (Observe the tongue at rest within the mouth.) Do this twice.
- *8: Ask the patient to tap his or her thumb, with each finger, as rapidly as possible for 10–15 seconds; separately with the right hand and then with the left hand. (Observe facial and leg movements.)

- 9: Flex and extend the patient's left and right arms (one at a time). (Note any rigidity and rate on NOTES.)
- 10: Ask the patient to stand up. (Observe in profile. Observe all body areas again, hips included.)
- *11: Ask the patient to extend both arms outstretched in front with the palms down. (Observe trunk, legs, and mouth.)
- *12: Have the patient walk a few paces, turn, and walk back to the chair. (Observe hand and gait.) Do this twice.

—

*Activated movements.

Appendix C

Simplified Diagnosis for Tardive Dyskinesia (SD-TD)

The following instructions accompany the Dyskinesia Identification System: Condensed User Scale (DISCUS). See Box 22.5.

PREREQUISITES. The three prerequisites are as follows. Exceptions may occur.

1. A history of at least 3 months' total cumulative neuroleptic exposure. Include amoxapine and metoclopramide in all categories below as well.
2. **SCORING/INTENSITY LEVEL.** The presence of a **TOTAL SCORE OF FIVE (5) OR ABOVE**. Also be alert for any change from baseline or scores below five which have at least a "moderate" (3) or "severe" (4) movement on any item or at least two "mild" (2) movements on two items located in different body areas.
3. Other conditions are not responsible for the abnormal involuntary movements.

DIAGNOSES. The diagnosis is based upon the current exam and its relation to the last exam. The diagnosis can shift depending upon: (a) whether movements are present or not, (b) whether movements are present for 3 months or more (6 months if on a semiannual assessment schedule), and (c) whether neuroleptic dosage changes occur and effect movements.

- **NO TD.** Movements **are not** present on this exam **or** movements are present, but some other condition is responsible for them. The last diagnosis must be NO TD, PROBABLE TD, or WITHDRAWAL TD.
- **PROBABLE TD.** Movements **are** present on this exam. This is the first time they are present or they have never been present for 3 months or more. The last diagnosis must be NO TD or PROBABLE TD.

- **PERSISTENT TD.** Movements are present on this exam **and** they have been present for 3 months or more with this exam or at some point in the past. The last diagnosis can be any except NO TD.
- **MASKED TD.** Movements **are not** present on this exam **but** this is due to a neuroleptic dosage increase or reinstitution after a prior exam when movements were present. Also use this conclusion if movements are not present due to the addition of a non-neuroleptic medication to treat TD. The last diagnosis must be PROBABLE TD, PERSISTENT TD, WITHDRAWAL TD, or MASKED TD.
- **REMITTED TD.** Movements **are not** present on this exam **but** PERSISTENT TD has been diagnosed and neuroleptic dosage increase or reinstitution has occurred. The last diagnosis must be PERSISTENT TD or REMITTED TD. If movements reemerge, the diagnosis shifts back to PERSISTENT TD.
- **WITHDRAWAL TD.** Movements **are not seen while** receiving neuroleptics or at the last dosage level **but are seen within** 8 weeks following a neuroleptic reduction or discontinuation. The last diagnosis must be NO TD or WITHDRAWAL TD. If movements continue for 3 months or more after the neuroleptic dosage reduction or discontinuation, the diagnosis shifts to PERSISTENT TD. If movements do not continue for 3 months or more after the reduction or discontinuation, the diagnosis shifts to NO TD.

INSTRUCTIONS

1. The rater completes the Assessment according to the standardized exam procedure. If the rater also completes Evaluation items 1 to 4, he/she must also sign the preparer box. The form is given to the physician. Alternatively, the physician may perform the assessment.
2. The physician completes the Evaluation section. The physician is responsible for the entire Evaluation section and its accuracy.
3. IT IS RECOMMENDED THAT THE PHYSICIAN EXAMINE ANY INDIVIDUAL WHO MEETS THE THREE PREREQUISITES OR WHO HAS MOVEMENTS NOT EXPLAINED BY OTHER FACTORS. NEUROLOGIC ASSESSMENTS OR DIFFERENTIAL DIAGNOSTIC TESTS WHICH MAY BE NECESSARY SHOULD BE OBTAINED.

OTHER CONDITIONS (partial list)

- | | |
|--|---------------------------------|
| 1. Age | 12. Huntington Chorea |
| 2. Blind | 13. Hyperthyroidism |
| 3. Cerebral Palsy | 14. Hypoglycemia |
| 4. Contact Lenses | 15. Hypoparathyroidism |
| 5. Dentures/No Teeth | 16. Idiopathic Torsion Dystonia |
| 6. Down Syndrome | 17. Meige Syndrome |
| 7. Drug Intoxication (specify) | 18. Parkinson Disease |
| 8. Encephalitis | 19. Stereotypies |
| 9. Extrapyramidal Side Effects (specify) | 20. Sydenham Chorea |

Glossary

ABCDE An acronym for the basic framework of rational emotive behavior therapy.

ABCs of psychological first aid Focusing on A (arousal), B (behavior), and C (cognition).

absorption Movement of drug from the site of administration into plasma.

abuse Use of alcohol or drugs for the purpose of intoxication or, in the case of prescription drugs, for purposes beyond the intended use.

accreditation Process by which a mental health agency is recognized or approved in accordance with established standards to be providing acceptable quality of care.

acculturation Act or process of assuming the beliefs, values, and practices of another, usually dominant culture.

acetylcholine (ACh) The primary cholinergic neurotransmitter. Found in the greatest concentration in the peripheral nervous system, ACh provides the basic synaptic communication for the parasympathetic neurons and part of the sympathetic neurons, which send information to the central nervous system. An important neurotransmitter associated with cognitive functioning; disruption of cholinergic mechanisms damages memory in animals

and humans.

acetylcholinesterase (AChE) Key enzyme that inactivates the neurotransmitter acetylcholine. AChE is found in high concentrations in the brain and is one of two cholinesterase enzymes capable of breaking down ACh.

acetylcholinesterase inhibitors (AChEI) Mainstay of pharmacologic treatment of dementia; these drugs inhibit AChE, resulting in an enhancement of cholinergic activity.

activating event The “A” in the ABCDE framework of rational emotive behavior therapy. It represents an external or internal stimulus. Not necessarily an actual event, it may be an emotion, or thought or expectation that is interpreted according to a set of beliefs.

active listening Focusing on what the patient is saying in order to interpret and respond to the message in an objective manner while using techniques such as open-ended statements, reflection, and questions that elicit additional responses from the patient.

acute pain A sudden, severe onset of pain symptoms at the time of injury or illness that generally subsides as the associated condition subsides or the injury heals.

acute stress disorder (ASD) A mental disorder characterized by persistent, distressing stress-related symptoms that last between 2 days and 1 month and that occur within 1 month after a traumatic experience.

adaptation A person’s capacity to survive and flourish as it affects health, psychological well-being, and social functioning.

adaptive behavior Behavior that is composed of three skill types: conceptual, social, and practical skills.

addiction A condition of continued use of substances (or reward-

seeking behaviors) despite adverse consequences.

adherence An individual's compliance to a therapeutic routine.

advance care directives Treatment directives (living wills) and appointment directives (power of attorney or health proxies) that apply only if the individual is unable to make his or her own decisions because the patient is incapacitated or, in the opinion of two physicians, is otherwise unable to make decisions for himself or herself.

advanced practice psychiatric–mental health nurse A licensed registered nurse who is educationally prepared at the graduate level and is nationally certified as a specialist by the American Nurses Credentialing Center (ANCC).

adverse reactions (adverse effects) Unwanted medication effects that may have serious physiologic consequences.

affect An expression of mood manifest in a person's outward emotional expression; varies considerably both within and among different cultures.

affective instability Rapid and extreme shifts in mood, erratic emotional responses to situations, and intense sensitivity to criticism or perceived slights; one of the core characteristics of borderline personality disorder.

affective lability Abrupt, dramatic, unprovoked changes in the types of emotions expressed.

affinity Degree of attraction or strength of the bond between a drug and its biologic target.

aggression Overt behavior intended to hurt, belittle, take revenge, or achieve domination and control; can be verbal or physical. Behaviors or attitudes that reflect rage, hostility, and the potential for physical or verbal destructiveness; usually occurs if the person

believes someone is going to do him or her harm.

agitation Inability to sit still or attend to others accompanied by heightened emotions and tension.

agnosia Failure to recognize or identify objects despite intact sensory function.

agonists Substances that initiate the same response as the chemical normally present in the body.

agoraphobia Fear of open spaces; commonly occurs with panic disorder.

agranulocytosis Dangerously low level of circulating neutrophils.

akathisia An extrapyramidal side effect characterized by the inability to sit still or restlessness; more common in middle-aged patients. Sometimes misdiagnosed as agitation or an increase in psychotic symptoms.

alcohol withdrawal syndrome A syndrome that occurs after the reduction of alcohol consumption or when abstaining from alcohol after prolonged use, causing changes in vital signs, diaphoresis, and other adverse gastrointestinal and central nervous system side effects.

Alcoholics Anonymous The first 12-step, self-help program; a worldwide fellowship of people with alcoholism who provide support, individually and at meetings, to others who seek help.

alexithymia Difficulty identifying and expressing emotion.

allodynia Pain unrelated to noxious stimuli; lowered pain threshold.

allostasis The dynamic regulatory process that maintains homeostasis through a process of adaptation.

allostatic load (AL) An increase in the number of abnormal biologic parameters as a consequence of wear and tear on the body and

brain; leads to ill health.

alogia Reduced fluency and productivity of thought and speech. Brief, empty verbal responses; often referred to as *poverty of speech*.

ambivalence Presence and expression of two opposing feelings, leading to inaction.

amino acids Building blocks of proteins that have different roles in intraneuronal metabolism. Amino acids function as neurotransmitters in as many as 60% to 70% of synaptic sites in the brain.

anger An internal affective state, usually temporary rather than an enduring negative attitude, that may or may not be expressed in overt behavior. If expressed, anger behavior can be constructive or destructive.

anger management A psychoeducational intervention for persons whose anger behavior is dysfunctional in some way (i.e., interfering with success in work or relationships) but *not violent*.

anhedonia Inability to experience pleasure.

anorexia nervosa A life-threatening eating disorder characterized by a mixture of biopsychosocial symptoms, including significantly low body weight, intense fear of gaining weight or becoming fat, and a disturbance in experiencing body weight or shape.

anorgasmia The inability to achieve an orgasm.

antagonists Chemicals blocking the biologic response at a given receptor site.

antisocial personality disorder A disorder characterized by a marked pattern of disregard for, and violation of, the rights of others.

anxiety Energy that arises when expectations that are present are not met (Peplau). An uncomfortable feeling of apprehension or dread that occurs in response to internal or external stimuli and can result in physical, emotional, cognitive, and behavioral symptoms.

apathy Reactions to stimuli that are decreased along with a diminished interest and desire.

aphasia Alterations in language ability.

appraisal The process whereby all aspects of a given event or situation are considered—the demands, constraints, and resources are balanced with personal goals and beliefs.

apraxia Impaired ability to execute motor activities despite intact motor functioning.

