1 Introduction

Overview

Evidence-based practice

What is evidence-based practice?
Grading evidence in *The Royal Marsden Manual of Clinical Nursing Procedures*

Structure of the Manual

Structure of chapters

Conclusion

References

Part One

Managing the patient journey

2 Assessment and discharge

Overview

Inpatient assessment and the process of care

Observation

Physical assessment/examination

Respiratory examination
Cardiovascular examination
Abdominal examination

Communication and discharge planning

References

Procedure guidelines for Chapter 2

2.1 Respiratory examination
2.2 Cardiovascular examination
2.3 Abdominal examination

3 Infection prevention and control

Overview

Infection prevention and control

Aseptic technique

Source isolation

Protective isolation

v	Prevention and management of inoculation injury	88
xiii	Management of waste in the healthcare environment	89
xiv	Management of soiled linen in the healthcare environment	91
xv	References	92
xix	Procedure guidelines for Chapter 3	
xxiii	3.1 Hand washing	61
xxvii	3.2 Hand decontamination using alcohol handrub	63

5 Elimination

Overview

Normal elimination

Vomiting	133
Insertion of a nasogastric drainage tube	134
Removal of a nasogastric drainage tube	134
Urinary elimination	135
Faecal elimination	138
Assisting the patient with elimination	138

Altered urinary elimination

Urinary incontinence	141
Urinary catheterization	144
Suprapubic catheterization	147
Intermittent catheterization	155
Bladder irrigation	155
Nephrostomy tubes	160
Surgical urinary diversions	166

Altered faecal elimination

Diarrhoea	173
Constipation	173
Enemas	175
Suppositories	179
Digital rectal examination	183
Digital removal of faeces	185

Stoma care

Complications	187
Websites	189
References	199

Procedure guidelines for Chapter 5

5.1 Care of a patient who is vomiting	135
5.2 Insertion of a nasogastric (NG) drainage tube	137
5.3 Removal of a nasogastric tube	138
5.4 Slipper bedpan use: assisting a patient	142
5.5 Commode use: assisting a patient	143
5.6 Penile sheath application	145
5.7 Urinary catheterization: male	151
5.8 Urinary catheterization: female	153
5.9 Urinary catheterization: intermittent self-catheterization patient guidance: male	156
5.10 Urinary catheterization: intermittent self-catheterization patient guidance: female	157
5.11 Urinary catheter bag: emptying	158
5.12 Urinary catheter removal	159
5.13 Commencing bladder irrigation	162
5.14 Care of the patient during bladder irrigation	164
5.15 Nephrostomy tube: weekly dressing and bag change	167
5.16 Nephrostomy tube: removal of locking pigtail drainage system	169
5.17 Continent urinary diversion stoma: self-catheterization	172
5.18 Enema administration	181
5.19 Suppository administration	184
5.20 Digital rectal examination	186
5.21 Digital removal of faeces	188
5.22 Stoma siting	193
5.23 Stoma bag change	195
5.24 Stoma bridge or rod removal	196

6 Moving and positioning

Overview

Moving and positioning: general principles

Risk assessment: prevention of falls	207
Positioning the patient: in bed	208

Positioning the patient: sitting in bed	214
Positioning the patient: side-lying	215
Positioning the patient: in a chair/wheelchair	217
Moving the patient from sitting to standing	218
Walking	219
Moving and positioning the unconscious patient	221
Moving and positioning the patient with an artificial airway	222
Moving and positioning the patient with respiratory compromise	225
Positioning to maximize ventilation/perfusion matching	225
Positioning to minimize the work of breathing	227
Positioning to maximize the drainage of secretions	228
Moving and positioning the patient with neurological impairment	230
Moving and positioning of the patient with actual or suspected spinal cord compression or spinal cord injury	235
Moving and positioning the patient with an amputation	246
Websites	249
References	249

Procedure guidelines for Chapter 6

6.1 Positioning the patient: supine	213
6.2 Positioning the patient: sitting in bed	214
6.3 Positioning the patient: side-lying	215
6.4 Positioning the patient: lying down to sitting up	216
6.5 Positioning the patient: in a chair/wheelchair	218
6.6 Moving from sitting to standing: assisting the patient	219
6.7 Assisting the patient to walk	220
6.8 Positioning the unconscious patient or patient with an airway in supine	222
6.9 Positioning the unconscious patient or patient with an airway in side-lying	224
6.10 Positioning the patient to maximize V/Q matching with unilateral lung disease in a self-ventilating patient	226
6.11 Positioning the patient to maximize V/Q matching for widespread pathology in a self-ventilating patient	227
6.12 Positioning to maximize the drainage of secretions	230
6.13 Positioning the neurological patient with tonal problems	233
6.14 Log rolling for suspected/confirmed cervical spinal instability	237
6.15 Positioning for suspected/confirmed cervical spinal instability: pelvic twist to right	240
6.16 Log rolling for suspected/confirmed thoracolumbar spinal instability	242
6.17 Early mobilization of the patient in bed	243
6.18 Positioning the pre-operative and post-operative amputation patient	247

7 Nutrition, fluid balance and blood transfusion

Overview	253
Fluid balance	254
Nutritional status	266
Provision of nutritional support: oral	272
Nutritional management of patients with dysphagia	277

Enteral tube feeding	279	Procedure guidelines for Chapter 8	
Enteral tube insertion	280	8.1 Bedbathing a patient	337
Enteral tube removal	287	8.2 Washing a patient's hair in bed	339
Enteral tube care	288	8.3 Eye swabbing	344
Administration of enteral tube feed	294	8.4 Eye irrigation	345
Enteral feeding tubes: administration of medication	296	8.5 Artificial eye care: insertion	347
Enteral feeding tubes: unblocking	298	8.6 Artificial eye care: removal	347
Parenteral nutrition	299	8.7 Contact lens removal: hard lenses	348
Transfusion of blood and blood components	302	8.8 Contact lens removal: soft lenses	349
Websites and useful addresses	323	8.9 Mouth care	357
References	324	8.10 Mouth care for the patient with dentures	359
Procedure guidelines for Chapter 7		8.11 Pain assessment	365
7.1 Fluid input: measurement	259	8.12 Acupuncture: preparation and administration	376
7.2 Fluid output: monitoring/measuring output if the patient is catheterized	261	8.13 Epidural/intrathecal sensory blockade: assessment	381
7.3 Fluid output: monitoring/measuring output if the patient is not catheterized	261	8.14 Epidural/intrathecal exit site dressing change	382
7.4 Fluid output: measuring output from drains	262	8.15 Epidural/intrathecal catheter removal	383
7.5 Fluid output: monitoring output from gastric outlets, nasogastric tubes, gastrostomy	263	8.16 Entonox administration	394
7.6 Fluid output: monitoring output from bowels	263	8.17 Abdominal paracentesis	399
7.7 Fluid output: monitoring output from stoma sites	264	8.18 Personal care after death	416
7.8 Measuring the weight and height of the patient	269		
7.9 Feeding an adult patient	276	9 Respiratory care	431
7.10 Nasogastric intubation with tubes using an internal guidewire or stylet	281	Overview	432
7.11 Removal of a nasogastric tube	287	Respiratory therapy	432
7.12 Percutaneous endoscopically placed gastrostomy (PEG) tube care	288	Oxygen therapy	434
7.13 Radiologically inserted gastrostomy (RIG) tube care	290	Humidification	441
7.14 Removal of T-fasteners	290	High-flow oxygen therapy	444
7.15 Checking the balloon volume on a balloon gastrostomy	291	Continuous positive airway pressure	446
7.16 Jejunostomy feeding tube care	292	Chest drains	452
7.17 Enteral feeding tubes: administration of feed	294	Tracheostomy and laryngectomy care	467
7.18 Enteral feeding tubes: administration of medication	296	Tracheostomy: dressing change	475
7.19 Enteral feeding tubes: unblocking	298	Tracheostomy: suctioning	476
7.20 Blood product request	312	Tracheostomy: changing the inner cannula	479
7.21 Blood sampling: pre-transfusion	313	Tracheostomy: tube change	481
7.22 Blood components: collection and delivery to the clinical area	314	Cardiopulmonary resuscitation	484
7.23 Blood component administration	316	References	502
8 Patient comfort and end-of-life care	331	Procedure guidelines for Chapter 9	
Overview	332	9.1 Oxygen therapy	438
Personal hygiene	332	9.2 Humidification for respiratory therapy	443
Eye care	340	9.3 High-flow oxygen therapy	444
Ear care	350	9.4 Continuous positive airway pressure	449
Mouth care	352	9.5 Chest drain: insertion	458
Pain	360	9.6 Chest drainage: suction	461
Pain management	366	9.7 Chest drain: priming ambulatory chest drain bag	461
Acupuncture	373	9.8 Chest drain: changing the bottle	462
Epidural and intrathecal analgesia	376	9.9 Chest drain: removal	463
Regional analgesia: local anaesthetic nerve blocks and infusions	388	9.10 Tracheostomy: dressing change	475
Entonox administration	391	9.11 Tracheostomy: suctioning a patient	478
Management of ascites	396	9.12 Tracheostomy: inner cannula change	480
End-of-life care	402	9.13 Tracheostomy: tube change	481
Care before death	403	9.14 Cardiopulmonary resuscitation	498
Care after death (last offices)	413		
Websites	421	Part Three	
References	421	Supporting the patient through the diagnostic process	507

Foreword to the ninth edition

As the Chief Nurse of the Royal Marsden Hospital NHS Foundation Trust, and a contributor and clinical user of the manual for many years, it is a special pleasure and honour to be asked to introduce the ninth edition of *The Royal Marsden Manual of Clinical Nursing Procedures*. The manual is internationally renowned and used by nurses across the world to ensure their practice is evidence based and effective. As information becomes ever more available to the consumers of healthcare, it is essential that the manual is updated frequently so that it reflects the most current evidence to inform our clinical practice.

More than ever in 2015, nurses need to be able to assure the public, patients and their families that care is based on the best available evidence. As nurses seeking to improve our care, it is essential that we are able to critically analyse our judgements in the light of current knowledge. For all of us working with patients and their families, there is an imperative to question and renew our practice using the many sources of knowledge available to us. In the busy world of clinical practice in a ward, unit or in the community, it can be challenging to find time to search for the evidence and this is where *The Royal Marsden Manual of Clinical Nursing Procedures* is a real practical help.