Asperger syndrome Formerly named Asperger syndrome, it is now diagnosed as autism spectrum disorder with persistent difficulty in social communication and interaction. It appears to be a milder form of autism.

assault The threat of unlawful force to inflict bodily injury on another. The threat must be imminent and cause reasonable apprehension in the individual.

assertive community treatment A model that calls for a multidisciplinary clinical team approach to providing 24-hour, intensive community-based services to help patients meet the requirements of community living during reintegration.

assessment The deliberate and systematic collection and interpretation of biopsychosocial information or data to determine current and past health, functional status, and human responses to mental health problems, both actual and potential.

assortative mating Tendency for individuals to select mates who are similar in genetically linked traits such as intelligence and

personality styles.

asylum Safe haven.

attachment Emotional bond formed between children and their parental figures at an early age; attaining and retaining interpersonal connection to a significant person, beginning at birth.

attachment disorganization A consequence of extreme insecurity that results from feared or actual separation from the attached figure. Infants appear to be unable to maintain the strategic adjustments in attachment behavior.

attention A complex mental process that involves concentrating on one activity to the exclusion of others, as well as sustaining interest over time.

attention-deficit hyperactivity disorder (ADHD) A persistent pattern of inattention, hyperactivity, and impulsiveness; typically diagnosed based on teacher and parent reports and direct observation of the behavior patterns described.

atypical antipsychotics Newer antipsychotics that are equally or more effective than conventional antipsychotics but have fewer side effects.

augmentation A strategy of adding another medication to enhance effectiveness.

autism spectrum disorders Disorders characterized by neurodevelopmental delays that are typically diagnosed in childhood. Children with autism spectrum disorders may or may not have an intellectual disability, but they commonly show an uneven pattern of intellectual strengths and weaknesses.

autistic thinking Thinking restricted to the literal and immediate so that the individual has private rules of logic and reasoning that

make no sense to others.

autonomic nervous system Part of the nervous system that regulates involuntary vital functions including cardiac muscle, smooth muscles, and glands. It is composed of the sympathetic and parasympathetic systems.

autonomy Concept that each person has the fundamental right of self-determination.

avoidant personality disorder A disorder characterized by avoiding social situations in which there is interpersonal contact with others. Individuals appear timid, shy, and hesitant; fear criticism; and feel inadequate. They are extremely sensitive to negative comments and disapproval and appraise situations more negatively than others do.

avolition Withdrawal and inability to initiate and persist in goal-directed activity.

basal ganglia Subcortical gray matter areas in both the right and the left hemisphere that contain many cell bodies or nuclei.

behaviorism A paradigm shift in understanding human behavior that was initiated by Watson, who theorized that human behavior is developed through a stimulus–response process rather than through unconscious drives or instincts.

behavior modification A specific therapy technique that can be applied to individuals, groups, or systems. The aim of behavior modification is to reinforce desired behaviors and extinguish undesired ones.

behavior therapy Interventions that reinforce or promote desirable behaviors or alter undesirable ones.

belief system The “B” in the ABCDE framework of rational emotive behavior therapy. Beliefs underlying thoughts and emotions are

shaped by rationality, which is self-constructive, and irrationality, which is self-defeating.

beneficence The health care provider uses knowledge of science and incorporates the art of caring to develop an environment in which individuals achieve maximum health care potential.

bereavement The process of mourning and coping with the loss of a loved one. It begins immediately after the loss, but it can last months or years.

beta-amyloid plaques Dense, mostly insoluble deposits of protein and cellular material outside and around neurons; pathology of Alzheimer disease.

bibliotherapy The use of provider-assigned books and other reading materials to help individuals gain therapeutic benefit.

binge eating Rapid, episodic, impulsive, and uncontrollable ingestion of a large amount of food during a short period of time, usually 1 to 2 hours, usually followed by feelings of guilt that result in purging.

binge-eating disorder A newly identified eating disorder in its infancy relative to research; individuals binge in the same way as those with bulimia nervosa but do not purge or compensate for binges through other behaviors.

bioavailability Amount of a drug that actually reaches the systemic circulation unchanged.

biogenic amines Small molecules manufactured in the neuron that contain an amine group. These include dopamine, norepinephrine, and epinephrine (all synthesized from the amino acid tyrosine) and serotonin (from tryptophan).

biologic markers Physical indicators of disturbances within the central nervous system that differentiate one disease state from

another; found using diagnostic testing.

biopsychosocial model An organizational model consisting of three separate but interdependent domains: biologic, psychological, and social. Each domain has an independent knowledge and treatment focus but can interact and be mutually interdependent with the other dimensions.

biosexual identity Anatomic and physiologic state of being male or female that results from genetic and hormonal influences.

biotransformation Metabolism of a drug or substance; the process by which the drug is altered and broken down into smaller substances, known as metabolites.

bipolar disorders Mood disorders that are characterized by periods of mania or hypomania that alternate with depression. These disorders can be further designated as bipolar I, bipolar II, and cyclothymic disorder depending on the severity of the manic and depressive symptoms.

bipolar I A type of bipolar disorder that is diagnosed when at least one manic episode or mixed episode is present.

bipolar II A type of bipolar disorder that has less dramatic symptoms than bipolar I. Hypomania (mild mania) and a major depressive episode are characteristic symptoms.

blood alcohol level The level of alcohol in the blood; used to determine intoxication.

board-and-care homes Facilities that provide 24-hour supervision and assistance with medications, meals, and some self-care skills but in which individualized attention to self-care skills and other activities of daily living is generally not available.

body dissatisfaction A sense of dissatisfaction and low self-esteem when one's own body is perceived to fall short of an ideal.

body dysmorphic disorder Disorder in which there is a preoccupation with an imagined or slight defect in appearance, such as a large nose, thinning hair, or small genitals.

body image How each individual perceives his or her own body, including such dimensions as size and attractiveness.

body image distortion Extreme discrepancy between one's perception of one's own body image and others' perceptions of one.

borderline personality disorder A disorder characterized by a disruptive pattern of instability related to self-identity, interpersonal relationships, and affects combined with marked impulsivity and destructive behavior.

boundaries Limits in which a person may act or refrain from acting within a designated time or place. Invisible barriers with varying permeabilities that surround family subsystems.

boxed warning Serious adverse effects that can occur with the use of a specific medication; noted in issued warning in the package insert.

bradykinesia An extrapyramidal condition characterized by a slowness of voluntary movement and speech.

brain stem Area of the brain containing the midbrain, pons, and medulla, which continues beneath the thalamus.

breach of confidentiality Release of patient information without the patient's consent in the absence of legal compulsion or authorization to release information.

brief intervention A negotiated conversation between professional and patient designed to reduce alcohol and drug use; any short-term intervention.

bulimia nervosa An eating disorder in which the individual engages

in recurrent episodes of binge eating and compensatory behavior to avoid weight gain through purging methods such as self-induced vomiting or use of laxatives, diuretics, enemas, or emetics or through nonpurging methods such as fasting or excessive exercise.

bullying Repeated, deliberate attempts to harm someone that are usually unprovoked. An imbalance in strength is a part of the pattern, with most victims having difficulty defending themselves.

carrier protein A membrane protein that transports a specific molecule across the cell membrane.

case finding Identifying people who are at risk for suicide to initiate proper treatment. Identification of depression and risk factors associated with suicide.

case management Service model in which a case manager locates services, links the patient with these services, and then monitors the patient's receipt of these services.

cataplexy Bilateral loss of muscle tone triggered by a strong emotion such as laughter. This muscle atonia can range from subtle (drooping eyelids) to dramatic (buckling knees). Respiratory muscles are not affected. Cataplexy usually lasts only seconds. Individuals are fully conscious, oriented, and alert during the episode. Prolonged episodes of cataplexy may lead to sleep episodes.

catastrophic reactions Overreactions or extreme anxiety reactions to everyday situations.

catatonic excitement Hyperactivity characterized by purposeless activity and abnormal movements like grimacing and posturing.

catharsis A Freudian concept meaning release of feelings, as in the venting of anger.

cerebellum Part of the brain that is responsible for controlling movement and postural adjustments; it receives information from all parts of the body.

chemical restraint Use of medication to control patients or manage behavior.

child abuse Any action that robs children of rights they should have including the rights to be and behave like a child; to be safe and protected from harm; and to be fed, clothed, and nurtured so the child can grow, develop, and fulfill his or her unique potential.

child neglect A form of child abuse defined as failure to provide for a child's physical, emotional, health care, or educational needs; failure to adequately supervise a child; or intentionally exposing a child to a dangerous environment.

chronic pain Pain on a daily basis or pain that is constant for more than 6 months.

chronic syndromes Symptom patterns that last for long periods of time. Medication-related movement disorders that develop from longer exposure to antipsychotic drugs.

chronobiology Study and measure of time structures or biologic rhythms.

chronopharmacotherapy Resetting the biologic clock by using short-acting hypnotics to induce sleep.

circadian cycle A biologic system that has a 24-hour cycle.

circadian rhythm Physiologic and psychological functions that fluctuate in a pattern that repeats itself in a 24-hour cycle.

circumstantiality Extremely detailed and lengthy discourse about a topic.

clang association Repetition of word phrases that are similar in

sound but in no other way, for example, “right, light, sight, might.”

classical conditioning A learning situation in which an unconditioned stimulus initially produces an unconditioned response; over time, a conditioned response is elicited for a specific stimulus (Pavlov).

clearance Total amount of blood, serum, or plasma from which a drug is completely removed per unit of time.

clinical reasoning Using critical thinking and reflection to address patient problems and interventions.

closed group A group in which all the members begin at one time. New members are not admitted after the first meeting.

codependence An “enabling” method of coping in which an individual in a relationship with a person who abuses alcohol inadvertently reinforces the drinking behavior of the other person.

cognition A high level of intellectual processing in which perceptions and information are acquired, used, or manipulated; for Beck, verbal or pictorial events in the stream of consciousness. A person’s ability to think and know. An internal process of perception, memory, and judgment through which an understanding of self and the world is developed.

cognitive behavioral therapy A highly structured psychotherapeutic method used to alter distorted beliefs and problem behaviors by identifying and replacing negative inaccurate thoughts and changing the rewards for behaviors.

cognitive distortions Automatic thoughts generated by organizing distorted information or inaccurate interpretation of a situation.

cognitive interventions or cognitive therapy Interventions or psychotherapy that aims to change or reframe an individual’s automatic thought patterns that develop over time and that

interfere with the ability to function optimally.

cognitive reserve The brain's ability to operate effectively even when there is disruption in functioning.

cognitive schema Patterns of thoughts that determine how a person interprets events. Each person's cognitive schema screen, code, and evaluate incoming stimuli.

cognitive theory An outgrowth of different theoretic perspectives, including the behavioral and the psychodynamic, that attempts to link internal thought processes with human behavior.

cognitive triad Thoughts about oneself, the world, and the future.

cohesion The ability of a group to stick together.

co-leadership When two people share responsibility for leading a group.

commitment to treatment statement Statement in which a patient verbally or in writing agrees to seek treatment or access emergency services if needed.

communication blocks Interruptions in the content flow of communication, such changes in topic that either the nurse or patient makes.

communication disorders Disorders that involve speech or language impairments.

communication pathways An aspect of group interaction based on interaction patterns related to who is most liked in the group, who occupies a position of power, what subgroups have formed, and who is isolated from the group.

communication triad A technique used to provide a specific syntax and order for patients to identify and express their feelings and seek relief. The "sentence" consists of three parts: (1) an "I"

statement to identify the prevailing feeling, (2) a nonjudgmental statement of the emotional trigger, and (3) a statement of what the person would like differently or what would restore comfort to the situation.

comorbidity (comorbid) Presence of a disorder simultaneously with and independently of another disorder.

competence The degree to which the patient is able to understand and appreciate the information given during the consent process; the patient's cognitive ability to process information at a specific time; the patient's ability to gather and interpret information and make reasonable judgments based on that information to participate fully as a partner in treatment.

complicated grief A reaction to the loss of a loved one in which a person is frozen or stuck in a state of chronic mourning.

compliments Affirmations of the patient.

comprehensive family assessment The collection of all relevant data related to family health, psychological well-being, and social functioning to identify problems for which the nurse can generate nursing diagnoses.

compulsions Behaviors that are performed repeatedly, in a ritualistic fashion, with the goal of preventing or relieving anxiety and distress caused by obsessions.

concrete thinking Lack of abstraction in thinking in which people are unable to understand punch lines, metaphors, and analogies.

conditional release Discharge of patients whose psychiatric symptoms have been stabilized and are no longer considered a danger to the community. Patients are monitored on an ongoing basis by the court and must follow established conditions and criteria to maintain their discharged status.

conduct disorder A disorder characterized by more serious violations of social norms, including aggressive behavior, destruction of property, and cruelty to animals.

confabulation Telling a plausible but imagined scenario to compensate for memory gaps.

confidentiality An ethical duty of nondisclosure; the patient has the right to disclose personal information without fear of it being revealed to others.

conflict resolution A specific type of counseling in which the nurse helps the patient resolve a disagreement or dispute.

confrontation Presenting evidence of inconsistencies in a person's thoughts, feelings, and actions.

confused speech and thinking Symptoms of schizophrenia that render the patient unable to respond accurately to the ordinary signs and sounds of daily living.

connections Mutually responsive and enhancing relationships.

constraints Limitations that are both personal (internalized cultural values and beliefs) and environmental (finite resources such as money and time).

containment The process of providing safety and security; involves the patient's access to food and shelter.

content themes Repetition of concerns or feelings that occur within the therapeutic relationship. Themes may emerge as symbolic representations of fears.

continuum of care Providing care in an integrated system of settings, services (physical, psychological, and social), and care levels appropriate to the individual's specific needs in a continuous manner over time, with channels of communication among the service providers.

conventional antipsychotics Also known as typical antipsychotics, “older” medications used to treat psychotic disorders with more side effects than “newer” atypical antipsychotics.

conversion disorder (functional neurologic symptom disorder) When severe emotional distress or unconscious conflict is expressed through physical symptoms.

co-occurring disorders (COD) Refers to the presence of comorbid mental illness and a substance use disorder in the same person.

coordination of care The integration of appropriate services so that individualized care is provided. When several agencies are involved, this allows a person’s needs to be met without duplication of services.

coping A deliberate, planned, and psychological effort to manage stressful demands.

cortex Outermost surface of the cerebrum of the mature brain.

cortical dementia A type of dementia that is characterized by amnesia, aphasia, apraxia, and agnosia. Results from a disease process that globally affects the cortex.

counseling (counseling interventions) Specific time-limited interactions between a nurse and a patient, family, or group experiencing intermediate or ongoing difficulties related to their health or well-being.

countertransference The therapist or nurse’s reactions to a patient that are based on interpersonal experiences, feelings, and attitudes. It can significantly interfere with the nurse–patient relationship.

court process counseling An approach that educates mentally ill patients about the impending legal procedures and prepares them for courtroom appearances.

craving The urge or desire to engage in a behavior such as drinking.

crisis A time-limited event that triggers adaptive or non-adaptive responses to maturational, situational, or traumatic experiences; results from stressful events for which coping mechanisms fail to provide adequate adaptive skills to address the perceived challenge or threat.

crisis intervention A specialized short-term (usually no longer than 6 hours) goal-directed therapy designed to assist patients in an immediate manner; focuses on stabilization, symptom reduction, and prevention of relapse requiring inpatient services.