As in the eighth edition, reviewing the evidence or sources of knowledge has been made more explicit with each level of evidence graded. This grading provides the reader with an understanding of whether the reference comes from a randomized controlled trial, national or international guidance, or from expert opinion. At its best, clinical nursing care is an amalgam of a sensitive therapeutic relationship coupled with effective care based on the best evidence that exists. Some areas of practice have attracted international research such as cardiopulmonary resuscitation and infection prevention and control; other areas of practice have not attracted such robust research and, therefore, it is more of a challenge to ensure evidence-based care. Each time a new edition of the manual is prepared we reflect on the gaps in research and knowledge; this provides the impetus to start developing new concept analyses and develop further research studies. In this new edition, the chapters have incorporated risk management, and legal and professional issues, as well as more guidelines for advanced nursing procedures, e.g. intraosseous

injections. In addition, the procedures were tried out by the student nurses from Kingston University and St Georges University of London to ensure they worked in practice.

As you look at the list of contributors to the manual you will see that this edition has continued to be written by nurses who are expert and active in clinical practice. This has the double advantage of ensuring that this manual reflects the reality of practice, but also ensures that nurses at the Royal Marsden Hospital NHS Foundation Trust are frequently reviewing the evidence and reflecting upon their care.

A textbook devoted to improving and enhancing clinical practice needs to be alive to the clinical practitioner. You will see that this edition has continued the improvement in format, including many more figures and photographs to make the manual more effective in clinical care.

As I commend this ninth edition of *The Royal Marsden Manual of Clinical Nursing Procedures* to you, I am aware that it will be used in many different countries and settings. Having had the privilege of visiting and meeting nurses across the world I know that there are more commonalities than differences between us. The common theme is, of course, the need to ensure that we as nurses provide care that is individually and sensitively planned and that it is based on the best available evidence. *The Royal Marsden Manual of Clinical Nursing Procedures* is a wonderful resource for such evidence and I hope it will be widely used in all clinical settings across the world.

Finally, I would like to pay a warm tribute to the excellent work undertaken by the two editors, Lisa Dougherty and Sara Lister, and to all the nurses and allied health professionals at the Royal Marsden Hospital who have worked so hard on this ninth edition.

Dr Shelley Dolan
Chief Nurse
The Royal Marsden Hospital NHS
Foundation Trust
Clinical Director
London Cancer Alliance

Acknowledgements

A book is a team effort and never more so than with this edition of *The Royal Marsden Manual of Clinical Nursing Procedures*.

Since the first edition was published in 1984, the range of procedures within the manual has grown in complexity, and the depth of the theoretical content underpinning them has increased considerably. Authors have, therefore, had to keep up-to-date with the ever-changing research evidence and write new, as well as update existing, material. This continues to be a collaborative task carried out by knowledgeable, expert nurses in partnership with members of the multidisciplinary team including pharmacists, physiotherapists, occupational therapists, dietitians, speech therapists, radiographers, anaesthetists, operating department practitioners and psychological care.

So, we must thank every member of the 'team' who has helped to produce this edition, for their time, effort and perseverance. An additional challenge has been to co-ordinate the increased number of contributors to each chapter. This responsibility has fallen to the lead chapter authors, so, for this, they deserve a special acknowledgement and thanks for their ability to integrate all the contributions and create comprehensive chapters.

We especially appreciate the work done by Anne Tibbles, Senior Lecturer Nursing, and the nursing students at Kingston University and St George's University of London, who reviewed all of the procedures used by students and gave us invaluable feedback on how they work in practice. We would also like to thank some other key people: Dale Russell and the library team of the David Adams Library at The Royal Marsden School of Cancer Nursing and Rehabilitation for their help and support in providing the references required by the authors and setting up the Endnote system; Stephen Millward and the medical photography team for all the new photographs; our families and friends who continue to encourage us, especially during the last two years – the time it takes to edit the manual; and, finally, our thanks go to Martin Davies, Magenta Styles, James Schultz, Tom Bates and Helen Harvey at Wiley-Blackwell for their advice and support in all aspects of the publishing process.

Lisa Dougherty
Sara Lister

List of contributors

Janice Barrett RN, BSc (Hons), PG Dip HE, MA
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Helen Bass RGN, BSc (Hons) Nursing, MSc (Advancing Healthcare)
Lead Nurse, Clinical Education
(Chapter 8: Patient comfort and end-of-life care)

Helen Benson GPhC, MPharm (Hons), MSc
Associate Chief Pharmacist, Clinical Research and Development
(Chapter 12: Medicines management)

Louise Bisset Dip HE (Adult Nursing), BN (ICU)
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Linda Bloomfield RGN, PG Cert, Dip HE (Nursing),
DN Cert, OND
Discharge/Safeguarding Deputy
(Chapter 2: Assessment and discharge)

Grainne Brady BSc, Cert MRCSLT
Highly Specialist Speech and Language Therapist
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Joanne Bull RN, MSc (Strategic Leadership and Expert Practice,
Cancer), BN (Hons), Dip (Oncology)
Matron, Admissions and Preassessment, Clinical Assessment
Unit, Outpatients and Rapid Diagnostic Assessment Centre
(Chapter 13: Perioperative care)

Nicholas Bultitude Registered ODP, BA (Hons), MSc
(Healthcare Management)
Formerly, Divisional Operational Manager, Anaesthetics and
Surgical Support
(Chapter 13: Perioperative care)

Maureen Carruthers RN, Dip (Oncology), BSc (Hons), MSc
Macmillan Matron, Palliative Care
(Chapter 8: Patient comfort and end-of-life care)

Suzanne Chapman MSc, BSc, RGN
Clinical Nurse Specialist, Pain Management
(Chapter 8: Patient comfort and end-of-life care)

Lydia Clark BA, BSc, Dip (Oncology)
Ward Sister
(Chapter 5: Elimination)

Michael Connolly MPhil, BSc, RGN
Consultant Nurse, Supportive and Palliative Care
(Chapter 4: Communication)

Jill Cooper MSc, DMS, DipCOT
Head Occupational Therapist
(Chapter 6: Moving and positioning)

Michelle Davies BSc (Hons), RD
Home Enteral Feeding/Community Dietitian
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Andrew Dimech RN, BN, MSc (ICU), Dip (Oncology)
Head, Clinical Technical Services
(Chapter 10: Interpreting diagnostic tests)

Laura Dopson BSc (Hons), RGN, NMP
Clinical Nurse Specialist, Pain Management
(Chapter 8: Patient comfort and end-of-life care)

Lisa Dougherty OBE, RN, MSc, DClinP
Nurse Consultant, Intravenous Therapy
(Chapter 12: Medicines management; Chapter 14: Vascular
access devices: insertion and management)

Andreia Fernandes RN, BSc, MSc
Clinical Nurse Specialist, Gynaecology Oncology
(Chapter 8: Patient comfort and end-of-life care; Chapter 10:
Interpreting diagnostic tests)

Cathryn Forsythe RN, Dip HE, BSc (Hons)
Senior Staff Nurse, Critical Care
(Chapter 10: Interpreting diagnostic tests)

Sharon Giles BSc (Hons), MSc
MRI Research Radiographer
(Chapter 10: Interpreting diagnostic tests)

Rosie Goatley BSc (General Nursing,
Intensive Care)
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Keetje Gull BSc (Hons), MSc RGN
Sister, Critical Care Unit
(Chapter 14: Vascular access devices: insertion and
management)

Amanda Gunning RGM
Lead Nurse, Stoma Care
(Chapter 5: Elimination)

Diz Hackman MSc, PG Dip (Physiotherapy)
Clinical Specialist Physiotherapist
(Chapter 6: Moving and positioning)

Ruth Hammond MSc (Advanced Cancer Practice) BSc
(Adult Nursing)
Clinical Practice Educator
(Chapter 11: Observations)

Michael Hansford RMN, PG Dip (Counselling), MA
(Counselling and Psychotherapy)
Staff Counsellor
(Chapter 4: Communication)

The Royal Marsden Manual of Clinical Nursing Procedures

Zoe Hayman Registered Paramedic, Cert HE (Para Sci)
Resuscitation Lead
(Chapter 9: Respiratory care)

Nikki Hunter RN, BSc, MSc, MA
Complex Discharge Nurse
(Chapter 2: Assessment and discharge)

Kate Jones MCSP, HCPC, Dip (Physiotherapy), MSc
Clinical Specialist Physiotherapist
(Chapter 6: Moving and positioning)

Jon M. Knox RGN, Dip HE, BSc (Hons), PG Dip, RNIP, SCP
Advanced Nurse Practitioner, Plastics and Reconstructive Surgery
(Chapter 15: Wound management)

Sara Lister RN, PGDAE, BSc (Hons), MSc, MBACP
Head of Pastoral Care and Psychological Support
(Chapter 1: Introduction; Chapter 4: Communication)

Perrie Luke BSc (General Nursing, Intensive Care),
Independent Nurse Prescriber
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Jennifer Mackenzie RN, BN, Cert (Intensive Care)
Sister, Critical Care
(Chapter 10: Interpreting diagnostic tests)

Katharine Malhotra MSc (Rehabilitation), PG Cert (Clinical Education), BSc (Hons) (Physiotherapy)
Lecturer Practitioner, Allied Health
(Chapter 6: Moving and positioning)

Rebecca Martin RN, MSc, BSc (Hons), Independent Nurse Prescriber
Advanced Nurse Practitioner, Urology
(Chapter 5: Elimination; Chapter 13: Perioperative care)

Nuala McClaren BSc (General Nursing, Intensive Care)
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Hayley McHugh BSc (Hons), RN, Cert (Intensive Care)
Senior Staff Nurse, Intensive Care
(Chapter 7: Nutrition, fluid balance and blood transfusion;
Chapter 10: Interpreting diagnostic tests)

Wendy McSporran RGN, BSc (Hons), PG Dip
Transfusion Practitioner
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Anita McWhirter GPhC, BSc (Hons), MSc
Pharmacy Clinical Services Manager
(Chapter 12: Medicines management)

Dee Mears DCR(R), DMS
CT Superintendent
(Chapter 10: Interpreting diagnostic tests)

Carolyn Moore MCSP, SRP
Superintendent Physiotherapist
(Chapter 6: Moving and positioning)

Philipa Nightingale BN, Nurse Practitioner
Senior Staff Nurse
(Chapter 2: Assessment and discharge)

Claire Nowell BSc (Hons), MSc
Senior Physiotherapist
(Chapter 6: Moving and positioning)

Scott Pollock Dip (Social Work), BA (Hons), MSc
Discharge and Vulnerable Adult Lead
(Chapter 2: Assessment and discharge; Chapter 4: Communication)

Tessa Renouf RN, MSc (Advanced Cancer Practice), BSc (Hons), Dip (Oncology)
Lead Sister, Admissions and Preassessment Unit
(Chapter 13: Perioperative care)

Justin Roe BA (Hons), PG Dip, MSc, PhD, Cert MRCSLT
Joint Head, Speech and Language Therapy and Allied Health Professions Researcher, Project Lead
(Chapter 4: Communication; Chapter 7: Nutrition, fluid balance and blood transfusion)

Lara Roskelly RN, Dip (General, Community Psychiatric Nursing and Midwifery), Dip (ICU), Independent Nurse Prescriber
Matron, Critical Care Outreach and Resuscitation
(Chapter 9: Respiratory care; Chapter 10: Interpreting diagnostic tests)

Janet Schmitt BSc (Hons), PG Cert (Ed), MSc
Neuro-therapy Manager
(Chapter 6: Moving and positioning; Chapter 9: Respiratory care)

Richard Schorstein RN, BSc, PG Dip, Nurse Practitioner
Matron/Nurse Practitioner
(Chapter 2: Assessment and discharge)

Clare Shaw PhD (Nutrition), BSc (Hons) (Nutrition), PG Dip (Dietetics)
Consultant Dietitian
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Louise Soanes RGN/RSCN, BSc, MSc
Teenage Cancer Trust Nurse Consultant, Adolescents and Young Adults
(Chapter 10: Interpreting diagnostic tests)

Heather Spurgeon RN, BSc (Critical Care Nursing), MSc (Adult Critical Care)
Matron, Critical Care and Theatres
(Chapter 11: Observations)

Anna-Marie Stevens MSc, BSc (Hons), RN
Macmillan Nurse Consultant, Palliative Care
(Chapter 8: Patient comfort and end-of-life care)

Nicola Tinne MSc (Advanced Cancer Practice), BSc (Cancer Nursing), Dip HE (Nursing Studies), RGN
Formerly, Clinical Nurse Specialist, Head and Neck Cancers
(Chapter 15: Wound management)

Richard Towers RGN, BSc (Hons), MSc, Professional Doctorate Nursing
Lead Nurse Counsellor/Lecturer Practitioner
(Chapter 4: Communication)

Simon Tuddenham RN, BN (Hons), BA (Hons)
Staff Nurse, Critical Care
(Chapter 10: Interpreting diagnostic tests)

Vanessa Franklin Urbina MSc (Nutrition and Dietetics), RD
Senior Specialist Dietitian
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Susan Vyoral BSc (Hons), RD
Dietitian
(Chapter 7: Nutrition, fluid balance and blood transfusion)

Victoria Ward RN, BN (Hons), MSc
Matron/Nurse Practitioner
(Chapter 2: Assessment and discharge)

Paul Weaving BSc, RGN, MSc
Formerly, Associate Director, Infection Prevention and Control
(Chapter 3: Infection prevention and control)

Alexandra West-Oram MSc, BSc (Hons), PG Dip (Ed), RN, RT
Programme Leader, The Royal Marsden School
(Chapter 5: Elimination)

Catherine Wilson PhD, MSc, BSc (Hons), PG Dip (Ed), RN, Dip HE (Palliative Care), Cert Oncology Nursing
Interim Head of School, Royal Marsden School
(Chapter 4: Communication)

Barbara Witt RN
Nurse, Phlebotomist
(Chapter 10: Interpreting diagnostic tests)

Luv Wootton BSc (General Nursing, Intensive Care)
Sister, Critical Care Outreach
(Chapter 9: Respiratory care)

Lynn Worley RGN, RMN, BSc (Hons) (Cancer Practice)
Clinical Nurse Specialist, Plastic Surgery and Tissue Viability
(Chapter 15: Wound management)

The authors and Wiley Blackwell are hugely grateful to the nursing staff and students at Kingston University and St George's University London for their help in the development of this edition.

Nursing staff

Cathy Chia RN, RM, RMN, Cert Ed, BSc (Hons), MSc
Senior Lecturer, Simulated Learning and Clinical Skills

Karen Elliott RN, BSc (Hons), PGCE
Senior Lecturer, Simulated Learning and Clinical Skills

Terry Firth RN, BA (Hons), RNT
Senior Lecturer, Simulated Learning and Clinical Skills.

Suchita Hathiramani MCSP, BSc, MSC, FHEA
Senior Lecturer, Simulated Learning and Clinical Skill

Francina Hyatt RN, Dip N, BSc (Hons)
Senior Lecturer, Simulated Learning and Clinical Skills

Jo Low
Clinical Skills Laboratory Manager

Tracey Marshall RN, BSc (Hons)
Nutrition Specialist Nurse, St George's Hospital

Barry Pearse RN, BA (Hons), PGCE
Senior Lecturer, Simulated Learning and Clinical Skills

Hazel Ridgers RN, DipHE, BA (Hons), MA
Senior Lecturer, Simulated Learning and Clinical Skills

Susan Rush RN, MSC, RNT
Associate Professor, Simulated Learning and Clinical Skills

Annie Spalton RN, Dip N, RNT
Senior Lecturer, Simulated Learning and Clinical Skills

Anne Tibbles TD, MSc, MA, PG Dip, PGCE, BSc (Hons), Dip N (Lond), RN
Senior Lecturer, Simulated Learning and Clinical Skills

Student cohorts

Diploma in Nursing students: September 10 and February 11

BSc Nursing students: September 11 and September 12

PG Dip Nursing students: February 12 and September 12

Abdominal examination	32	Drainage systems: changing the dressing around the	
Abdominal paracentesis	399	drain site for both open and closed drains	838
Acupuncture: preparation and administration	376	Dressing a wound	945
Arterial blood gas sampling: arterial cannula	532	Early mobilization of the patient in bed	243
Arterial cannula insertion: preparation and setting up of monitoring set	921	Electrocardiogram	608
Arterial cannula: removal	923	Enema administration	181
Arterial puncture: radial artery	530	Enteral feeding tubes: administration of feed	294
Artificial eye care: insertion	347	Enteral feeding tubes: administration of medication	296
Artificial eye care: removal	347	Enteral feeding tubes: unblocking	298
Aseptic technique example: changing a wound dressing	78	Entonox administration	394
Assisting the patient to walk	220	Epidural/intrathecal catheter removal	383
Bedbathing a patient	337	Epidural/intrathecal exit site dressing change	382
Blood component administration	316	Epidural/intrathecal sensory blockade: assessment	381
Blood components: collection and delivery to the clinical area	314	Extravasation management: peripheral cannula	774
Blood cultures: central venous access device	538	Extravasation: performing flush-out following an extravasation	776
Blood cultures: peripheral (winged device collection method)	537	Eye irrigation	345
Blood glucose monitoring	649	Eye swabbing	344
Blood pressure measurement (manual)	616	Faecal sampling	572
Blood product request	312	Feeding an adult patient	276
Blood sampling: antimicrobial drug assay	541	Fluid input: measurement	259
Blood sampling: pre-transfusion	313	Fluid output: measuring output from drains	262
Cardiopulmonary resuscitation	498	Fluid output: monitoring output from bowels	263
Cardiovascular examination	28	Fluid output: monitoring output from gastric outlets, nasogastric tubes, gastrostomy	263
Care of a patient who is vomiting	135	Fluid output: monitoring output from stoma sites	264
Care of the patient during bladder irrigation	164	Fluid output: monitoring/measuring output if the patient is catheterized	261
Caring for the patient in the anaesthetic room	816	Fluid output: monitoring/measuring output if the patient is not catheterized	261
Central venous access devices: taking a blood sample for syringe sampling	526	Hand decontamination using alcohol handrub	63
Central venous access devices: taking a blood sample for vacuum sampling	525	Hand washing	61
Central venous access devices: unblocking an occlusion	872	Handover in post-anaesthetic care unit: scrub nurse/ODP to recovery practitioner	827
Central venous catheter (skin-tunnelled): surgical removal	912	High-flow oxygen therapy	444
Central venous catheter: insertion site dressing change	870	Humidification for respiratory therapy	443
Cervical uterine smear using a wooden spatula	552	Implanted ports: insertion and removal of non-coring needles	916
Cervical uterine smear using an endocervical brush	555	Inserting an intraosseous needle	743
Cervical uterine smear using liquid-based cytology	554	Insertion of a nasogastric (NG) drainage tube	137
Checking the balloon volume on a balloon gastrostomy	291	Jejunostomy feeding tube care	292
Chest drain: changing the bottle	462	Log rolling for suspected/confirmed cervical spinal instability	237
Chest drain: insertion	458	Log rolling for suspected/confirmed thoracolumbar spinal instability	242
Chest drain: priming ambulatory chest drain bag	461	Lumbar puncture	544
Chest drain: removal	463	Measuring the weight and height of the patient	269
Chest drainage: suction	461	Medication: administration by inhalation using a metered dose inhaler	710
Clip removal	961	Medication: administration by inhalation using a nebulizer	711
Closed drainage systems: changing a vacuum bottle	839	Medication: continuous infusion of intravenous drugs	757
Commencing bladder irrigation	162	Medication: controlled drug administration	694
Commode use: assisting a patient	143	Medication: ear drop administration	718
Contact lens removal: hard lenses	348	Medication: eye administration	715
Contact lens removal: soft lenses	349	Medication: injection (bolus or push) of intravenous drugs	763
Continent urinary diversion stoma: self-catheterization	172	Medication: injection administration	727
Continuous positive airway pressure	449		
Digital rectal examination	186		
Digital removal of faeces	188		
Donning a sterile gown and gloves: closed technique	73		
Donning sterile gloves: open technique	71		