Crisis Intervention Teams (CIT) Teams that train police officers to recognize and intervene in crisis situations in the community and determine whether emergency psychiatric services are needed.

Critical Time Intervention (CTI) A “bridge” between inpatient and outpatient treatment by coordinating care between staff in these settings.

cue elimination Emotional and environmental cues are identified and alternative responses are suggested, tried, and reinforced. When a cue or stimulus leads to a dysfunctional or unhealthy response, the response can be eliminated or an alternate, healthier response to the cue can be substituted, tried, and then reinforced.

cultural brokering Act of bridging, linking, or mediating between groups or individuals of different cultural systems for the purpose of reducing conflict or producing change. Cultural competence is a set of academic and interpersonal skills that are respectful of and responsive to the health belief practices and cultural and linguistic needs of diverse patients to bring about positive health care outcomes.

cultural competence A set of academic and interpersonal skills that allows individuals to increase their understanding and appreciation of cultural differences and similarities within, among, and between

groups.

cultural identity A set of cultural beliefs with which one looks for standards of behavior; many consider themselves to have multiple cultural identities.

cultural idiom of distress A linguistic term, phrase, or a way of talking about suffering among individuals of a cultural group (*DSM-5*).

cultural syndrome A cluster or group of co-occurring symptoms found in a specific cultural group, community, or context.

culture Any group of people who identify or associate with each other on the basis of some common purpose, need, or similarity of background; the set of learned, socially transmitted beliefs, values, and behaviors that arise from interpersonal transactions among members of the cultural group.

cyberstalking Use of the Internet, e-mail, or other telecommunications technology to harass or stalk another person.

cycle of violence A three-phase pattern of tension, abuse, and kindness in which the abuser engages first in abuse and then in seemingly sincere expressions of love, contrition, and remorse.

cyclothymic disorder Chronic fluctuating mood disturbance. Does not meet criteria for hypomania or depressive disorder.

cytochrome P-450 (CYP450) system A set of microsomal enzymes (usually hepatic) referred to as CYP1, CYP2, and CYP3.

day treatment A bridge between institutional and community care for severely mentally ill and substance-abusing people. Participation in structured day treatment programs provides emotional and practical support and strengthens ties to community services and potentially to family and friends.

debriefing The reconstruction of the traumatic events by the victim

as a psychological intervention.

deescalation An interactive process of calming and redirecting a patient who has an immediate potential for violence directed at others or self.

defense mechanisms Coping styles; the automatic psychological process protecting the individual against anxiety and creating awareness of internal or external dangers or stressors.

deinstitutionalization Release of patients with severe and persistent mental illness from state mental hospitals into the community for treatment, support, and rehabilitation as the result of a national movement that began in the 1960s.

delayed ejaculation (DE) Delay or absence of ejaculation.

delirium A disorder of acute cognitive impairment that can be caused by a medical condition (e.g., infection) or substance abuse, or it may have multiple etiologies.

delirium tremens An acute symptom of alcohol withdrawal syndrome that is characterized by autonomic hyperarousal, disorientation, hallucinations, and tremors or grand mal (tonic-clonic) seizures.

delusional disorder A psychotic disorder characterized by delusions that occur in the absence of other psychiatric disorders; includes several subtypes: erotomania, grandiose, jealous, somatic, mixed, and unspecified. Individual can function fairly well and abnormal behavior is not observable.

delusions Erroneous fixed, false beliefs that cannot be changed by reasonable argument. They usually involve a misinterpretation of experience and are unchanged by reasonable arguments.

demands Pulls put on an individual's resources that are generated by physiologic and psychological needs. Includes external pulls

(crowding, crime, noise, pollution) imposed by the physical environment and internal pulls (behavior and role expectations) imposed by the social environment.

dementia From the Latin *de* (from or out of) and *mens* (mind); characterized by chronic cognitive impairments. It is differentiated from delirium by underlying cause, not by symptom patterns.

denial The patient's inability to accept loss of control over substance use or the severity of the consequences associated with substance abuse.

dependence The state of being psychologically or physiologically dependent on a drug after a prolonged period of use.

dependent personality Person who clings to others in a desperate attempt to keep them close. Their need to be taken care of is so great that it leads to doing anything to maintain the closeness, including total submission and disregard for self.

depersonalization A nonspecific experience in which the individual loses a sense of personal identity and feels strange or unreal.

depression The primary mood of depressive disorders defined as an overwhelming state of sadness, loss of interest or pleasure, feelings of guilt, disturbed sleep patterns and appetite, low energy, and an inability to concentrate.

depression not otherwise specified A category that includes disorders with depressive features that do not meet strict criteria for major depressive disorder.

depressive disorders Also referred to as unipolar depression, a specific subset of mood disorders consisting of major depression, dysthymia, and depression not otherwise specified (NOS).

derealization Feelings of unreality.

desensitization A rapid decrease in drug effects that may develop

within a few minutes of exposure to a drug.

desynchronized Two or more circadian rhythms reaching their peaks at different times.

deteriorating relationship A type of nontherapeutic relationship with several defined phases during which the patient and nurse feel very frustrated and keep varying their approach with each other in an attempt to establish a meaningful relationship.

detoxification Process of safely and effectively withdrawing a person from an addictive substance, usually under medical supervision.

developmental crisis A significant maturational event, such as leaving home for the first time, completing school, or accepting the responsibility of adulthood.

developmental delay An impairment of normal growth and development that may not be reversible. Delays slow a child's progress and can interfere with the development of self-esteem.

dialectical behavior therapy (DBT) An important biosocial approach to treatment that combines numerous cognitive and behavior therapy strategies. It requires patients to understand their disorders by actively participating in formulating treatment goals by collecting data about their own behavior, identifying treatment targets in individual therapy, and working with the therapists in changing these target behaviors.

diathesis A genetic predisposition that increases susceptibility to developing a disorder.

dichotomous thinking Evaluating experiences, people, and objects in terms of mutually exclusive categories (e.g., good or bad, success or failure, trustworthy or deceitful), which informs extreme interpretations of events that would normally be viewed as including both positive and negative aspects.

dietary restraint Instituting severe dieting (e.g., setting rules such as no sweets, no fats) to eliminate out-of-control feelings related to binge eating.

differentiation of self An individual's resolution of attachment to his or her family's emotional chaos. It involves an intrapsychic separation of thinking from feelings and an interpersonal freeing of oneself from the chaos.

difficult temperament Characterized by withdrawal from stimuli, low adaptability, and intense emotional reactions. Four key behaviors are present in a difficult temperament: aggression, inattention, hyperactivity, and impulsivity.

diminished emotional expression One of the core negative symptoms of schizophrenia.

direct leadership The leader controls the interaction of the group by giving directions and information and allowing little discussion.

disaster A sudden overwhelming catastrophic event that causes great damage and destruction that may involve mass casualties and human suffering that require assistance from all available resources.

disconnections Lack of mutually responsive and enhancing relationships.

disinhibition A concept borrowed from physics and biology and based on the idea of a dynamic, self-regulatory model of equilibrium in which equilibrium is defined (Piaget) as compensation for external disturbance; a mechanism for providing the self-regulation by which intelligence adapts to internal and external changes. A symptom of Alzheimer disease in which a patient acts on thoughts and feelings without exercising appropriate social judgment.

disorganized symptoms Symptoms of schizophrenia that make it difficult for the person to understand and respond to the ordinary sights and sounds of daily living. These include confused speech and thinking and disorganized behavior.

dissociation A disruption in the normally occurring linkages among subjective awareness, feelings, thoughts, behavior, and memories (i.e., a person is physically present but mentally in another place).

distraction The purposeful focusing of attention away from undesirable sensations.

distribution The amount of a drug that may be found in various tissues at the site of the drug action for which it is intended.

disturbance of executive functioning Problems in the ability to think abstractly, plan, initiate, sequence, monitor, and stop complex behavior.

dopamine An excitatory neurotransmitter found in distinct regions of the central nervous system involved in cognition, motor, and neuroendocrine function.

dosing Administration of medication over time so that therapeutic levels may be achieved or maintained without reaching toxic levels.

drive for thinness A characteristic of anorexia nervosa in which individuals experience an intense physical and emotional drive to be thinner that overrides all physiologic body cues.

drug–drug interaction Reaction of two or more drugs with each other; may cause unexpected side effects. Can occur if one substance inhibits an enzyme system.

DSM-IV-TR Abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision; contains criteria for the diagnosis of mental disorders.

DSM-5 Abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, which provides revised diagnostic criteria for mental disorders.

dual process model A model of bereavement where a person adjusts to loss by oscillating between loss-oriented coping that includes preoccupation with the deceased and restoration-oriented coping in which the bereaved is preoccupied with stressful events as a result of the death.

dyad A group of only two people who are usually related, such as a married couple, siblings, or parent and child.

dysfunctional The state of a group, such as a family, whose interactions, decisions, or behaviors interfere with the positive development of the group as a whole and its individual members.

dysfunctional consequences Part of the “C” in the ABCDE framework of rational emotive behavior therapy. The result of the interaction between A (an activating event) and B (the person’s belief system) that follows from absolute, rigid, irrational beliefs.

dyslexia Significantly lower score for mental age on standardized test in reading that is not caused by low intelligence or inadequate schooling.

dyspareunia Pain during sexual intercourse.

dysphagia Difficulty swallowing.

dysphoric (mood) Depressed, disquieted, or restless.

dysthymic disorder A milder but more chronic form of major depressive disorder that is diagnosed when the depressed mood is present for most days for at least 2 years with two or more of the following symptoms: poor appetite or overeating, insomnia or oversleeping, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feelings of

hopelessness.

dystonia An impairment in muscle tone that is generally the first extrapyramidal symptom to occur, usually within a few days of initiating an antipsychotic. Dystonia is characterized by involuntary muscle spasms, especially of the head and neck muscles.

early intervention programs Community outreach efforts designed to work with infants and preschool-aged children and their caretakers to foster healthy physical, psychological, social, and intellectual development.

early recognition Anticipating aggressive behavior based on the premise that even though behavior is idiosyncratic, it is reconstructable and therefore can provide early signs when violent behavior is likely.

echolalia Repetition of another's words that is parrot like and inappropriate.

echopraxia Involuntary imitation of another person's movements and gestures.

efficacy Ability of a drug to produce a response.

egocentric thinking A type of thinking in which children naturally view themselves as the center of their own universe.

egocentrism Tendency to view the world as revolving around oneself. A preoccupation with one's own appearance, behavior, thoughts, and feelings.

elation Feeling "high," "ecstatic," "on top of the world," or "up in the clouds."

elder abuse Abuse or neglect of adults older than 60 years of age.

elder mistreatment Actions (or inaction) by caregivers or trusted

persons that cause harm or the possibility of harm to a vulnerable older adult.

elevated mood A mood that is expressed as euphoria (exaggerated feelings of well-being) or elation (feeling “high,” “ecstatic,” “on top of the world,” or “up in the clouds”).

e-mental health The use of electronics and the Internet to provide assessment and interventions.

emotion-focused coping A type of coping in which a person reduces stress by reinterpreting the situation to change its meaning.

emotions Psychophysiologic reaction that defines a person’s mood and can be categorized as negative (anger, fright, anxiety guilt, shame, sadness, envy, jealousy, and disgust), positive (happiness, pride, relief, and love), borderline (hope, compassion, empathy, sympathy, and contentment), or nonemotions (confidence, awe, confusion, excitement).

emotional cutoff If a member cannot differentiate from his or her family, that member may flee from the family either by moving away or avoiding personal subjects of conversation. A brief visit from parents can render these individuals helpless.