Medication: intermittent infusion of intravenous drugs	760	Positioning the unconscious patient or patient with an airway in side-lying	224
Medication: intradermal injection	729	Positioning to maximize the drainage of secretions	230
Medication: intramuscular injection	741	Pre-operative care: checking that the patient is fully prepared for surgery	811
Medication: multidose vial: powder preparation using equilibrium method	726	Protective isolation: entering the isolation room	88
Medication: multidose-vial: powder preparation using a venting needle	724	Protective isolation: preparing the room	87
Medication: nasal drop administration	716	Pulse measurement	602
Medication: oral drug administration	701	Putting on and removing a disposable apron	66
Medication: self-administration	688	Putting on and removing a disposable mask or respirator	67
Medication: single-dose ampoule: powder preparation	723	Putting on and removing non-sterile gloves	64
Medication: single-dose ampoule: solution preparation	722	Putting on or removing goggles or a face shield	68
Medication: subcutaneous administration using a McKinley T34 syringe pump	736	Radiologically inserted gastrostomy (RIG) tube care	290
Medication: subcutaneous infusion of fluids	734	Removal of a nasogastric tube	138
Medication: subcutaneous injection	732	Removal of a nasogastric tube	287
Medication: topical applications	703	Removal of T-fasteners	290
Medication: transdermal applications	704	Removing an intraosseous needle	746
Medication: vaginal administration	706	Respiratory assessment and pulse oximetry	627
Midline catheter insertion	891	Respiratory examination	25
Mouth care	357	Safe disposal of foul, infected or infested linen	92
Mouth care for the patient with dentures	359	Safe management of the patient in the PACU	829
Moving from sitting to standing: assisting the patient	219	Semen collection	550
Nasogastric intubation with tubes using an internal guidewire or stylet	281	Short-term central venous catheter (non-cuffed/tunnelled) insertion into the internal jugular vein	906
Nasopharyngeal wash: syringe method	575	Short-term central venous catheter (non-cuffed/tunnelled): removal	909
Nasopharyngeal wash: vacuum-assisted aspirate method	577	Slipper bedpan use: assisting a patient	142
Negative pressure wound therapy	964	Source isolation: entering the isolation room	84
Nephrostomy tube: removal of locking pigtail drainage system	169	Source isolation: leaving the isolation room	85
Nephrostomy tube: weekly dressing and bag change	167	Source isolation: preparing an isolation room	83
Neurological observations and assessment	662	Source isolation: transporting infected patients outside the source isolation area	86
Operating theatre procedure: maintaining the safety of a patient while undergoing surgery	824	Sputum sampling	574
Oxygen therapy	438	Step-by-step guide to measuring and applying antiembolic stockings	802
Pain assessment	365	Stoma bag change	195
Peak flow reading using a manual peak flow meter	632	Stoma bridge or rod removal	196
Penile sheath application	145	Stoma siting	193
Percutaneous endoscopically placed gastrostomy (PEG) tube care	288	Suppository administration	184
Peripheral cannula insertion	881	Surgical scrub technique	69
Personal care after death	416	Suture removal	960
PICC insertion using modified Seldinger technique with ultrasound	897	Suturing a simple wound	956
PICC removal	902	Swab sampling: ear	558
Positioning for suspected/confirmed cervical spinal instability: pelvic twist to right	240	Swab sampling: eye	559
Positioning the neurological patient with tonal problems	233	Swab sampling: nose	559
Positioning the patient to maximize V/Q matching for widespread pathology in a self-ventilating patient	227	Swab sampling: penis	560
Positioning the patient to maximize V/Q matching with unilateral lung disease in a self-ventilating patient	226	Swab sampling: rectum	561
Positioning the patient: in a chair/wheelchair	218	Swab sampling: skin	562
Positioning the patient: lying down to sitting up	216	Swab sampling: throat	563
Positioning the patient: side-lying	215	Swab sampling: vagina	564
Positioning the patient: sitting in bed	214	Swab sampling: wound	564
Positioning the patient: supine	213	Temperature measurement	638
Positioning the pre-operative and post-operative amputation patient	247	Tracheostomy: dressing change	475
Positioning the unconscious patient or patient with an airway in supine	222	Tracheostomy: inner cannula change	480
		Tracheostomy: suctioning a patient	478
		Tracheostomy: tube change	481
		Urinalysis: reagent strip procedure	644
		Urinary catheter bag: emptying	158
		Urinary catheter removal	159
		Urinary catheterization: female	153
		Urinary catheterization: intermittent self-catheterization patient guidance: male	156
		Urinary catheterization: intermittent self-catheterization patient guidance: female	157
		Urinary catheterization: male	151
		Urine sampling: 24-hour urine collection	570

Urine sampling: catheter specimen of urine (CSU)	568	Venepuncture	519
Urine sampling: midstream specimen of urine: female	567	Washing a patient's hair in bed	339
Urine sampling: midstream specimen of urine: male	566	Wound drain removal: closed drainage system	841
Urine sampling: sampling from an ileal conduit	569	Wound drain shortening for closed drainage systems	845
Vascular access devices: maintaining patency	872	Wound drain shortening for open drainage systems	843

How to use your manual

Features contained within your manual

The **overview page** gives a summary of the topics covered in each part.

Part Two

Supporting the patient with human functioning

Chapters

- 4 Communication 97
- 5 Elimination 133
- 6 Moving and positioning 207
- 7 Nutrition, fluid balance and blood transfusion 253
- 8 Patient comfort and end-of-life care 331
- 9 Respiratory care 431

Every chapter begins with a **list of procedures** found within the chapter.

Problem-solving table 4.2 Prevention and resolution (Principles table 4.8)

Box 4.8 Managing the patient with depression: NICE guidance, step 1

- 1 During the last month, have you often been bothered by:
 - feeling down, depressed or hopeless?
 - having little interest or pleasure in doing things?
- 2 How long have you felt like this for?

If the patient answers 'yes' to question 1 and the time scale is longer than 2 weeks, it is important that a referral is made for further assessment by a healthcare professional with clinical competence in managing depression, such as a clinical psychologist or a registered mental health nurse, so they can determine if the patient has been bothered by 'feelings of worthlessness, poor concentration or thoughts of death' (NICE 2009a, p.4).

- Other physical health problems that may be significantly affecting their mood such as uncontrolled pain, sleep disruption, excessive nausea and vomiting, physical limitations on their independence or body image disturbance.
- A history of psychological illness such as depression.
- A consideration of the medication the patient is taking, specifically medication for mental health problems. Have they been able to take it and absorb it or have they had any digestive issues?
- Social support for the patient: who else is around to support the person, are they isolated?

Definition

Definition
Anger is an emotional state experienced as the impulse to behave in order to protect, defend or attack in response to a threat or

challenge. Of itself, anger is not classified as an emotional disorder. This emotional state may range in intensity from mild irritation to intense fury and rage and becomes a problem when it is associated with poor impulse control.

Nurses may be exposed to anger and aggression. Poor communication is frequently a precursor to aggressive behaviour (Duxbury and Whittington 2005). Aggression and abuse tend to be discussed synonymously in the literature and are reported to occur with some frequency in nursing (McLaughlin et al. 2009). Anger is felt or displayed when someone's annoyance or irritation has increased to a point where they feel or display extreme displeasure. Verbal aggression is the expression of anger via hostile language; this language causes offence and may result in physical assault. Verbal abuse may actually be experienced as worse than a minor physical assault (Adams and Whittington 1995).

Whatever the cause of anger or conflict, people can behave in a number of challenging ways and with varying degrees of resistance to social and hospital rules. People may simply refuse to comply with a request or may behave more aggressively, for example by pushing someone aside (without intent to harm) or by deliberately striking out at others. Mental capacity issues should be considered when assessing the causes of aggressive behaviours.

When patients do feel anger, they may feel too depleted by experiences of disease and treatment to express it (Bowes et al 2002).

For some people, anger may be the least distressing emotion to display. Sometimes helplessness, sadness and loss are far harder to explore and show to others. Anger therefore can be a way of controlling intimacy and disclosure, but it can escalate to threatening, abusive or violent behaviour.

Prevention is the most effective method of managing anger; that is, diffusing stressful or difficult interactions before they become a crisis. Understanding why angry or challenging behaviour occurs can be helpful in establishing a

Figure 4.6 Managing and assessing risk behaviours. A framework for explaining challenging behaviour. *Source:* NHS Protect (2013). Reproduced with permission from NHS Protect (www.nhsprotect.nhs.uk/reducingdistress).

comprehensive approach to prevention. NHS Protect (2013) proposes a framework for explaining challenging behaviour. This includes considering:

- **historical factors:** such as substance and alcohol abuse
- **current presentation:** diagnosis, physical factors such as pain
- **triggers or antecedents:** which include environmental factors such as other agitated individuals, busy or noisy areas and situational factors such as inconsistent staff attitude, time of day. Figure 4.6 presents this in more detail.

In some instances, challenging or difficult behaviour can be seen to be related to underlying stress and difficulty in a

person's situation. Anger, aggression and violence may have biological, psychological, social and environmental roots (Krug 2002, p. 25). People frequently get angry when they feel that they are not being heard or when their control of a situation and self-esteem are compromised. Institutional pressures can influence healthcare professionals to act in controlling ways and may contribute to people's angry responses (Hadjisocial, 2004). Patients are often unhappy with procedures that threaten them and they may consequently feel vulnerable and react aggressively as a result (NIHS Protect 2013). Another source of anger can be when personal beliefs in the form of rules are broken by others. We therefore need to strive to be aware of our own personal values and work with them to avoid frustration and upset.

People also can become angry when they feel that they have not been communicated with honestly or are misled about treatments and their outcomes. To prevent people's frustration escalating into anger or worse, health professionals need to ensure that they are communicating openly, honestly and frequently (NHS Protect 2013).

Some patients may appear or sound aggressive when they are not intending to be and the nurse must therefore use good judgement to clarify their behaviour in these instances. Nurses need to be aware of their own boundaries and capabilities when dealing with challenging or abusive situations.

Threats, uncertainty and disempowerment may predispose people to anger, and living with and being treated for any serious condition can be sufficiently threatening and disempowering (NHS Protect 2013).

Nurses may be inclined to accept aggressive behaviour as part of the job (McLaughlin et al. 2009) due to being encouraged to be caring, compassionate and accepting of others. Despite this, nurses have the right to work without feeling intimidated or threatened and should not tolerate verbal or physical abuse, threats or assault. Personal comments, sarcasm and innuendo are all unacceptable.

Employers have a responsibility to adhere to Management of Health and Safety at Work Regulations (HM Government 2000, NHS Protect 2013). This involves providing a safe environment for people to work in and one that is free from threats and abuse. With any physical assault, the police should be involved.

▲ ــ▲

Assessment
Box 4.9 lists signs indicating that people may be angry. It is necessary to engage people sensitively and carefully to attempt to help them whilst maintaining a safe environment for all.

It is frequently possible to engage with and manage some of the underlying features without endangering anyone. People who are behaving aggressively probably do not normally act that way and may apologize when helped.

Talking down or de-escalation of situations where someone is being non-compliant can be achieved with careful assessment

- Tense, angry facial signs, restlessness and increased volume of speech
- Prolonged eye contact and a refusal to communicate
- Unclear thought process, delusions or hallucinations
- Verbal threats and reporting angry feelings

Chapter 1

Introduction

2 Overview

This introductory chapter gives an overview of the purpose and structure of the book. Nurses have a central role to play in helping patients to manage the demands of the procedures described in this manual. We also need to be mindful of the evidence upon which we are basing the care we deliver. We hope that through increasing the clarity with which the evidence for the procedures in this edition are presented you will be better able to underpin the care you deliver to your patients in your day-to-day practice.

The chapter also highlights how the risk management implications of the areas of practice are now integrated into each chapter. The chapter then goes on to explain how the structure of the book is organized into three broad sections that represent, as far as possible, the needs of a patient along their care pathway.

The first edition of *The Royal Marsden Manual of Clinical Nursing Procedures* was produced in the early 1980s as a core procedure manual for safe nursing practice within The Royal Marsden Hospital, the first cancer hospital in the world. Implicit behind that first edition was the drive to ensure that patients received the very best care – expertise in carrying out clinical procedures combined with an attitude of respect and compassion.

Thirty years later these attitudes are still fundamental. The Chief Nurse Jane Cummings has ‘committed to make sure all patients receive the very best care with compassion and clinical skill’ (DH 2013). The values and behaviours of this compassionate practice are: *Care, Compassion, Competence, Communication, Courage and Commitment* – the 6Cs (DH 2013). This manual of clinical procedures focuses on bringing together current evidence, acting as an essential resource for practice and providing the theory underpinning *Competence*, one of the 6Cs.

This ninth edition focuses for the first time on procedures that are applicable in all areas of acute inpatient hospital care. (Procedures specific to the care of the cancer patient can be found in the new companion volume *The Royal Marsden Clinical Cancer Nursing Procedures*.) The Manual is informed by the day-to-day practice in the hospital and conversely is the corporate policy and procedure document for the adult inpatient service of the organization. It therefore does not cover all aspects of acute nursing practice or those relating to children’s or community nursing. However, it does contain the procedures and changes in practice that reflect modern acute nursing care.

Core to nursing, wherever it takes place, is the commitment to care for individuals and to keep them safe so that when and wherever the procedures are used, they are to be carried out within the framework of the Nursing and Midwifery Code, (NMC 2015). In respect of clinical competency, the NMC Code states that you must:

- have the knowledge and skills for safe and effective practice without direct supervision
- keep your knowledge and skills up to date throughout your working life
- recognize and work within the limits of your competence (NMC 2015).

The Manual has been structured to enable nurses to develop competency, recognizing that competence is not just about knowing how to do something but also about understanding the rationale for doing it and the impact it may have on the patient.

Some of the procedures in the Manual will be newer for nursing, carried out by nurses such as advanced nurse practitioners. Developing new roles and taking responsibility for new procedures have obvious risks attached and, although every individual nurse is accountable for their own actions, every healthcare organization has to take vicarious liability for the care, treatment and procedures that take place. An organization will have expectations of all its nurses in respect of keeping patients, themselves

and the environment safe. There are obvious ethical and moral reasons for this: ‘Nurses have a moral obligation to protect those we serve and to provide the best care we have available’ (Wilson 2005, p.118). Risk management has therefore become an integral part of day-to-day nursing work. For this reason, the risk management implications of the areas of practice have been integrated into each chapter.

Evidence-based practice

The moral obligation described above extends to the evidence upon which we base our practice. Nursing now exists in a health-care arena that routinely uses evidence to support decisions and nurses must justify their rationales for practice. Where historically, nursing and specifically clinical procedures were based on rituals rather than research (Ford and Walsh 1994, Walsh and Ford 1989), evidence-based practice (EBP) now forms an integral part of practice, education, management, strategy and policy. Nursing care must be appropriate, timely and based on the best available evidence.

What is evidence-based practice?

Evidence-based practice has been described by Sackett, a pioneer in introducing EBP in UK healthcare, as:

‘the conscientious, explicit and judicious use of current best evidence in making decisions about the care of the individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research’ (Sackett et al. 1996, p.72).

Despite the emphasis on research in EBP, it is important to note that where research is lacking, other forms of evidence can be equally informative when making decisions about practice. Evidence-based practice goes much wider than research-based practice and encompasses clinical expertise as well as other forms of knowing, such as those outlined in Carper’s seminal work (1978) in nursing. These include:

- empirical evidence
- aesthetic evidence
- ethical evidence
- personal evidence.

This issue is evident throughout this Manual where clinical expertise and guidelines inform the actions and rationale of the procedures. Indeed, these other types of evidence are highly important as long as we can still apply scrutiny to their use.

Porter (2010) describes a wider empirical base upon which nurses make decisions and argues for nurses to take into account and be transparent about other forms of knowledge such as ethical, personal and aesthetic knowing, echoing Carper (1978). By doing this, and through acknowledging limitations to these less empirical forms of knowledge, nurses can justify their use of them to some extent. Furthermore, in response to Paley’s (2006) critique of EBP as a failure to holistically assess a situation, nursing needs to guard against cherry-picking, ensure EBP is not brandished ubiquitously and indiscriminately and know when judicious use of, for example, experiential knowledge (as a form of personal knowing) might be more appropriate.

Evidence-based nursing (EBN) and EBP are differentiated by Scott and McSherry (2009) in that EBN involves additional elements in its implementation. Evidence-based nursing is regarded as an ongoing process by which evidence is integrated into practice and clinical expertise is critically evaluated against patient involvement and optimal care (Scott and McSherry 2009). For

nurses to implement EBN, four key requirements are outlined (Scott and McSherry 2009).

- 1 To be aware of what EBN means.
- 2 To know what constitutes evidence.
- 3 To understand how EBN differs from evidence-based medicine and EBP.
- 4 To understand the process of engaging with and applying the evidence.

We contextualize our information and decisions to reach best practice for patients and the ability to use research evidence and clinical expertise together with the preferences and circumstances of the patient to arrive at the best possible decision for that patient is recognized (Guyatt et al. 2004).

Knowledge can be gained that is both propositional, that is from research and generalizable, and non-propositional, that is implicit knowledge derived from practice (Rycroft-Malone et al. 2004). In more tangible, practical terms, evidence bases can be drawn from a number of different sources, and this pluralistic approach needs to be set in the context of the complex clinical environment in which nurses work in today's NHS (Pearson et al. 2007, Rycroft-Malone et al. 2004). The evidence bases can be summarized under four main areas.

- 1 Research
- 2 Clinical experience/expertise/tradition
- 3 Patient, clients and carers
- 4 The local context and environment (Pearson et al. 2007, Rycroft-Malone et al. 2004)

Grading evidence in *The Royal Marsden Manual of Clinical Nursing Procedures*

The type of evidence that underpins procedures is made explicit by using a system to categorize the evidence which is broader than that generally used. It has been developed from the types of evidence described by Rycroft-Malone et al. (2004) in an attempt to acknowledge that 'in reality practitioners draw on multiple sources of knowledge in the course of their practice and interaction with patients' (Rycroft-Malone et al. 2004, p.88).

The sources of evidence, along with examples, are identified as follows.

- 1 *Clinical experience (E)*
 - Encompasses expert practical know-how, gained through working with others and reflecting on best practice.
 - *Example:* (Dougherty 2008: E). This is drawn from the following article that gives expert clinical opinion: Dougherty, L. (2008) Obtaining peripheral vascular access. In: Dougherty, L. & Lamb, J. (eds) *Intravenous Therapy in Nursing Practice*, 2nd edn. Oxford: Blackwell Publishing.
- 2 *Patient (P)*
 - Gained through expert patient feedback and extensive experience of working with patients.
 - *Example:* (Diamond 1998: P). This has been gained from a personal account of care written by a patient: Diamond, J. (1998) *C: Because Cowards Get Cancer Too*. London: Vermilion.
- 3 *Context (C)*
 - Can include audit and performance data, social and professional networks, local and national policy, guidelines from professional bodies (e.g. Royal College of Nursing [RCN]) and manufacturer's recommendations.
 - *Example:* (DH 2001: C). This document gives guidelines for good practice: DH (2001) *National Service Framework for Older People*. London: Department of Health.
- 4 *Research (R)*
 - Evidence gained through research.
 - *Example:* (Fellowes et al. 2004: R). This has been drawn from the following evidence: Fellowes, D., Wilkinson, S. & Moore,

P. (2004) Communication skills training for healthcare professionals working with cancer patients, their families and/or carers. *Cochrane Database of Systematic Reviews*, 2, CD003751. DOI: 10.1002/14651858.CD003751.pub2.

The levels that have been chosen are adapted from Sackett et al. (2000) as follows.

- 1 a. Systematic reviews of randomized controlled trials (RCTs)
b. Individual RCTs with narrow confidence limits
- 2 a. Systematic reviews of cohort studies
b. Individual cohort studies and low-quality RCTs
- 3 a. Systematic reviews of case-control studies
b. Case-control studies
- 4 Case series and poor-quality cohort and case-control studies
- 5 Expert opinion

The evidence underpinning all the procedures has been reviewed and updated. To reflect the current trends in EBP, the evidence presented to support the procedures within the current edition of the Manual has been graded, with this grading made explicit to the reader. The rationale for the system adopted in this edition will now be outlined.

As we have seen, there are many sources of evidence and ways of grading evidence, and this has led us to a decision to consider both of these factors when referencing the procedures. You will therefore see that references identify if the source of the evidence was from:

- clinical experience and guidelines (Dougherty 2008: E)
- patient (Diamond 1998: P)
- context (DH 2001: C)
- research (Fellowes et al. 2004: R).

If there is no written evidence to support a clinical experience or guidelines as a justification for undertaking a procedure, the text will be referenced as an 'E' but will not be preceded by an author's name.

For the evidence that comes from research, this referencing system will be taken one step further and the research will be graded using a hierarchy of evidence. The levels that have been chosen are adapted from Sackett et al. (2000) and can be found in Box 1.1.

Taking the example above of Fellowes et al. (2004) 'Communication skills training for healthcare professionals working with cancer patients, their families or carer', this is a systematic review of RCTs from the Cochrane Centre and so would be identified in the references as: Fellowes et al. (2004: R 1a).

Through this process, we hope that the reader will be able to more clearly identify the nature of the evidence upon which the care of patients is based and that this will assist when using these procedures in practice. You may also like to consider the evidence base for other procedures and policies in use in your own organization.

Box 1.1 Levels of evidence

- 1 a. Systematic reviews of RCTs
b. Individual RCTs with narrow confidence limits
- 2 a. Systematic reviews of cohort studies
b. Individual cohort studies and low-quality RCTs
- 3 a. Systematic reviews of case-control studies
b. Case-control studies
- 4 Case series and poor-quality cohort and case-control studies
- 5 Expert opinion

RCTs, randomized controlled trials.

4 Structure of the Manual

The chapters have been organized into four broad sections that represent as far as possible the needs of a patient along their care pathway. The first section, *Managing the patient journey*, presents the generic information that the nurse needs for every patient who enters the acute care environment. The second section of procedures, *Supporting the patient with human functioning*, relates to the support a patient may require with normal human functions such as elimination, nutrition and respiration. The third section, *Supporting the patient through the diagnostic process*, includes procedures that relate to any aspect of supporting a patient through the diagnostic process, from simple procedures such as taking a temperature to preparing a patient for complex procedures such as a liver biopsy. The final section, *Supporting the patient through treatment*, includes the procedures related to specific types of treatment or therapies the patient is receiving.

Structure of chapters

The structure of each chapter is consistent throughout the book.