emotional dysregulation Inability to control emotion in social interactions.

emotional vulnerability Sensitivity and reactivity to environmental stress.

empathic linkage Ability to feel in oneself the feelings being expressed by another person or persons.

empathy The ability to experience, in the present, a situation as another did at some time in the past; the ability to put oneself in another person’s circumstances and feelings.

empty nest A home devoid of children and caregiving

responsibilities.

encopresis Soiling clothing with feces or depositing feces in inappropriate places.

endorphins Neurotransmitters that have opiate-like behavior and produce an inhibitory effect at opioid receptor sites; probably responsible for pain tolerance.

engagement Establishing a treatment relationship and enhancing motivation to make behavior changes and a commitment to treatment.

enmeshment An extreme form of intensity in family interactions that results in low individual autonomy in a family.

enuresis Involuntary excretion of urine after the age at which a child should have attained bladder control.

enzymes Any of numerous proteins that act as catalysts for physiologic reactions and can be targets for drugs.

epidemiology The study of patterns of disease distribution and determinants of health within populations; contributes to the overall understanding of the mental health status of population groups, or aggregates, and associated factors.

erectile dysfunction Inability of a man to achieve or maintain an erection sufficient for completion of sexual activity.

erotomanic Subtype of delusional disorder characterized by the delusional belief that the person is loved intensely by the “loved object,” who is usually married and of a higher socioeconomic status or otherwise unattainable.

ethnopsychopharmacology The study of cultural variations and differences that influence the effectiveness of pharmacotherapies used in mental health; includes genetics and psychosocial factors.

euphoria An exaggerated feeling of well-being.

euphoric (mood) An elated mood.

euthymic (mood) A normal mood.

evidence-based practice The use of current best evidence in making decisions; the search for and appraisal of the most relevant evidence to answer a clinical question.

exception questions Questions used to help the patient identify times when whatever is bothering him or her is not present or is present with less intensity based on the underlying assumption that during these times the patient is usually doing something to make things better.

excitement Phase of the human sexual response cycle marked by erotic feelings that lead to penile erection in men and vaginal lubrication in women. Heart rate and respirations also increase.

excretion The removal of drugs from the body either unchanged or as metabolites.

expansive mood A mood characterized by inappropriate lack of restraint in expressing one's feelings and frequently overvaluing one's own importance. Expansive qualities include an unceasing and indiscriminate enthusiasm for interpersonal, sexual, or occupational interactions.

exposure therapy The treatment of choice for agoraphobia in which the patient is repeatedly exposed to real or simulated anxiety-provoking situations until he or she becomes desensitized and anxiety subsides.

extended family Several nuclear families who may or may not live together and who function as one group.

external advocacy system Organizations that operate independently of mental health agencies and serve as advocates for the treatment

and rights of mental health patients.

externalizing disorders Disorders that are characterized by acting-out behavior.

extinction The loss of a learned conditioned emotional response after repeated presentations of the conditioned fear stimulus without a contiguous traumatic event.

extrapyramidal motor system Collection of neuronal pathways that provides significant input in involuntary motor movements; a bundle of nerve fibers connecting the thalamus to the basal ganglia and cerebral cortex.

extrapyramidal side effects See *extrapyramidal syndromes*.

extrapyramidal symptoms (EPS) Acute abnormal movements developing early in the course of treatment with antipsychotic agents. Include dystonia, pseudoparkinsonism, and akathisia.

factitious disorder A type of psychiatric disorder characterized by somatization in which the person intentionally causes an illness for the purpose of becoming a patient.

factitious disorder on another Sometimes called Munchausen's by proxy; involves a person who inflicts injury on another person in order to gain the attention of a health care provider (i.e., a mother who inflicts injury on her child).

fairness In the criminal judicial process, a term meaning that the individual who is charged with a crime should know the legal rules and be able to explain the events surrounding the alleged crime or be "fit to stand trial."

family A group of people connected by birth, adoption, or marriage who have a shared history and future.

family development A broad term that refers to all the processes connected with the growth of a family, including changes

associated with work, geographic location, migration, acculturation, and serious illness.

family dynamics The patterned interpersonal and social interactions that occur within the family structure over the life of a family.

family life cycle A process of expansion, contraction, and realignment of relationship systems to support the entry, exit, and development of family members.

family preservation Efforts made by professionals to preserve the family unit by preventing the removal of children from their homes through parental support and education and through work to facilitate a secure attachment between the child and parent.

family projection process In a triangulated family situation, the triangulated member becomes the center of family conflicts.

family structure According to Minuchin, the organized pattern within which family members interact.

fear conditioning A type of classic conditioning that occurs when a neutral stimulus (the conditioned stimulus [CS]) is paired with an aversive unconditioned stimulus (US) that elicits an unconditioned fear response (UR). After repeated pairing, the CS alone will elicit the fear response, which is now the conditioned response (CR).

fetal alcohol syndrome A syndrome that occurs in infants whose mothers abuse alcohol during pregnancy; includes symptoms such as permanent brain damage, often resulting in mental retardation.

fetishism When an object such as women's undergarments or foot apparel is used for sexual arousal.

fidelity Faithfulness to obligations and duties.

first-pass effect Metabolism of part of oral drugs after being absorbed from the gastrointestinal tract and carried through the portal circulation to the liver. Only part of the drug dose reaches

systemic circulation.

fitness to stand trial Ability to consult with a lawyer with a reasonable degree of rational understanding of the facts of the alleged crime and of the legal proceedings.

flight of ideas Repeated and rapid changes in the topic of conversation, generally after just one sentence or phrase.

flooding A technique used to desensitize the patient to the fear associated with a particular anxiety-provoking stimulus. Desensitizing is done by presenting feared objects or situations repeatedly without session breaks until the anxiety dissipates.

forensic In mental health, a term that pertains to legal proceedings and mandated treatment of persons with a mental illness.

forensic examiner A mental health specialist, usually a psychiatrist or psychologist, who is certified as a forensic examiner and assigned by the judge to assess and testify to the patient's competency and responsibility for the crime, including the mental state at the time of an offense.

formal group roles The designated leader and members of a group.

formal operations The ability to use abstract reasoning to conceptualize and solve problems.

formal support system Large organizations that provide care to individuals, such as hospitals and nursing homes.

frontal, parietal, temporal, occipital lobes Lobes of the brain located on the lateral surface of each hemisphere.

frotteurism A paraphilia characterized by sexually arousing urges, fantasies, and behaviors resulting from touching or rubbing one's genitals against the breasts, genitals, or thighs of a nonconsenting person.

functional activities Activities of daily living necessary for self-care (i.e., bathing, toileting, dressing, and transferring).

functional consequences Part of the “C” in the ABCDE framework of rational emotive behavior therapy. The results of the interaction between A (an activating event) and B (a person’s belief system) that follow from flexible, rational beliefs.

functional imaging The aspect of neuroimaging that visualizes processing of information.

functional neurologic symptoms New name recommended to replace conversion disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), for which severe emotional distress or unconscious conflict is expressed through physical symptoms.

functional status Extent to which a person has the ability to carry out independent personal care, home management, and social functions in everyday life in a way that has meaning and purpose.

GABA Gamma-aminobutyric acid, the primary inhibitory neurotransmitter for the central nervous system (CNS). The pathways of GABA exist almost exclusively in the CNS, with the largest GABA concentrations in the hypothalamus, hippocampus, basal ganglia, spinal cord, and cerebellum.

gambling disorder (also referred to as pathologic gambling) Persistent and recurrent gambling leading to clinically significant impairment or distress.

gate-control theory The leading explanation of pain; holds that neurologic gates can either inhibit or allow pain signals to be transmitted to the brain. Led to the recognition that there is not a single pain mechanism but that the processing of pain occurs on at least three levels—peripheral, spinal, and supraspinal.

gender, culture, and ethnic differences Factors that must be taken

into consideration before planning interventions; for example, when considering interventions for the expression of anger, cultural norms should be understood.

gender dysphoria Incongruence between an individual's experienced/expressed gender and assigned gender.

gender identity A sense of self as being male or female.

gender identity disorders A category of dysfunction in which there is a persistent cross-gender identification with accompanying discomfort about one's assigned sex.

genetic susceptibility A concept that suggests that an individual may be at increased risk for a psychiatric disorder based on genetic transmission.

genogram A multigenerational schematic diagram that lists family members and their relationships.

geropsychiatric nursing assessment The comprehensive, deliberate, and systematic collection and interpretation of biopsychosocial data that is based on the special needs and problems of older adults.

gerotranscendence A concept of Erikson; continued growth in dimensions such as spirituality and inner strength during old age.

glutamate The most widely distributed excitatory neurotransmitter; the main transmitter in the associational areas of the cortex.

grandiosity Elevated self-esteem.

grief An intense, biopsychosocial response that often includes spontaneous expressions of pain, sadness, and desolation, such as with the loss of a loved one.

group Two or more people who develop interactive relationships and share at least one common goal or issue.

group dynamics All of the verbal and nonverbal interactions within groups.

group process The culmination of the session-to-session interactions of the members that move the group toward its goals.

group themes The collective conceptual underpinnings of a group that express the members' underlying concerns or feelings, regardless of the group's purpose.

groupthink The tendency of many groups to avoid conflict and adopt a normative pattern of thinking that is often consistent with the group leader's ideas.

guided imagery The purposeful use of imagination to achieve relaxation or direct attention away from undesirable sensations.

guilty but mentally ill (GBMI) Persons with a mental illness who demonstrate they knew the wrongfulness of their actions and had the ability to act otherwise.

half-life The time required for plasma concentrations of a drug to be reduced by 50%.

hallucinations Perceptual experiences that occur in the absence of actual external sensory stimuli and may be auditory, visual, tactile, gustatory, or olfactory.

hallucinogen A class of drug that produces euphoria or dysphoria, altered body image, distorted or sharpened visual and auditory perception, confusion, uncoordination, and impaired judgment and memory.

harm reduction A community health intervention designed to reduce the harm of substance use to the individual, the family, and society that has replaced a moral or criminal approach to drug use and addiction.

hippocampus Subcortical gray matter embedded within each

temporal lobe of the brain that may be involved in determining the best way to store information, especially the emotions attached to a memory.

histamine A neurotransmitter derived from the amino acid histidine that originates predominantly in the hypothalamus and projects to all major structures in the cerebrum, brain stem, and spinal cord. Its functions are not well known, but it appears to have a role in autonomic and neuroendocrine regulation.

histrionic personality Type of person who could be described as “attention seeking,” “excitable,” and “emotional,” with an insatiable need for attention and approval. Also tend to be highly dependent on others, making them overly trusting and gullible. They are moody and experience helplessness when others are disinterested in them. They are also sexually seductive in attempts to gain attention are often uncomfortable within a single relationship.

HIV-associated neurocognitive disorder (HAND) One of the most common CNS manifestations of HIV, it is a chronic neurodegenerative condition characterized by cognitive, central motor, and behavioral changes. HAND can affect any psychologic domain, but the most commonly reported deficits are in attention and concentration, psychomotor speed, memory and learning, information processing, and executive function.

home visits Delivery of nursing care in a patient’s living environment.

homelessness State of being without a consistent residence or living in nighttime residences that are temporary shelters or any place not designated as sleeping accommodations.

homeostasis The body’s tendency to resist physiologic change and hold bodily functions relatively consistent, well-coordinated, and

usually stable. Introduced as a concept by Walter Cannon in the 1930s.

hopelessness A belief that nothing positive will happen or negative events will occur.

hostile aggression Aggression that is intended solely to inflict injury or pain on the victim with no reward or advantage to the aggressor.