- **Overview:** as the chapters are larger and have considerably more content, each one begins with an overview to guide the reader, informing them of the scope and the sections included in the chapter.
- **Definition:** each section begins with a definition of the terms and explanation of the aspects of care, with any technical or difficult concepts explained.
- **Anatomy and physiology:** each section includes a discussion of the anatomy and physiology relating to the aspects of nursing care in the chapter. If appropriate, this is illustrated with diagrams so the context of the procedure can be fully understood by the reader.
- **Related theory:** if an understanding of theoretical principles is necessary to understand the procedure then this has been included.
- **Evidence-based approaches:** this provides background and presents the research and expert opinion in this area. If appropriate, the indications and contraindications are included as well as any principles of care.
- **Legal and professional issues:** this outlines any professional guidance, law or other national policy that may be relevant to the procedures. If necessary, this includes any professional competences or qualifications required in order to perform the procedures. Any risk management considerations are also included in this section.
- **Pre-procedural considerations:** when carrying out any procedure, there are certain actions that may need to be completed, equipment prepared or medication given before the procedure begins. These are made explicit under this heading.
- **Procedure:** each chapter includes the current procedures that are used in the acute hospital setting. They have been drawn from the daily nursing practice at The Royal Marsden NHS Foundation Trust. Only procedures about which the authors have knowledge and expertise have been included. Each procedure gives detailed step-by-step actions, supported by rationale, and where available the known evidence underpinning this rationale has been indicated.
- **Problem solving and resolution:** if relevant, each procedure will be followed by a table of potential problems that may be encountered while carrying out the procedure as well as suggestions as to the cause, prevention and any action that may help resolve the problem.
- **Post-procedural considerations:** care for the patient does not end with the procedure. This section details any documentation the nurse may need to complete, education/information that needs to be given to the patient, ongoing observations or referrals to other members of the multiprofessional team.

- **Complications:** any ongoing problems or potential complications are discussed in a final section which includes evidence-based suggestions for resolution.
- **Illustrations:** colour illustrations have been used to demonstrate the steps of some procedures. This will enable the nurse to see in greater detail, for example, the correct position of hands or the angle of a needle.
- **References and reading list:** the chapter finishes with a combined reference and reading list. Only recent texts from the last 10 years have been included unless they are seminal texts. A list of websites has also been included.

This book is intended as a reference and a resource, not as a replacement for practice-based education. None of the procedures in this book should be undertaken without prior instruction and subsequent supervision from an appropriately qualified and experienced professional. We hope that *The Royal Marsden Hospital Manual of Clinical Nursing Procedures* will continue to be a resource to deliver high-quality care that maximizes the well-being and improves the health outcomes of patients in acute hospital settings.

Conclusion

It is important to remember that even if a procedure is very familiar to us and we are very confident in carrying it out, it may be new to the patient, so time must be taken to explain it and gain consent, even if this is only verbal consent. The diverse range of technical procedures that patients may be subjected to should act as a reminder not to lose sight of the unique person undergoing such procedures and the importance of individualized patient assessment in achieving this.

When a nurse
Encounters another
What occurs is never a neutral event
A pulse taken
Words exchanged
A touch
A healing moment
Two persons
Are never the same
(Anon in Dossey et al. 2005)

Nurses have a central role to play in helping patients to manage the demands of the procedures described in this Manual. It must not be forgotten that for the patient, the clinical procedure is part of a larger picture, which encompasses an appreciation of the unique experience of illness. Alongside this, we need to be mindful of the evidence upon which we are basing the care we deliver. We hope that through increasing the clarity with which the evidence for the procedures in this edition is presented, you will be better able to underpin the care you deliver to your patients in your day-to-day practice.

Overview

10

This chapter will give an overview of a patient's care from assessment through to discharge.

Assessment forms an integral part of patient care and is considered to be the first step in the process of individualized nursing care. It provides information that is critical to the development of a plan of action that enhances personal health status.

Assessment decreases the potential for, or the severity of, chronic conditions and helps the individual to gain control over their health through self-care (RCN 2004). Early and continued assessments are vital to the success of the management of patient care. It is critical that nurses have the ability to assess patients and document their findings in a systematic way.

Advanced nursing practice provides a high quality of care (McLoughlin et al. 2012), and has emerged in response to changing healthcare demands and the need for a flexible approach to care delivery. Key roles within advanced nursing practice include conducting comprehensive health assessments, demonstrating expert skills in diagnosing and treating acute or chronic illness and making specialist referrals as required. Physical assessment is a core procedure for those undertaking this role so has been incorporated into this chapter.

Discharge planning is key to ensuring that patients return to the community with the appropriate care to support them and their carers at home. The process can also reduce hospital length of stay and unplanned readmission to hospital, and improve the co-ordination of services following discharge from hospital (Shepperd et al. 2013).

The nurse's ability to assess the needs of the patient and carer (Atwal 2002) is central to a good discharge.

Inpatient assessment and the process of care

Definition

Assessment is the systematic and continuous collection, organization, validation and documentation of information (Berman et al. 2010). It is a deliberate and interactive process that underpins every aspect of nursing care (Heaven and Maguire 1996). It is the process by which the nurse and patient together identify needs and concerns. It is seen as the cornerstone of individualized care, a way in which the uniqueness of each patient can be recognized and considered in the care process (Holt 1995).

Related theory

Principles of assessment

The purpose of the nursing assessment is to get a complete picture of the patient and how they can be helped. An effective assessment will provide the nurse with information on the patient's background, lifestyle, family history and the presence of illness or injury (Crouch and Meurier 2005). The nursing assessment should focus on the patient's response to a health need rather than disease process and pathology (Wilkinson 2007). The process of assessment requires nurses to make accurate and relevant observations, to gather, validate and organize data and to make judgements to determine care and treatment needs. It should have physical, psychological, spiritual, social and cultural dimensions, and it is vital that these are explored with the person being assessed. The patient's perspective of their level of daily activity functioning (Horton 2002) and their educational needs is essential to help maximize their understanding and self-care abilities (Alfaro-LeFevre 2014). It is only after making observations of the person and involving them in the process that the nurse can validate their perceptions and make appropriate clinical judgements.

Effective patient assessment is integral to the safety, continuity and quality of patient care, and fulfils the nurse's legal and

Box 2.1 Principles of assessment

- 1 Patient assessment is patient focused, being governed by the notion of an individual's actual, potential and perceived needs.
- 2 It provides baseline information on which to plan the interventions and outcomes of care to be achieved.
- 3 It facilitates evaluation of the care given and is a dimension of care that influences a patient's outcome and potential survival.
- 4 It is a dynamic process that starts when problems or symptoms develop, and continues throughout the care process, accommodating continual changes in the patient's condition and circumstances.
- 5 It is essentially an interactive process in which the patient actively participates.
- 6 Optimal functioning, quality of life and the promotion of independence should be primary concerns.
- 7 The process includes observation, data collection, clinical judgement and validation of perceptions.
- 8 Data used for the assessment process are collected from several sources by a variety of methods, depending on the healthcare setting.
- 9 To be effective, the process must be structured and clearly documented.

professional obligations in practice. The main principles of assessment are outlined in Box 2.1.

Structure of assessment

Structuring patient assessment is vital to monitoring the success of care and detecting the emergence of new problems. There are many conceptual frameworks or nursing models, such as Roper's Activities of Daily Living (Roper et al. 2000), Orem's self-care model (Orem et al. 2001) or Gordon's Functional Health Patterns Framework (Gordon 1994). There remains, however, much debate about the effectiveness of such models for assessment in practice, some arguing that individualized care can be compromised by fitting patients into a rigid or complex structure (Kearney 2001, McCrae 2012). Nurses therefore need to take a pragmatic approach and utilize assessment frameworks that are appropriate to their particular area of practice. This is particularly relevant in today's rapidly changing healthcare climate where nurses are taking on increasingly advanced roles, working across boundaries and setting up new services to meet patients' needs (DH 2006a).

Nursing models can serve as a guide to the overall approach to care within a given healthcare environment and therefore provide a focus for the clinical judgements and decision-making processes that result from the process of assessment. During any patient assessment, nurses engage in a series of cognitive, behavioural and practical steps but do not always recognize them as discrete decision-making entities (Ford and McCormack 1999). Nursing models give novice practitioners a structure with which to identify these processes and to reflect on their practice in order to develop the analytical, problem-solving and judgement skills needed to provide an effective patient assessment.

Nursing models have been developed according to different ways of perceiving the main focus of nursing. These include adaptation models (e.g. Roy 1984), self-care models (e.g. Orem et al. 2001) and activities of daily living models (e.g. Murphy et al. 2000). Each model represents a different view of the relationship between four key elements of nursing: health, person, environment and nursing. It is important that the appropriate model is used to ensure that the focus of assessment data collected is effective for

Box 2.2 Gordon's functional health patterns

- Health perception – health management
- Nutrition – metabolic
- Elimination
- Activity – exercise
- Sleep – rest
- Cognitive – perceptual
- Self-perception – self-concept
- Coping – stress tolerance
- Role – relationship
- Sexuality – reproductivity
- Value – belief

particular areas of practice (Alfaro-LeFevre 2014, Murphy et al. 2000). Nurses must also be aware of the rationale for implementing a particular model since the choice will determine the nature of patient care in their day-to-day work. The approach should be sensitive enough to discriminate between different clinical needs and flexible enough to be updated on a regular basis (Allen 1998, Smith and Richardson 1996).

The framework of choice at the Royal Marsden Hospital is based on Gordon's Functional Health Patterns (Gordon 1994; Box 2.2). The framework facilitates an assessment that focuses on patients' and families' problems and functional status and applies clinical cues to interpret deviations from the patient's usual patterns (Johnson 2000). The model is applicable to all levels of care, allowing all problem areas to be identified. The information derived from the patient's initial functional health patterns is crucial for interpreting both the patient's and their family's pattern of response to the disease and treatment.

Evidence-based approaches

Collecting data

Data collection is the process of gathering information about the patient's health needs. This information is collected by means of interview, observation and physical examination and consists of both objective and subjective data. Objective data are measurable and can be detected by someone other than the patient. They include vital signs, physical signs and symptoms, and laboratory results. Subjective data, on the other hand, are based on what the patient perceives and may include descriptions of their concerns, support network, their awareness and knowledge of their abilities/disabilities, their understanding of their illness and their attitude to and readiness for learning (Wilkinson 2007). Nurses working in different settings rely on different observational and physical data. A variety of methods have been developed to facilitate nurses in eliciting both objective and subjective assessment data on the assumption that, if assessment is not accurate, all other nursing activity will also be inaccurate.

Studies of patient assessment by nurses are few but they indicate that discrepancies between the nurses' perceptions and those of their patients are common (Brown et al. 2001, Lauri et al. 1997, McDonald et al. 1999, Parsaie et al. 2000). Communication is therefore key for, as Suhonen et al. (2000) suggest, 'there are two actors in individual care, the patient and the nurse' (p. 1254). Gaining insight into the patient's preferences and individualized needs is facilitated by meaningful interaction and depends both on the patient's willingness and capability in participating in the process and the nurse's interviewing skills. The initial assessment interview not only allows the nurse to obtain baseline information about the patient, but also facilitates the establishment of a therapeutic relationship (Crumbie 2006). Patients may find it difficult to disclose some problems and these may only be

identified once the nurse–patient relationship develops and the patient trusts that the nurse's assessment reflects concern for their well-being.