Housing First A mental health approach that places people who are homeless, usually also experiencing severe mental illness, substance abuse, or release from prison, into affordable housing.

human sexual response cycle A theory of sexual response described by Masters and Johnson (1966) as consisting of four phases: excitement, plateau, orgasm, and resolution.

hyperactivity Excessive motor activity, movement, or utterances that may be either purposeless or aimless.

hyperalgia Increased sensation of pain.

hyperesthesia Increased nociceptor sensitivity.

hyperkinetic delirium A type of delirium in which the patient demonstrates behaviors most commonly recognized as delirium, including psychomotor hyperactivity, marked excitability, and a tendency toward hallucinations.

hypersexuality Inappropriate and socially unacceptable sexual behavior.

hypervigilance Sustained attention to external stimuli as if expecting something important or frightening to happen.

hypervocalization Screams, curses, moans, groans, and verbal repetitiveness that are common in the later stages of cognitively impaired older adults, often occurring during a hospitalization or nursing home placement.

hypnagogic hallucinations Intense dream-like images that occur when an individual is falling asleep and usually involve the immediate environment.

hypnotic Medication that causes drowsiness and facilitates the onset and maintenance of sleep.

hypochondriasis When individuals are fearful of developing a serious illness based on their misinterpretation of body sensations.

hypofrontality Reduced cerebral blood flow and glucose metabolism in the prefrontal cortex.

hypokinetic delirium A type of delirium in which the patient is lethargic, somnolent, and apathetic and exhibits reduced psychomotor activity.

hypomania A mild form of mania.

hypomanic episode A less intense manic episode in which there is little impairment in social or occupational functioning and normal judgment is mostly intact.

identity diffusion Occurs when parts of a person's identity are absent or poorly developed; a lack of consistent sense of identity.

illness anxiety disorder A preoccupation with having or acquiring a serious, undiagnosed medical illness, but somatic symptoms are not present or, if present, only mild.

illusions Disorganized perceptions that create an oversensitivity to colors, shapes, and background activities, which occur when the person misperceives or exaggerates stimuli in the external environment.

imagery rehearsal therapy A technique in which patients change the endings of the nightmares while awake.

impaired consciousness Less environmental awareness and loss of

the ability to focus, sustain, and shift attention. Associated cognitive changes include problems in memory, orientation, and language.

implosive therapy A provocative technique useful in treating agoraphobia in which the therapist identifies individual phobic stimuli for the patient and then presents highly anxiety-provoking imagery in a dramatic, vivid fashion.

impulse-control disorders A disorder that often coexists with other disorders. Characterized by an inability to resist an impulse or temptation to complete an activity that is considered harmful to oneself or others.

impulsiveness The tendency to act on urges, notions, or desires without adequately considering the consequences.

impulsivity Acting without considering the consequences of the act or alternative actions.

incidence A rate that includes only new cases that have occurred within a clearly defined time period.

incompetent A person is legally determined not to be able to understand and appreciate the information given during the consent process.

indirect leadership Leader who primarily reflects the group members' discussion and offers little guidance or information to the group.

individual roles Group roles that either enhance or detract from the group's functioning but have nothing to do with either the group task or maintenance.

inducer Drugs or substances that speed up metabolism, which in turn increases the clearance of the substrate and decreases its plasma level.

informal caregivers Unpaid individuals who provide care.

informal group roles Positions within the group with implicit rights and duties that can either help or hinder the group's process. These positions are not formally sanctioned.

informal support systems Family members, friends, and neighbors who can provide care and support to an individual.

informed consent The right mandated by state laws for a patient to determine what shall be done with one's own body and mind. To provide informed consent, the patient must be given adequate information on which to base decisions about care and actively participate in the decision-making process.

inhalants Organic solvents, also known as volatile substances, that are central nervous system depressants and when inhaled cause euphoria, sedation, emotional lability, and impaired judgment.

inhibited grieving A pattern of repetitive, significant trauma and loss together with an inability to fully experience and personally integrate or resolve these events.

inhibitor Drugs or substances that slow down metabolism, which in turn decreases the clearance of the substrate and elevates its plasma level.

in-home mental health care The provision of skilled mental health nursing care under the direction of a psychiatrist or physician for individuals in their residences. Emphasizes personal autonomy of patient.

insight The ability of the individual to be aware of his or her own thoughts and feelings and to compare them with the thoughts and feelings of others.

insomnia (initial) Difficulty falling asleep.

institutionalization The forced confinement of individuals for long

periods of time in large state hospitals. This was the primary treatment for people with mental illness in the period from 1900 to 1955.

instrumental activities of daily living (IADLs) Activities that facilitate or enhance the performance of activities of daily living (e.g., shopping, using the telephone, transportation); these aspects are critical to consider for any older adult living alone.

instrumental aggression Aggression that provides some reward or advantage to the aggressor, is premeditated, and is unrelated to the person's pain.

integrated treatment Treatment for both mental illness and substance use disorders is combined in a single session or interaction or series of interactions.

intellectual disability Limitations in intellectual functioning and adaptive behavior that develop before the age of 18 years. The term is currently used interchangeably with *mental retardation*.

intensive case management An approach targeted for adults with serious mental illnesses or children with serious emotional disturbances. Managers of such cases have fewer caseloads and higher levels of professional training than do traditional case managers.

intensive outpatient program Program focused on continued stabilization and prevention of relapse in vulnerable individuals who have returned to their previous lifestyle (i.e., job or school), usually with sessions running 2 to 3 days per week and lasting 3 to 4 hours per day.

intensive residential services Intensively staffed residential care and mental health services that may include medical, nursing, psychosocial, vocational, recreational, or other support services. May be short or long term.

intergenerational transmission of violence Social learning theory concept that explains the process of violence being transmitted from one generation to the next. Children who witness violence in their homes often perpetuate violent behavior in their families as adults.

intermittent explosive disorder Impulse-control disorder characterized by episodes of uncontrolled aggressiveness that result in assault or destruction of property; the severity of aggressiveness is out of proportion to the provocation.

internal rights protection system Patient protective mechanisms developed by the U.S. mental health care system's organizations to help combat any violation of mental health patients' rights, including investigating any incidents of abuse or neglect.

internalizing disorders Disorders of mood, such as anxiety disorders and depression, in which the symptoms tend to be within the individual.

interoceptive awareness The sensory response to emotional and visceral cues, such as hunger.

interoceptive conditioning Pairing a somatic discomfort, such as dizziness or palpitations, with an impending panic attack.

interpersonal functioning Ability to relate to others with empathy or intimacy.

interpersonal relations Characteristic interaction patterns that occur between human beings that are the basis of human development and behavior and the health or sickness of one's personality.

intervention fit Finding and implementing interventions that are appropriate to a patient's particular needs and circumstances.

intimate partner violence (IPV) Defined by the Centers for Disease Control and Prevention (2009) as psychological, physical, or

sexual harm perpetrated by a current or former spouse or partner.

intrinsic activity The ability of a drug to produce a biologic response when it becomes attached to its receptor.

introspective The self-examination of personal beliefs, attitudes, and motivations.

intrusion Thoughts, memories, or dreams of traumatic events occur involuntarily, especially when there are cues that symbolize or resemble the events, causing psychological and sometimes physiological distress.

invalidating environment A highly personal social situation that negates the individual's emotional responses and communication.

invincibility fable An aspect of egocentric thinking in adolescence that causes teens to view themselves as immune to dangerous situations and death.

involuntary commitment The confined hospitalization of a person without his or her consent but with a court order (because the person has been judged to be a danger to him- or herself or others).

inwardly directed anger Anger that is stifled despite strong arousal.

irritable mood Being easily annoyed and provoked to anger, particularly when wishes are challenged or thwarted.

ischemic cascade Cell breakdown resulting from brain cell injury.

judgment The ability to reach a logical decision about a situation and to choose a course after looking at and analyzing various possibilities.

justice Duty to treat all fairly, distributing the risks and benefits equally.

kleptomania A disorder in which the patient is unable to resist the

urge to steal and independently steals items that he or she could easily afford. These items are not particularly useful or wanted. The underlying issue is the act of stealing.

Korsakoff amnestic syndrome An amnestic syndrome associated with alcoholism in which there is a problem acquiring new information and retrieving memories involving the heart and vascular and nervous systems; considered to be the chronic stage of Wernicke–Korsakoff syndrome.

label avoidance Type of stigma that occurs when an individual avoids treatment or care in order not to be labeled as being mentally ill.

labile (lability of mood) Changeable mood.

late adulthood The period of life beginning at age 65 years; divided into three chronologic groups: young-old, middle-old, and old-old.

learning disorder A discrepancy between actual achievement and expected achievement that is based on a person's age and intellectual ability.

least restrictive environment The patient has the right to be treated in the least restrictive environment possible for the exercise of free will; an individual cannot be restricted to an institution when he or she can be successfully treated in the community.

lethality The probability that a person will successfully complete suicide, determined by the seriousness of the person's intent and the likelihood that the planned method of death will succeed.

libido The energy or psychic drive associated with the sexual instinct that resides in the id, literally translated from Latin to mean "pleasure" or "lust."

life events Major times or experiences such as marriage, divorce, and bereavement.

limbic system (limbic lobe) A “system” of several small structures within the brain that work in a highly organized way. These structures include the hippocampus, thalamus, hypothalamus, amygdala, and limbic midbrain nuclei.

linguistic competence The ability to communicate in a way that is easily understood by diverse audiences.

living will An advanced care directive that states what treatment should be omitted or refused in the event that a person is unable to make those decisions because of incapacitation.

locus coeruleus A tiny cluster of neurons that fans out and innervates almost every part of the brain, including most of the cortex, the thalamus and hypothalamus, the cerebellum, and the spinal cord.

loose associations Absence of the normal connectedness of thoughts and ideas; sudden shifts without apparent relationship to preceding topic.

loss-oriented coping Part of the dual process model of bereavement that includes preoccupation with the deceased.

luminotherapy Light therapy used to manipulate the circadian system.

maintenance roles The informal role of group members that encourages the group to stay together.

major depressive episodes A depressed mood or a loss of interest or pleasure in nearly all activities for at least 2 weeks. Four of seven additional symptoms must be present: disruption in sleep, appetite (or weight), concentration, or energy; psychomotor agitation or retardation; excessive guilt or feelings of worthlessness; and suicidal ideation.

maladaptive anger Excessive outwardly directed anger or

suppressed anger; linked to psychiatric conditions, such as depression, as well as medical conditions.

malinger To produce illness symptoms intentionally with an obvious self-serving goal such as being classified as disabled or avoiding work.

mania A symptom of bipolar disorder that is primarily characterized by an abnormally and persistently elevated, expansive, or irritable mood.

manic episode A distinct period during which there is an abnormally and persistently elevated, expansive, or irritable mood.

maturation Healthy development of the brain and nervous system during childhood and adolescence.

medical battery Intentional and unauthorized (without informed consent) treatment that is harmful or offensive.

memory One aspect of cognitive function; an information storage system composed of short-term memory (retention of information over a brief period of time) and long-term memory (retention of an unlimited amount of information over an indefinite period of time); the ability to recall or reproduce what has been learned or experienced.

mental disorders Health conditions characterized by alterations in thinking, mood, or behavior. They are associated with distress or impaired functioning.

mental health The emotional and psychological well-being of an individual who has the capacity to interact with others, deal with ordinary stress, and perceive one's surroundings realistically.

mental health recovery A journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice while striving

to achieve his or her full potential.

mental status examination An organized systematic approach to assessment of an individual's current psychiatric condition.

metabolism Biotransformation, or the process by which a drug is altered and broken down into smaller substances, known as metabolites.

metabolites Result when drugs are altered and broken down into smaller substances by metabolism. Substance necessary for or taking part in a particular metabolic process.

methadone maintenance The treatment of opioid addiction with a daily, stabilized dose of methadone.

metonymic speech Use of words with similar meanings interchangeably.

middle-age adulthood A term used to describe adults approximately ages 45 to 65 years.

middle-old A term used to describe adults ages 75 to 84 years.

mild cognitive impairment (MCI) A transitional state between normal cognition and Alzheimer disease.

milieu therapy An approach that provides a stable and coherent social organization to facilitate an individual's treatment; often used interchangeably with *therapeutic environment*. The design of the physical surroundings, structure of patient activities, and promotion of a stable social structure and cultural setting enhance the setting's therapeutic potential.

military sexual trauma (MST) Sexual assault and sexual Harassment experienced during a veteran's military service.

military veteran Persons who served in the armed forces.

miracle questions Patients are asked to use their imagination in

crafting their response to very specific questions about a scenario.

mixed episode When mania and depression occur at the same time, which leads to extreme anxiety, agitation, and irritability.

mixed variant delirium Behavior that fluctuates between the hyperactive and hypoactive states.

modeling Pervasive imitation; one person trying to be similar to another person.

mood The prominent, sustained, overall emotions that a person expresses and exhibits; influences one's perception of the world and how one functions.

mood disorder Recurrent disturbances or alterations in mood that cause psychological distress and behavioral impairment.

mood episode A severe mood change that lasts at least 2 weeks that causes clinically significant distress or impairment.

mood lability The rapid shifts in moods that often occur in patients with bipolar disorder with little or no change in external events.

moral injury The lasting psychological, biological, spiritual, behavioral, and social impact of perpetrating, failing to prevent, or bearing witness to acts that transgress deeply held moral beliefs and expectations.

moral treatment An approach to curing mental illness, popular in the 1800s, that was built on the principles of kindness, compassion, and a pleasant environment.

motivation A goal-oriented attitude that propels action for change and can help sustain the development of new activities and behaviors.

motivational interventions One to several sessions delivered within a few weeks or less during which a patient is motivated to become

involved in treatment.

motivational interviewing A method of therapeutic intervention often used with those with substance abuse that seeks to elicit self-motivational statements from patients, supports behavioral change, and creates a discrepancy between the patient's goals and his or her continued alcohol and other drug use.

motor tics Usually quick, jerky movements of the eyes, face, neck, and shoulders, although they may involve other muscle groups as well.

multigenerational transmission process The transmission of emotional processes from one generation to the next.

multiple sleep latency test (MSLT) A standardized procedure that measures the amount of time a person takes to fall asleep during a 20-minute period.

Munchausen syndrome Term (no longer used) used to describe the most severe form of factitious disorder characterized by fabricating a physical illness, having recurrent hospitalizations, and going from one provider to another.

narcissistic personality Person who could be described as grandiose, with an inexhaustible need for admiration. Beginning in childhood, they believe themselves to be superior, special, and unique, and want recognition for such. They also lack empathy.

negative symptoms A lessening or loss of normal functions, such as restriction or flattening in the range of intensity of emotion; reduced fluency and productivity of thought and speech; withdrawal and inability to initiate and persist in goal-directed activity; and inability to experience pleasure.

negligence A breach of duty of reasonable care for a patient for whom the nurse is responsible that results in personal injuries. A clinician who does get consent but does not disclose the nature of

the procedure and the risks involved is subject to a negligence claim.

neologisms Words that are made up that have no common meaning and are not recognized.

neurocircuitry The complex neural functional networks that link brain structures, including the prefrontal cortex, striatum, hippocampus, and amygdala. Research indicates that a dysfunctional neurocircuitry underlies most psychiatric disorders.

neurocognitive impairment An impairment in memory, vigilance, verbal fluency, and executive functioning that exists in schizophrenia. May be independent of positive and negative symptoms.

neurodevelopmental delay When a child's development in attention, cognition, language, affect, and social or moral behavior is outside the norm. It is manifested by delayed socialization, communication, peculiar mannerisms, and idiosyncratic interests.

neurofibrillary tangles Fibrous proteins, or *tau proteins*, that are chemically altered and twisted together and spread throughout the brain, interfering with nerve functioning in cholinergic neurons. It is hypothesized that formation of these neurofibrillary tangles is related to the apolipoprotein E4 (apoE4).

neurohormones Hormones produced by cells within the nervous system, such as antidiuretic hormone (ADH).

neuroleptic malignant syndrome A life-threatening condition that can develop in reaction to antipsychotic medications. Patients develop severe muscle rigidity with elevated temperature and a rapidly accelerating cascade of symptoms (occurring during the next 48 to 72 hours), which can include two or more of the following: hypertension, tachycardia, tachypnea, prominent diaphoresis, incontinence, mutism, leukocytosis, changes in level

of consciousness, and laboratory evidence of muscle injury.

neuromodulators Chemical messengers that make the target cell membrane or postsynaptic membrane more or less susceptible to the effects of the primary neurotransmitter.

neuron Nerve cells responsible for receiving, organizing, and transmitting information. Each neuron has a cell body, or soma, which holds the nucleus containing most of the cell's genetic information.

neuropeptides Short chains of amino acids that exist in the central nervous system and have a number of important roles, including as neurotransmitters, neuromodulators, or neurohormones.

neuroplasticity The continuous process of modulation of neuronal structure and function in response to the changing environment.

neurosis A category used by Freud and his followers to define those with less severe mental illness but who were often distressed about their problems.

neurotransmitters Small molecules that directly and indirectly control the opening or closing of ion channels.

night terrors Episodes of screaming, fear, and panic while sleeping, causing clinical distress or impairing social, occupational, or other areas of functioning.

nociceptors Pain receptors.

nonbizarre delusions Beliefs that are characterized by adherence to possible situations that could appear in real life and are plausible in the context of the person's ethnic and cultural background.

nonmaleficence The duty to cause no harm, both individually and for all.

non-rapid eye movement (NREM) sleep A sleep cycle state of

non-rapid eye movement that occurs about 90 minutes after falling asleep.

nontherapeutic relationship A nontrusting relationship between the nurse and patient. Both feel very frustrated and keep varying their approach with each other in an attempt to establish a meaningful relationship.

nonverbal communication The gestures, expressions, and body language used in communications.

norepinephrine An excitatory neurochemical that plays a major role in generating and maintaining mood states. Heavily concentrated in the terminal sites of sympathetic nerves, it can be released quickly to ready the individual for a fight-or-flight response to threats in the environment.

normal aging Changes that occur with age associated with some physical decline, such as decreased sensory abilities and decreased pulmonary and immune function, but many important functions do not change.

normalization Teaching families what are normal behaviors and expected responses.

not guilty by reason of insanity (NGRI) Persons who demonstrate they had no understanding of their actions and no control over them when they committed the crime.

nuclear family Two or more people related by blood, marriage, or adoption.

nuclear family emotional process Patterns of emotional functioning in a family within single generations.

nurse-patient relationship A dynamic, time-limited interpersonal process that can be viewed in steps or phases with characteristic behaviors during each phase for both the patient and the nurse.

nursing diagnosis A clinical judgment about the individual, family, or community response to actual or potential health problems and life processes. It provides the basis for the selection of interventions and outcomes.

nursing interventions Nursing actions or treatment, selected based on clinical judgment, that are designed to achieve patient, family, community outcomes; can be direct or indirect.

nursing process The basis of clinical decision-making for evidence-based practice.

object relations The psychological attachment to another person or object.

obsessions Excessive, unwanted, intrusive, and persistent thoughts, impulses, or images that cause anxiety and distress and are incongruent with the patient's usual thought patterns.

obsessive-compulsive personality disorder (OCPD) Persons with OCPD do not demonstrate obsessions and compulsions but rather a pervasive pattern of preoccupation with orderliness, perfectionism, and control. They attempt to maintain control by careful attention to rules, trivial details, procedures, and lists.

oculogyric crisis A medication side effect resulting from an imbalance of dopamine and acetylcholine in which the muscles that control eye movements tense and pull the eyeball so that the patient is looking toward the ceiling; may be followed by torticollis or retrocollis.

off-label Use of medication for a condition that is not approved by the Food and Drug Administration.

old-old A term used to describe adults ages 85 years and older.

open communication Staff and patient willingly share information about relevant topics.

open group A group in which new members can join at any time, and old members may leave at different sessions.

operant behavior A type of learning that is a consequence of a particular behavioral response, not a specific stimulus.

opioid Any substance that binds to an opioid receptor in the brain to produce an agonist action.

oppositional defiant disorder A disruptive behavior disorder characterized by a persistent pattern of disobedience; argumentativeness; angry outbursts; low tolerance for frustration; and tendency to blame others for misfortunes, large and small.

orgasmic disorder The inability to reach orgasm or reduced intensity by any means.

orgasmic phase Phase in the human sexual response cycle that includes ejaculation of semen for men and rhythmic contractions of the vaginal muscles for women.

orientation phase The first phase of the nurse–patient relationship in which the nurse and the patient get to know each other. During this phase, the patient develops a sense of trust.

oscillation Part of the dual process model of bereavement that involves a person moving between the process of confronting (loss-oriented coping) and avoiding (restoration-oriented coping) the stresses associated with bereavement.

outcomes A patient's response to care received; the end result of the process of nursing.

outpatient detoxification A specialized form of partial hospitalization for patients requiring medical supervision during withdrawal from alcohol or other addictive substances, with or without use of a 23-hour bed during the initial withdrawal phase.

outwardly directed anger Anger expression particularly the hostile,

attacking forms.

oxidative stress A condition of increased oxidant production in cells characterized by the release of free radicals and resulting in cellular degeneration.

package insert The approved Food and Drug Administration product labeling that includes approved indications for the medication, side effects, adverse effects, contraindications, and other important information.

panic A normal but extreme overwhelming form of anxiety often experienced when an individual is placed in a real or perceived life-threatening situation.

panic attacks Sudden, discrete periods of intense fear or discomfort that are accompanied by significant physical and cognitive symptoms.

panic control treatment Intentional exposure through exercise to panic-invoking sensations such as dizziness, hyperventilation, tightness in chest, and sweating.

panicogenic Substances that produce panic attacks.

paranoia Suspiciousness and guardedness that are unrealistic and often accompanied by grandiosity.

paranoid personality Marked by traits including longstanding suspiciousness and mistrust of persons in general, a refusal to assume personal responsibility for one's own feelings, and avoidance of relationships in which the person is not in control or loses power.

paraphilias Problematic sexual behaviors characterized by recurrent, intense sexual urges, fantasies, or behaviors involving unusual objects, activities, or situations. These cause significant distress to the individual or impair social or occupational

functioning.

parasuicidal behavior Deliberate self-injury with intent to harm oneself.

parasuicide Deliberate, apparent attempt at suicide, commonly called a suicidal gesture, in which the aim is not death (e.g., taking a sublethal drug); also called *parasuicidal behavior*.

partial agonist A drug that has some intrinsic activity (although weak) to initiate the same response in the body as a chemical that is normally present.

partial hospitalization A time-limited (usually full or half day), ambulatory, active treatment program that offers therapeutically intensive, coordinated, and structured clinical services for patients with acute psychiatric symptoms who are experiencing a decline in social or occupational functioning, who cannot function autonomously on a daily basis, or who do not pose imminent danger to themselves or others. The aim is patient stabilization without hospitalization or a reduced length of inpatient care.

passive listening A nontherapeutic mode of interaction that involves sitting quietly and allowing the patient to talk without focusing on guiding the thought process; includes body language that communicates boredom, indifference, or hostility.

paternalism The belief that knowledge and education authorizes professionals to make decisions for the good of the patient.

patient observation The ongoing assessment of the patient's mental status to identify and subvert any potential problem.

peak marriage age An age when the person is most likely to have a successful marriage; currently between the ages of 23 and 27 years.

pedophilia Sexual activity with a child usually 13 years of age or

younger by an individual at least 16 years of age or 5 years older than the child.

peer assistance programs Programs developed by state nurses' associations to offer consultation, referral, and monitoring for nurses whose practice is impaired or potentially impaired because of the use of drugs or alcohol or a psychological or physiologic condition.

perfectionism Setting high personal standards for oneself combined with concern over mistakes and their consequences for self-worth and others' opinions.

persecutory delusions Delusions in which the person believes that he or she is being conspired against, cheated, spied on, followed, poisoned, drugged, maliciously maligned, harassed, or obstructed in the pursuit of long-term goals.

personal identity Knowing "who I am" formed through the numerous biologic, psychological, and social challenges and demands faced throughout the stages of life.

personality A complex pattern of psychological characteristics, largely outside a person's awareness, that comprise the individual's distinctive pattern of perceiving, feeling, thinking, coping, and behaving.

personality disorder An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment.

personality traits Prominent aspects of personality that are exhibited in a wide range of social and personal contexts; intrinsic and pervasive, personality traits emerge from a complicated interaction of biologic dispositions, psychological experiences,

and environmental situations that ultimately comprise a distinctive personality.

person–environment relationship The interaction between the individual and the environment that changes throughout the stress experience.

pharmacodynamics The study of the biologic actions of drugs on living tissue and the human body in general.

pharmacogenomics Blends pharmacology with genetic knowledge; understanding and determining an individual's specific CYP450 makeup and then individualizing medications to match the person's CYP450 profile.

pharmacokinetics The process by which a drug is absorbed, distributed, metabolized, and eliminated by the body.

phenotype Observable characteristics or expressions of a specific trait.

phobia Persistent, unrealistic fears of situations, objects, or activities that often lead to avoidance behaviors.

phonic tics Tics that typically include repetitive throat clearing, grunting, or other noises but may also include more complex sounds, such as words; parts of words; and in a minority of patients, obscenities.

phonologic processing Thought to be the cause of reading disability; a process that involves the discrimination and interpretation of speech sounds. Reading disability is believed to be caused by some disturbance in the development of the left hemisphere.

phototherapy Also known as *light therapy*; involves exposing the patient to an artificial light source during winter months to relieve seasonal depression.

pineal body Located in the epithalamus; contains secretory cells that

emit the neurohormone melatonin (as well as other substances), which has been associated with sleep and emotional disorders and modulation of immune function.

plasticity Permanent change in central pain interpretation.

plateau Phase of the human sexual response cycle that is represented by sexual pleasure and increased muscle tension, heart rate, and blood flow to the genitals.

polypharmacy Using more than one group from a class of medications at one time.

polysomnography A special procedure that involves the recording of the electroencephalogram throughout the night. This procedure is usually conducted in a sleep laboratory.

polyuria Excessive need to urinate.

population genetics The study of the inheritance of illness or traits from generation to generation.

positive self-talk Countering fearful or negative thoughts by using preplanned and rehearsed positive coping statements.

positive symptoms An excess or distortion of normal functions, including delusions and hallucinations.