While the patient is the primary source of information, data may be elicited from a variety of other secondary sources including family and friends, other healthcare professionals and the patient's medical records (Kozier 2012, Walsh et al. 2007).

Assessment interviews

An assessment interview needs structure to progress logically in order to facilitate the nurse's thinking (an example of such a structure can be found in Box 2.3) and to make the patient feel comfortable in telling their story. It can be perceived as being in three phases: the introductory, working and end phases (Crumbie 2006).

It is important at the beginning to build a rapport with the patient. It is vital that the nurse demonstrates interest and respect in the patient from the very start of the interview. Some of the questions asked are likely to be of a searching and intimate nature, which may be difficult for the patient to disclose. The nurse should emphasize the confidential nature of the discussion and take steps to reduce anxiety and ensure privacy since the patient may modify their words and behaviour depending on the environment. Taking steps to establish trust and develop the relationship early will set the scene for effective and accurate information exchange (Aldridge et al. 2005, Silverman et al. 2013).

In the middle working phase, various techniques can be employed to assist with the flow of information. Open questions are useful to identify broad information that can then be explored more specifically with focused questions to determine the nature and extent of the problem. Other helpful techniques include restating what has been said to clarify certain issues, using verbal and non-verbal cues to encourage the patient, verbalizing the implied meaning, using silence and summarizing (Kozier 2012, Silverman et al. 2013). It is important to recognize that there may be times when it is not possible to obtain vital information directly from the patient; they may be too distressed, unconscious or unable to speak clearly, if at all. In such situations, appropriate details should be taken from relatives or friends and recorded as such. Effort should equally be made to overcome language or cultural barriers by the use of interpreters.

The end phase involves a further summary of the important points and an explanation of any referrals made. In order to gain the patient's perspective on the priorities of care and to emphasise the continuing interest in their needs, a final question asking about their concerns can be used (Alfaro-LeFevre 2014). Examples include: 'Tell me the most important things I can help you with', 'Is there anything else you would like to tell me?', 'Is there anything that we haven't covered that still concerns you?' or 'If there are any changes or you have any questions, do let me know'. Box 2.4 provides a summary of the types of assessment.

Legal and professional issues

The NHS *Knowledge and Skills Framework* (DH 2004a) states that the specific dimensions of 'assessment and care planning to meet people's health and wellbeing needs' and 'assessment and treatment planning related to the structure and function of physiological and psychological systems' are core to nursing posts in all settings. In undertaking this work, staff will need to be aware of their legal obligations and responsibilities, the rights of the different people involved, and the diversity of the people they are working with.

Nurses have an obligation to record details of any assessments and reviews undertaken, and provide clear evidence of the arrangements that have been made for future and ongoing care (NMC 2010). This should also include details of information given about care and treatment.

Box 2.3 Carrying out a patient assessment using functional health patterns

12

Pattern	Assessment and data collection are focused on
Health perception – management	<ul style="list-style-type: none"> The person's perceived level of health and well-being, and on the practices they use for maintaining health. Habits that may be detrimental to health are also evaluated. Actual or potential problems related to safety and health management may be identified as well as needs for modifications in the home or for continued care in the home.
Nutrition and metabolism	<ul style="list-style-type: none"> The pattern of food and fluid consumption relative to metabolic need. Actual or potential problems related to fluid balance, tissue integrity. Problems with the gastrointestinal system.
Elimination	<ul style="list-style-type: none"> Excretory patterns (bowel, bladder, skin). Excretory problems such as incontinence, constipation, diarrhoea and urinary retention may be identified.
Activity and exercise	<ul style="list-style-type: none"> The activities of daily living requiring energy expenditure, including self-care activities, exercise and leisure activities. The status of major body systems involved with activity and exercise is evaluated, including the respiratory, cardiovascular and musculoskeletal systems.
Sleep and rest	<ul style="list-style-type: none"> The person's sleep, rest and relaxation practices. Dysfunctional sleep patterns, fatigue, and responses to sleep deprivation may be identified.
Cognitive and perceptual ability	<ul style="list-style-type: none"> The ability to comprehend and use information. The sensory and neurological functions.
Perception/ concept of self	<ul style="list-style-type: none"> The person's attitudes toward self, including identity, body image and sense of self-worth. The person's level of self-esteem and response to threats to their self-concept may be identified.
Stress and coping	<ul style="list-style-type: none"> The person's perception of stress and its effects on their coping strategies. Support systems are evaluated, and symptoms of stress are noted. The effectiveness of a person's coping strategies in terms of stress tolerance may be further evaluated.
Roles and relationships	<ul style="list-style-type: none"> The person's roles in the world and relationships with others. Satisfaction with roles, role strain or dysfunctional relationships may be further evaluated.
Sexuality and reproduction	<ul style="list-style-type: none"> The person's satisfaction or dissatisfaction with sexuality patterns and reproductive functions. Concerns with sexuality may be identified.
Values and belief	<ul style="list-style-type: none"> The person's values, beliefs (including spiritual beliefs) and goals that guide their choices or decisions.

Source: Adapted from Gordon (1994). Reproduced with permission from Elsevier.

Box 2.4 Types of patient assessment**Mini assessment**

A snapshot view of the patient based on a quick visual and physical assessment. Consider patient's ABC (airway, breathing and circulation), then assess mental status, overall appearance, level of consciousness and vital signs before focusing on the patient's main problem.

Comprehensive assessment

An in-depth assessment of the patient's health status, physical examination, risk factors, psychological and social aspects of the patient's health that usually takes place on admission or transfer to a hospital or healthcare agency. It will take into account the patient's previous health status prior to admission.

Focused assessment

An assessment of a specific condition, problem, identified risks or assessment of care; for example, continence assessment, nutritional assessment, neurological assessment following a head injury, assessment for day care, outpatient consultation for a specific condition.

Ongoing assessment

Continuous assessment of the patient's health status accompanied by monitoring and observation of specific problems identified in a mini, comprehensive or focused assessment.

Source: Ahern and Philpot (2002), Holmes (2003), White (2003).

Pre-procedural considerations**Assessment tools**

The use of assessment tools enables a standardized approach to obtaining specific patient data. This can facilitate the documentation of change over time and the evaluation of clinical interventions and nursing care (O'Connor and Eggert 1994). Perhaps more importantly, assessment tools encourage patients to engage in their care and provide a vehicle for communication to allow nurses to follow patients' experiences more effectively.

Assessment tools in clinical practice can be used to assess a patient's general needs, for example the supportive care needs survey (Bonevski et al. 2000), or to assess a specific problem, for example the oral assessment guide (Eilers et al. 1988). The choice of tool depends on the clinical setting although, in general, the aim of using an assessment tool is to link the assessment of clinical variables with measurement of clinical interventions (Frank-Stromborg and Olsen 2004). To be useful in clinical practice, an assessment tool must be simple, acceptable to patients, have a clear and interpretable scoring system and demonstrate reliability and validity (Brown et al. 2001).

More tools are used in practice to assess treatment-related symptoms than other aspects of care, possibly because these symptoms are predictable and of a physical nature and are therefore easier to measure. The most visible symptoms are not always those that cause most distress (Holmes and Eburn 1989); however, an acknowledgement of the patient's subjective experience is therefore an important element in the development of assessment tools (McClement et al. 1997, Rhodes et al. 2000).

The use of patient self-assessment tools appears to facilitate the process of assessment in a number of ways. It enables patients to indicate their subjective experience more easily, gives them an increased sense of participation (Kearney 2001) and prevents them from being distanced from the process by nurses rating their symptoms and concerns (Brown et al. 2001). Many authors have demonstrated the advantages of increasing patient participation in assessment by the use of patient self-assessment questionnaires (Rhodes et al. 2000).

The methods used to facilitate patient assessment are important adjuncts to assessing patients in clinical practice. There is a danger that too much focus can be placed on the framework, system or tool that prevents nurses thinking about the significance of the information that they are gathering from the patient (Harris et al.

1998). Rather than following assessment structures and prompts rigidly, it is essential that nurses utilize their critical thinking and clinical judgement throughout the process in order to continually develop their skills in eliciting information about patients' concerns and using this to inform care planning (Edwards and Miller 2001).

Principles of an effective nursing assessment

The admitting nurse is responsible for ensuring that an initial assessment is completed when the patient is admitted. The patient's needs identified following this process then need to be documented in their care plan.

Box 2.5 discusses each area of assessment, indicating points for consideration and suggesting questions that may be helpful to ask the patient as part of the assessment process.

Box 2.5 Points for consideration and suggested questions for use during the assessment process

1 Cognitive and perceptual ability

Communication

The nurse needs to assess the level of sensory functioning with or without aids/support such as hearing aid(s), speech aid(s), glasses/contact lenses, and the patient's capacity to use and maintain aids/support correctly. Furthermore, it is important to assess whether there are or might be any potential language or cultural barriers during this part of the assessment. Knowing the norm within the culture will facilitate understanding and lessen miscommunication (Galanti 2000).

- How good are the patient's hearing and eyesight?
- Is the patient able to express their views and wishes using appropriate verbal and non-verbal methods of communication in a manner that is understandable by most people?
- Are there any potential language or cultural barriers to communicating with the patient?

Information

During this part of the assessment, the nurse will assess the patient's ability to comprehend the present environment without showing levels of distress. This will help to establish whether there are any barriers to the patient understanding their condition and treatment. It may help them to be in a position to give informed consent.

- Is the patient able and ready to understand any information about their forthcoming treatment and care? Are there any barriers to learning?
- Is the patient able to communicate an understanding of their condition, plan of care and potential outcomes/responses?
- Will he or she be able to give informed consent?

Neurological

It is important to assess the patient's ability to reason logically and decisively, and determine that he or she is able to communicate in a contextually coherent manner.

- Is the patient alert and orientated to time, place and person?

Pain

To provide optimal patient care, the assessor needs to have appropriate knowledge of the patient's pain and an ability to identify the pain type and location. Assessment of a patient's experience of pain is a crucial component in providing effective pain management. Dimond (2002) asserts that it is unacceptable for patients to experience unmanaged pain or for nurses to have inadequate knowledge about pain. Pain should be measured using an assessment tool that identifies the quantity and/or quality of one or more of the dimensions of the patient's experience of pain.

Assessment should also observe for signs of neuropathic pain, including descriptions such as shooting, burning, stabbing, allodynia (pain associated with gentle touch) (Australian and New Zealand College of Anaesthetists 2005, Jensen et al. 2003, Rowbotham and Macintyre 2003).