posttraumatic stress disorder A mental disorder characterized by persistent, distressing symptoms lasting longer than 1 month after exposure to an extreme traumatic stressor.

potency The dose of drug required to produce a specific effect.

power of attorney As it relates to health care, an advanced care directive through which a proxy, usually a relative or trusted friend, is appointed to make health care decisions on behalf of an individual if that person is incapacitated.

premature ejaculation (PE) The inability to control ejaculation

before or shortly after penetration.

pressured speech Speaking as if the words are being forced out.

privacy The part of an individual's personal life that is not governed by society's laws and governmental intrusion.

proband A person who has a genetic disorder or a trait of a mental disorder.

probation A sentence of conditional or revocable release under the supervision of a probation officer for a specified time.

problem-focused coping A type of coping in which a person attacks the source of stress and solves the problem (eliminating it or changing its effects), which changes the person–environment relationship.

process recording A verbatim transcript of a verbal interaction usually organized according to the nurse–patient interaction. It often includes analysis of the interaction.

prodromal An early symptom indicating the development of a disease or syndrome.

prostaglandins An unsaturated fatty acid that helps control smooth muscle contraction, blood pressure, inflammation, and body temperature. One of the most common nociceptive transmitters.

protective factors Characteristics that reduce the probability that a person will develop a mental health disorder or problem or decrease the severity of existing problems.

protective identification A psychoanalytic term used to describe behavior of people with borderline personality disorder when they falsely attribute to others their own unacceptable feelings, impulses, or thoughts.

protein binding The degree to which a drug binds to plasma

proteins.

pseudologia fantastica Fascinating but false stories of personal triumph. Stories that are not entirely improbable and often contain a matrix of truth and falsehood.

pseudoparkinsonism Sometimes referred to as *druginduced parkinsonism*; presents identically as Parkinson disease without the same destruction of dopaminergic cells.

psychiatric–mental health nurse A registered nurse who demonstrates specialized competence and knowledge, skills, and abilities in caring for persons with mental health issues and problems and psychiatric disorders.

psychiatric–mental health nursing A specialized area of nursing practice committed to promoting mental health through the assessment, diagnosis, and treatment of human responses to mental health problems and psychiatric disorders.

psychiatric rehabilitation programs Programs that are focused on reintegrating people with psychiatric disabilities back into the community through work, educational, and social avenues while also addressing their medical and residential needs.

psychoanalysis The Freudian treatment of choice; therapy focused on repairing the trauma of the original psychological injury through the process of accessing the unconscious conflicts that originate in childhood and then resolving the issues with a mature adult mind. Includes attempts to reconstruct the personality by examining free associations (spontaneous, uncensored verbalizations of whatever comes to mind) and the interpretation of dreams.

psychoeducation An educational approach used to enhance knowledge and shape behavior by adapting teaching strategies to a patient's disorder-related deficits.

psychoeducational programs A form of mental health intervention in which basic coping skills for dealing with various stressors are taught.

psychological abuse Emotional abuse that includes behaviors such as criticizing, insulting, humiliating, or ridiculing someone in private or in public. It can also involve actions such as destroying another's property, threatening or harming pets, controlling or monitoring spending and activities, or isolating a person from family and friends.

psychoneuroimmunology The study of relationships among the immune system, nervous system, and endocrine system and our behaviors, thoughts, and feelings.

psychopath Also called a sociopath, a person with a tendency toward antisocial and criminal behavior with little regard for others; a term often used by the general public to refer to persons with an antisocial personality disorder.

psychosis A category used by Freud and his followers to define those with severe mental illness that impaired daily functioning. Today, the term is used to describe a state in which the individual is experiencing hallucinations, delusions, or disorganized thoughts, speech, or behavior.

psychosomatic Term traditionally used to describe, explain, and predict the psychological origins of illness and disease.

public stigma Type of stigma that occurs after individuals are publicly "marked" as being mentally ill.

pyromania Irresistible impulses to start fires.

quadrants of care A conceptual framework that classifies patients according to symptom severity, not diagnosis.

rape The most severe form of sexual assault; the penetration of any

bodily orifice by the penis, fingers, or an object.

rapid cycling In bipolar disorder, the occurrence of four or more mood episodes that meet criteria for a manic, mixed, hypomanic, or depressive episode during the previous 12 months.

rapid eye movement (REM) sleep A sleep cycle state of rapid eye movement.

rapproach Interpersonal harmony characterized by understanding and respect that is established through interpersonal warmth, a nonjudgmental attitude, and a demonstration of understanding.

rational emotive behavior therapy (REBT) A psychotherapeutic approach that proposes that unrealistic and irrational beliefs cause many emotional problems. Its primary emphasis is on changing irrational beliefs into thoughts that are more reasonable and rational.

reappraisal Appraisal after coping that provides feedback about the outcomes and allows for continual adjustment to new information.

receptors Proteins that receive released neurotransmitters. Each neurotransmitter has a specific receptor, or protein, for which it and only it will fit; serves a physiologic regulatory function.

recovery Recovery from mental disorders and/or substance use disorders is a process of change through which individuals improve their health and wellness, live a self-directed life, and strive to reach their full potential.

referential thinking Belief that neutral stimuli have special meaning to the individual, such as a television commentator speaking directly to the individual.

referral Act of sending an individual from one clinician to another or from one service setting to another for care or consultation.

reflection Continual self-evaluation through observing, monitoring,

and judging nursing behaviors with the goal of providing ideal interventions.

regressed behavior Behaving in a manner of a less mature life stage; childlike and immature.

reintegration A term used to describe the process of the return and acceptance of a person as a fully participating member of a community through work, educational, and social avenues.

relapse Recurrence or marked increase in severity of the symptoms of the disease, especially after a period of apparent improvement or stability; the recurrence of alcohol- or drug-dependent behavior in an individual who has previously achieved and maintained abstinence for a significant time beyond the period of detoxification.

relapse cycle When reemerging psychiatric symptoms lead to ineffective coping strategies, increased anxiety, substance use to avoid painful feelings, adverse consequences, and attempted abstinence until psychiatric symptoms reemerge and the cycle repeats itself.

relapse prevention An approach that focuses on preventing recurrence of symptoms.

relational aggression A type of bullying, more commonly used by girls, that involves disrupting peer relationships by excluding or manipulating others and spreading rumors.

relationship questions Questions used to amplify and reinforce positive responses to the other questions.

relaxation training A variety of procedures to reduce somatic arousal, such as progressive muscle relaxation, autogenic training, and biofeedback.

religiousness The participation in a community of people who gather

around common ways of worshiping.

reminiscence Thinking about or relating past experiences.

repetitive transcranial magnetic stimulation Noninvasive, painless method to stimulate the cerebral cortex, which activates inhibitory and excitatory neurons.

residential services A place for people to reside during a 24-hour period or any portion of the day on an ongoing basis.

resilience Ability to recover readily from illness, depression, adversity, or the like. The ability to recover or adjust to challenges over time. Attaining good mental health despite the presence of risk factors and genetic predisposition.

resolution The termination phase of the nurse–patient relationship that lasts from the time the problems are resolved to the close of the relationship. Also, in regards the human sexual response cycle, the gradual return of the organs and body systems to the unaroused state.

restoration-oriented coping Part of the dual process model of bereavement during which the bereaved person is preoccupied with stressful events as a result of the death (financial issues, new identity as a widow[er]).

restraint The use of any manual, physical, or mechanical device or material that when attached to the patient's body (usually to the arms and legs) restricts the patient's movements.

retrocollis The neck muscles pull back the head.

revictimization A reoccurrence of violence toward the survivor.

rhythm Movement with a cadence. A measured flow that occurs at regular intervals, with a cycle of coming and going, ebbing and rising, to return at the start point and begin again.

risk factors Characteristics, conditions, situations, or events that increase the patient's vulnerability to threats to safety or well-being.

Safe Havens A form of supportive housing that serves hard-to-reach people with severe mental illness.

sandwich generation People with caregiving responsibilities toward the elder generation above and two generations of children below them.

scaling questions Questions that quantify exceptions noted in intensity and in tracking change over time using a scale of 1 to 10.

schema A cognitive structure, or an individual's life rules, that act as a filter that screens, codes, and evaluates the incoming stimuli through which the individual interprets events.

schizoaffective disorder (SAD) A disorder characterized by periods of intense symptom exacerbation alternating with quiescent periods, during which psychosocial functioning is adequate. This disorder is at times marked by symptoms of schizophrenia; at other times, it appears to be a mood disorder. In other cases, both psychosis and pervasive mood changes occur concurrently.

schizoid personality Personality trait characterized as being expressively impassive and interpersonally unengaged.

schizotypal personality disorder A disorder characterized by a pattern of social, interpersonal deficits, and impairments in capacity for close relationships. Perceptual distortions are usually present.

schizotypy Traits that are similar to the symptoms of schizophrenia but less severe. Cognitive perceptual symptoms are a primary characteristic and include magical beliefs (similar to delusions) and perceptual aberrations (similar to hallucinations). Other common symptoms include referential thinking (interpreting

insignificant events as personally relevant) and paranoia (suspicious of others).

school phobia Anxiety in which the child refuses to attend school in order to stay at home and with the primary attachment figure. School phobia is a common presenting complaint in child psychiatric clinics and is diagnosed as a separation anxiety disorder.

seclusion Solitary confinement in a full protective environment for the purpose of safety or behavior management.

Section 8 housing Federally subsidized housing units that are supervised or operated by the state or city; tenants are responsible for paying one third of the monthly income toward rent.

sedative–hypnotics Medications that induce sleep and reduce anxiety.

sedatives Medications that reduce activity, nervousness, irritability, and excitability without causing sleep, but if given in large enough doses, they have an hypnotic effect.

selectivity The ability of a drug to be specific for a particular receptor, interacting only with specific receptors in the areas of the body where the receptors occur and therefore not affecting tissues and organs where these receptors do not occur.

self-awareness Being cognizant of one's own beliefs, thoughts, motivations, biases, physical and emotional limitations, and the impact one may have on others.

self-care The ability to perform activities of daily living (ADLs) successfully.

self-concept The sum of beliefs about oneself, which develops over time. Includes three interrelated dimensions: body image, self-esteem, and personal identity.

self-determinism Being empowered or having the free will to make moral judgments. Includes the right to choose one's own health-related behaviors, which at times differ from those recommended by health professionals.

self-disclosure The act of revealing personal information about oneself.

self-efficacy Self-effectiveness; a person's belief in his or her own abilities.

self-esteem Attitude about oneself. Healthy self-esteem includes feelings of self-acceptance, self-worth, self-love, and self-nurturing.

self-harm Deliberate self-injurious behavior with the intent to hurt oneself.

self-identity The development of a separate and distinct personality.

self-medicate Using medication, usually over the counter or substances without professional prescription or supervision, to alleviate an illness or condition.

self-monitoring Observing and recording one's own information, usually behavior, thoughts, or feelings.

self-stigma Type of stigma that occurs when negative stereotypes are internalized by people with mental illness.

self-system An important concept in Peplau model. Drawing from Sullivan, Peplau defined the self as an "antianxiety system" and a product of socialization.

sensate focus A method of sex therapy in which partners learn what each finds arousing and how to communicate those preferences.

separation anxiety disorder Developmentally inappropriate fear and anxiety around separation from home or attachment figure.

separation-individuation A normal developmental process during which the child develops a sense of self, a permanent sense of significant others (object constancy), and an integration of both bad and good as a component of the self-concept.

serotonin Also called 5-hydroxytryptamine or 5-HT, this is primarily an excitatory neurotransmitter that is diffusely distributed within the cerebral cortex, limbic system, and basal ganglia of the central nervous system. Serotonergic neurons also project into the hypothalamus and cerebellum. Plays a role in emotions, cognition, sensory perceptions, and essential biologic functions (e.g., sleep and appetite).

serotonin syndrome A potentially life-threatening side effect that occurs as a result of an overactivity of serotonin or an impairment of the serotonin metabolism. Symptoms include mental status changes (hallucinations, agitation, and coma), autonomic instability (tachycardia, hyperthermia, changes in blood pressure), neuromuscular problems (hyperreflexia, incoordination), and gastrointestinal disturbance (nausea, vomiting, diarrhea).

sex role identity Outward expression of gender.

sex therapist A therapist who blends education and counseling with psychotherapy and specific sexual exercises.

sexual arousal A state of mounting sexual tension characterized by vasoconstriction and myotonia.

sexual assault Any form of nonconsenting sexual activity, ranging from fondling to penetration.

sexual desire Ability, interest, or willingness to receive or a motivational state to seek sexual stimulation.

sexual disorders Called sexual dysfunction in the *DSM-5*. A disturbance in sexual desire or sexual response or pain associated with intercourse.

sexual maturation The aspect of sexual development that encompasses biosexual identity, gender identity, sex role identity, and sexual orientation.

sexual orientation (sexual preference) An individual's feelings of sexual attraction and erotic potential.

sexual sadism The real act of experiencing sexual excitement from causing physical or psychological suffering of another individual.

sexuality Basic dimension of every individual's personality encompassing all that is male or female, undergoing periods of growth and development, and influenced by biologic and psychosocial factors.

Shelter Plus Care Program A continuum of care program that allows for various housing choices and a range of supportive services.

sibling position The relative social status of the children in the family based on birth order.

side effects Unintended effects of medications.

simple relaxation techniques Interventions that encourage and elicit relaxation to decrease undesirable signs and symptoms.

situational crisis A crisis that occurs whenever a specific stressful event threatens a person's biopsychosocial integrity and results in some degree of psychological disequilibrium.

skills groups An integral part of dialectical behavior therapy; skills are taught in group settings in which patients practice emotional regulation, interpersonal effectiveness, distress tolerance, core mindfulness, and self-management skills.

sleep architecture A predictable pattern during a night's sleep that includes the timing, amount, and distribution of REM and NREM

stages.

sleep debt Interruption of basic restoration after recurrent long-term sleep deprivation.

sleep diary A written account of the sleep experience.

sleep disorders Ongoing disruptions of normal waking and sleeping patterns that lead to excessive daytime sleepiness; inappropriate naps; chronic fatigue; and the inability to perform safely or properly at work, school, or home.

sleep efficiency Expressed as the ratio of total sleep time to time in bed.

sleep latency Amount of time it takes for an individual to fall asleep. It is the time period measured from “lights out,” or bedtime, to initiation of sleep.

sleep paralysis Being unable to move or speak when falling asleep or waking.

sleep restriction Deliberately spending less time in bed and avoiding napping.

sleepiness The urge to fall asleep.

sleep–wake cycle The biphasic 24-hour cycle that makes up the patterned activity of sleep.

slow-wave sleep Deepest state of sleep.

social change The structural and cultural evolution of society.

social distance Degree to which the values of a formal organization and its primary group members differ.

social functioning Performance of daily activities within the context of interpersonal relations and family and community roles.

social network Linkages among a defined set of people, among

whom there are personal contacts.

social skills training A psychoeducational approach that involves instruction, feedback, support, and practice with learning behaviors that help people interact more effectively with peers and children and with adults.

social support Positive and harmonious interpersonal interactions that occur within social relationships.

sociopath Also called a psychopath, a person with a tendency toward antisocial and criminal behavior with little regard for others; a term often used by the general public to refer to persons with an antisocial personality disorder.

solubility Ability of a drug to dissolve.

solution-focused brief therapy A cognitive therapy approach that differs from other cognitive approaches in its deemphasis on the patient's "problems," or symptoms, and an emphasis on what is functional and healthful.

somatic symptom disorder (SSD) Multiple current, somatic symptoms that are distressing and disruptive of daily life. Individuals report all aspects of their health as poor. Physical symptoms may last 6 to 9 months.

somatization Experiencing multiple physical symptoms that are distressing and disruptive of daily life.

somnambulism Sleep walking.

speed-accuracy shift A type of mental processing in which an older adult focuses more on accuracy than speed in responding.

spiritual support Assisting patients to feel balance and connection within their relationships; involves listening to expressions of loneliness, using empathy, and providing patients with desired spiritual articles.

spirituality Beliefs and values related to hope and meaning in life.

splitting Defense mechanism in which the person views the world in absolutes, alternately categorizing people as all good or all bad; also used to describe a person manipulating one group against another.

stabilization Short-term care, usually lasting fewer than 7 days, with a symptom-based indication for hospital admission. Primary focus is on control of precipitating symptoms with medications, behavioral interventions, and coordination with other agencies for appropriate after care.

stalking A pattern of repeated unwanted contact, attention, and harassment that often increases in frequency.

standardized nursing language Language readily understood by all nurses to describe care in order to provide a common means of communication.

standards of practice Standards that guide nursing practice. These are organized around the nursing process and include assessment, diagnosis, outcome identification, planning, implementation, and evaluation.

steady state Absorption equals excretion and the therapeutic level plateaus.

stereotypic behavior Repetitive, driven, nonfunctional, and potentially self-injurious behavior, such as head banging, rocking, and hand flapping, seen in autistic disorder, with an extraordinary insistence on sameness.

stereotypy Repetitive, purposeless movements that are idiosyncratic to the individual and to some degree outside of the individual's control.

stigma A mark of shame, disgrace, or disapproval that results in an

individual being shunned or rejected by others.

stilted language Overly and inappropriately artificial formal language.

stimulus control A technique used when the bedroom environment no longer provides cues for sleep but has become the cue for wakefulness. Patients are instructed to avoid behaviors in the bedroom that are incompatible with sleep.

stress A transactional process arising from real or perceived internal or external environmental demands that are appraised as threatening or benign.

stress response Physiologic, behavioral, and cognitive reaction to an appraised threatening person–environment event.

structural imaging The aspect of neuroimaging that visualizes the structure of brain and allows diagnosis of gross intracranial disease and injury.

structured interaction Purposeful interaction that allows patients to interact with others in a useful way.

subcortical dementia Dementia that is caused by dysfunction or deterioration of deep gray or white matter structures inside the brain and brain stem.

substance P A peptide found in body tissues, especially nervous tissue, that is involved in the transmission of pain and in inflammation. It is the most common nociceptive transmitter that is released and transported along the central and peripheral pain synapses in the presence of noxious stimuli.

substrate The drug or compound that is identified as a target of an enzyme.

subsystems A systems term used by family theorists to describe subgroups of family members who join together for various

activities.

sudden sniffing death Sudden death for inhalant users when the inhaled fumes take the place of oxygen in the lungs and central nervous system, causing the user to suffocate.

suicidal behavior The occurrence of persistent thought patterns and actions that indicate a person is thinking about, planning, or enacting suicide.

suicidal ideation Thinking about and planning one's own death without actually engaging in self-harm.

suicidality All suicide-related behaviors and thoughts of completing or attempting suicide and suicide ideation.

suicide The act of killing oneself voluntarily.

suicide attempt A nonfatal, self-inflicted destructive act with explicit or implicit intent to die.

suicide contagion Suicide behavior that occurs after the suicide death of a known other (i.e., a friend, acquaintance, or idolized celebrity). Also called *cluster suicide*.

supportive housing Permanently subsidized housing with attendant social services.

symbolism The use of a word or a phrase to represent an object, event, or feeling.

synaptic cleft A junction between one nerve and another; the space where the electrical intracellular signal becomes a chemical extracellular signal.

synchronized Two or more circadian rhythms reaching their peak at the same time.

syndrome A set of symptoms that cluster together that may have multiple causes and may represent several different disease states

that have not yet been defined.

systematic desensitization A method used to desensitize patients to anxiety-provoking situations by exposing the patient to a hierarchy of feared situations. Patients are taught to use muscle relaxation as levels of anxiety increase through multisituational exposure.

tangentiality When the topic of conversation changes to an entirely different topic that is within a logical progression but causes a permanent detour from the original focus.

tardive dyskinesia A late-appearing extrapyramidal side effect of antipsychotic medication that involves irregular, repetitive involuntary movements of the mouth, face, and tongue, including chewing, tongue protrusion, lip smacking, puckering of the lips, and rapid eye blinking. Abnormal finger movements are common as well.

target symptoms Specific measurable symptoms expected to improve with treatment for which psychiatric medications are prescribed. Examples include hallucinations, delusions, paranoia, agitation, assaultive behavior, bizarre ideation, social withdrawal, disorientation, catatonia, blunted affect, thought blocking, insomnia, and anorexia.

task roles The group role of an individual that is concerned about the purpose of the group and keeps the focus on the task of the group.

tau A protein that is the main component found in neurofibrillary tangles inside the cells.

temperament A person's characteristic intensity, activity level, rhythmicity, adaptability, energy expenditure, and mood.

therapeutic communication The ongoing process of interaction in which meaning emerges; may be verbal or nonverbal.

therapeutic foster care The placement of patients in residences of families specially trained to handle individuals with mental illnesses. Indicated for patients in need of a family-like environment and a high level of support.

therapeutic index A ratio of the maximum nontoxic dose to the minimum effective dose.

thought stopping A practice in which a person identifies negative feelings and thoughts that exist together, says “stop,” and then engages in a distracting activity.

thymoleptic Mood stabilizing.

tics Sudden, rapid, repetitive, stereotyped motor movements or vocalizations.

token economy The application of behavior modification techniques to multiple behaviors. In a token economy, patients are rewarded with tokens for selected desired behaviors that they can then redeem for special privilege or similar.

tolerance A gradual decrease in the action of a drug at a given dose or concentration in the blood. The ability to ingest an increasing amount of alcohol before a “high” and cognitive and motor effects are experienced.

torticollis The neck muscles pull the head to the side.

Tourette disorder The most severe tic disorder. Defined by multiple motor and phonic tics for at least 1 year.

toxicity The point at which concentrations of a drug in the bloodstream become harmful or poisonous to the body.

transaction Transfer of value between two or more individuals.

transfer The formal shifting of responsibility for the care of an individual from one clinician to another or from one care unit to

another.

transference The unconscious assignment to a therapist or nurse of a patient's feelings and attitudes that were originally associated with important figures such as parents or siblings.

transition times Times of addition, subtraction, or change in status of family members.

transitional housing Temporary housing such as a halfway house, short-stay residence or group home, or a room at a hotel designated for people who are homeless and looking for permanent housing.

traumatic brain injury (TBI) An intracranial injury that occurs when an outside force traumatically injures the brain.

traumatic crisis A crisis initiated by unexpected, unusual events in which people face overwhelming hazards that entail injury, trauma, destruction, or sacrifice. May affect an individual or a multitude of people at once.

traumatic grief A difficult and prolonged grief.

triad A group consisting of three people.

triangles A three-person system and the smallest stable unit in human relations.

trichotillomania Chronic, self-destructive hair pulling that results in noticeable hair loss, usually in the crown, occipital, or parietal areas, and sometimes of the eyebrows and eyelashes.

23-hour observation A short-term treatment that serves the patient in immediate but short-term crisis. This type of care admits individuals to an inpatient setting for as long as 23 hours during which time services are provided at a less-than-acute care level.

uncomplicated grief Grief that is painful and disruptive within

normal expectations after the loss of a loved one.

unconditional positive regard A nonjudgmental caring for a client.

unfit to stand trial (UST) Persons who are determined to be unable to understand the proceedings against them or assist in their own defense because of mental or physical condition.

uptake receptors See *carrier proteins*.

use The drinking of alcohol or the swallowing, smoking, sniffing, or injecting of a mind-altering substance.

vaginismus Condition characterized by a psychologically induced spastic, involuntary constriction of the perineal and outer vaginal muscles fostered by imagined, anticipated, or actual attempts at vaginal penetration.

validation A process that affirms patient individuality and reflects the staff member respect for a patient in any interaction.

veracity The duty to tell the truth.

verbal communication The use of the spoken word, including its underlying emotion, context, and connotation.

veteran identity The degree to which the veteran role is central or important to how they think about themselves and how they want others to view them.

verbigeration Purposeless repetition of words or phrases.

violence (violent behavior) An extreme form of aggression involving the physical act of force intended to cause harm to a person or an object.

voluntary admission (voluntary commitment) The legal status of a patient who has consented to being admitted to the hospital for treatment, during which time he or she maintains all civil rights and is free to leave at any time even if it is against medical advice.

vulnerable child syndrome A phenomenon that occurs when family members view a child as sick despite current good health and as a result are overprotective of the child.

waxy flexibility Posture held in an odd or unusual fixed position for extended periods of time.

Wernicke encephalopathy An alcohol-induced degenerative brain disorder caused by a thiamine deficiency and characterized by vision impairment, ataxia, hypotension, confusion, and coma.

Wernicke–Korsakoff syndrome An alcohol-induced amnestic disorder that includes an acute phase of Wernicke encephalopathy and a chronic phase of Korsakoff amnestic syndrome.

withdrawal The adverse physical and psychological symptoms that occur when a person ceases to use a substance.

word salad A string of words that are not connected in any way.

working memory An important aspect of the brain's frontal lobe function, including the ability to plan and initiate activity with future goals in mind.

working phase The second phase of the nurse–patient relationship in which patients can examine specific problems and learn new ways of approaching them.

xerostomia Dry mouth.

young adulthood A term used to describe adults ages 18 to 44 years.

young-old A term used to describe adults ages 65 to 74 years.

Zeitgebers Specific events that function as time givers or synchronizers and that result in the setting of biologic rhythms.