- Is the patient pain free at rest and/or on movement?
 - Is the pain a primary complaint or a secondary complaint associated with another condition?
 - What is the location of the pain and does it radiate?
 - When did it begin and what circumstances are associated with it?
 - How intense is the pain, at rest and on movement?
 - What makes the pain worse and what helps to relieve it?
 - How long does the pain last, for example, continuous, intermittent?
 - Ask the patient to describe the character of pain using quality/sensory descriptors, for example, sharp, throbbing, burning.
- For further details regarding pain assessment, see Chapter 8: Patient comfort and end-of-life care.

2 Activity and exercise

Respiratory

Respiratory pattern monitoring addresses the patient's breathing pattern, rate and depth.

- Does the patient have any difficulty breathing?
- Is there any noise when they are breathing such as wheezing?
- Does breathing cause them pain?
- How deep or shallow is their breathing?

(continued)

Box 2.5 Points for consideration and suggested questions for use during the assessment process (*continued*)

14

- Is their breathing symmetrical?
- Does the patient have any underlying respiratory problems such as chronic obstructive pulmonary disease, emphysema, tuberculosis, bronchitis, asthma or any other airway disease?

In this section it is also important to assess and monitor smoking habits. It is helpful to document the smoking habit in the format of pack-years. A *pack-year* is a term used to describe the number of cigarettes a person has smoked over time. One pack-year is defined as 20 manufactured cigarettes (one pack) smoked per day for 1 year. At this point in the assessment, it would be a good opportunity, if appropriate, to discuss smoking cessation. A recent meta-analysis indicates that if interventions are given by nurses to their patients with regard to smoking cessation the benefits are greater (Rice and Stead 2008).

For further details see Chapter 9: Respiratory care.

Cardiovascular

A basic assessment is carried out and vital signs such as pulse (rhythm, rate and intensity) and blood pressure should be noted. Details of cardiac history should be taken for this part of the assessment. Medical conditions and experience of previous surgery should be noted.

- Does the patient take any cardiac medication?
- Does he/she have a pacemaker?

Physical abilities, personal hygiene/mobility/toileting, independence with activities of daily living

The aim during this part of the nursing assessment is to establish the level of assistance required by the person to tackle activities of daily living such as walking and steps/stairs. An awareness of obstacles to safe mobility and dangers to personal safety is an important factor and part of the assessment.

- Is the patient able to stand, walk and go to the toilet?
- Is the patient able to move up and down, roll and turn in bed?
- Does the patient need any equipment to mobilize?
- Has the patient good motor power in their arms and legs?
- Does the patient have any history of falling?

The nurse should also evaluate the patient's ability to meet personal hygiene, including oral hygiene, needs. This should include the patient's ability to make arrangements to preserve standards of hygiene and the ability to dress appropriately for climate, environment and their own standards of self-identity.

- Can the patient take care of their own personal hygiene needs independently or do they need assistance?
- What type of assistance do they need: help with mobility or fine motor movements such as doing up buttons or shaving?

It might be necessary to complete a separate manual handling risk assessment – see Chapter 6: Moving and positioning.

3 Elimination**Gastrointestinal**

During this part of the assessment it is important to determine a baseline with regard to independence.

- Is the patient able to attend to their elimination needs independently and is he/she continent?
- What are the patient's normal bowel habits? Are bowel movements within the patient's own normal pattern and consistency?
- Does the patient have any underlying medical conditions such as Crohn's disease or irritable bowel syndrome?
- Does the patient have diarrhoea or is he/she prone to or have constipation?
- How does this affect the patient?

For further discussion see Chapter 5: Elimination.

Genitourinary

The assessment is focused on the patient's baseline observations with regard to urinary continence/incontinence. It is also important to note whether there is any penile or vaginal discharge or bleeding.

- Does the patient have a urinary catheter *in situ*? If so, list the type and size. Furthermore, note the date the catheter was inserted and/or removed. Urinalysis results should also be noted here.
- How often does the patient need to urinate? (Frequency)
- How immediate is the need to urinate? (Urgency)
- Do they wake in the night to urinate? (Nocturia)
- Are they able to maintain control over their bladder at all times? (Incontinence – inability to hold urine)

For further discussion see Chapter 5: Elimination.

4 Nutrition**Oral care**

As part of the inpatient admission assessment, the nurse should obtain an oral health history that includes oral hygiene beliefs, practices and current state of oral health. During this assessment it is important to be aware of treatments and medications that affect the oral health of the patient.

- If deemed appropriate, use an oral assessment tool to perform the initial and ongoing oral assessment.

During the admission it is important to note the condition of the patient's mouth.

- Lips – pink, moist, intact.
- Gums – pink, no signs of infection or bleeding.
- Teeth – dentures, bridge, crowns, caps.

For full oral assessment, see Chapter 8: Patient comfort and end-of-life care.

Hydration

An in-depth assessment of hydration and nutritional status will provide the information needed for nursing interventions aimed at maximizing wellness and identifying problems for treatment. The assessment should ascertain whether the patient has any difficulty eating or drinking. During the assessment the nurse should observe signs of dehydration, for example dry mouth, dry skin, thirst or whether the patient shows any signs of altered mental state.

- Is the patient able to drink adequately? If not, please explain why not.
- How much and what does the patient drink?
- Note the patient's alcohol intake in the format of units per week and the caffeine intake measured in number of cups per day.

Nutrition

A detailed diet history provides insight into a patient's baseline nutritional status. Assessment includes questions regarding chewing or swallowing problems, avoidance of eating related to abdominal pain, changes in appetite, taste or intake, as well as use of a special diet or nutritional supplements. A review of past medical history should identify any relevant conditions and highlight increased metabolic needs, altered gastrointestinal function and the patient's capacity to absorb nutrients.

- What is the patient's usual daily food intake?
- Do they have a good appetite?
- Are they able to swallow/chew the food – any dysphagia?
- Is there anything they don't or can't eat?
- Have they experienced any recent weight changes or taste changes?
- Are they able to eat independently?

(Arrowsmith 1999, BAPEN and Malnutrition Advisory Group 2000, DH 2005)

For further information, see Chapter 7: Nutrition, fluid balance and blood transfusion.

Nausea and vomiting

During this part of the assessment you want to ascertain whether the patient has any history of nausea and/or vomiting. Nausea and vomiting can cause dehydration, electrolyte imbalance and nutritional deficiencies (Marek 2003), and can also affect a patient's psychosocial well-being. They may become withdrawn, isolated and unable to perform their usual activities of daily living.

Assessment should address questions such as:

- Does the patient feel nauseous?
- Is the patient vomiting? If so, what is the frequency, volume, content and timing?
- Does nausea precede vomiting?
- Does vomiting relieve nausea?
- When did the symptoms start? Did they coincide with changes in therapy or medication?
- Does anything make the symptoms better?
- Does anything make the symptoms worse?
- What is the effect of any current or past antiemetic therapy including dose, frequency, duration, effect, route of administration?
- What is the condition of the patient's oral cavity?

(Adapted from Perdue 2005). For further discussion see Chapter 5: Elimination.

5 Skin

A detailed assessment of a patient's skin may provide clues to diagnosis, management and nursing care of the existing problem. A careful skin assessment can alert the nurse to cutaneous problems as well as systemic diseases. In addition, a great deal can be observed in a person's face, which may give insight to his or her state of mind.

- Does the patient have any sore places on their skin?
- Does the patient have any dry or red areas?

Furthermore, it is necessary to assess whether the patient has any wounds and/or pressure sores. If so, you would need to complete a further wound assessment. For further information see Chapter 15: Wound management.

6 Controlling body temperature

This assessment is carried out to establish baseline temperature and determine if the temperature is within normal range, and whether there might be intrinsic or extrinsic factors for altered body temperature. It is important to note whether any changes in temperature are in response to specific therapies (e.g. antipyretic medication, immunosuppressive therapies, invasive procedures or infection (Bickley et al. 2013)). White blood count should be recorded to determine whether it is within normal limits. See Chapter 11: Observations.

- Is the patient feeling excessively hot or cold?
- Have they been shivering or sweating excessively?

7 Sleep and rest

This part of the assessment is performed to find out sleep and rest patterns and reasons for variation. Description of sleep patterns, routines and interventions applied to achieve a comfortable sleep should be documented. The nurse should also include the presence of emotional and/or physical problems that may interfere with sleep.

- Does the patient have enough energy for desired daily activities?
- Does the patient tire easily?
- Has he/she any difficulty falling asleep or staying asleep?
- Does he/she feel rested after sleep?
- Does he/she sleep during the day?
- Does he/she take any aids to help them sleep?
- What are the patient's normal hours for going to bed and waking?

8 Stress and coping

Assessment is focused on the patient's perception of stress and on his or her coping strategies. Support systems should be evaluated and symptoms of stress should be noted. It includes the individual's reserve or capacity to resist challenge to self-integrity, and modes of handling stress. The effectiveness of a person's coping strategies in terms of stress tolerances may be further evaluated (adapted from Gordon 1994).

(continued)

Box 2.5 Points for consideration and suggested questions for use during the assessment process (*continued*)

16

- What are the things in the patient's life that are stressful?
- What do they do when they are stressed?
- How do they know they are stressed?
- Is there anything they do to help them cope when life gets stressful?
- Is there anybody who they go to for support?

9 Roles and relationships

The aim is to establish the patient's own perception of the roles and responsibilities in their current life situation. The patient's role in the world and their relationships with others are important to understand. Assessment in this area includes finding out about the patient's perception of the major roles and responsibilities they have in life, satisfaction or disturbances in family, work or social relationships. An assessment of home life should be undertaken which should include how they will cope at home post discharge from hospital and how those at home will cope while they are in hospital, for example dependants, children or animals and if there are any financial worries.

- Who is at home?
- Are there any dependants (include children, pets, anybody else they care for)?
- What responsibilities does the patient have for the day-to-day running of the home?
- What will happen if they are not there?
- Do they have any concerns about home while they are in hospital?
- Are there any financial issues related to their hospital stay?
- Will there be any issues related to employment or study while they are in hospital?

10 Perception/concept of self**Body image/self-esteem**

Body image is highly personal, abstract and difficult to describe. The rationale for this section is to assess the patient's level of understanding and general perception of self. This includes their attitudes about self, perception of abilities (cognitive, affective or physical), body image, identity, general sense of worth and general emotional pattern. An assessment of body posture and movement, eye contact, voice and speech patterns should also be included.

- How do you describe yourself?
- How do you feel about yourself most of the time?
- Has it changed since your diagnosis?
- Have there been changes in the way you feel about yourself or your body?

11 Sexuality and reproduction

Understanding sexuality as the patient's perceptions of their own body image, family roles and functions, relationships and sexual function can help the assessor to improve assessment and diagnosis of actual or potential alterations in sexual behaviour and activity.

Assessment in this area is vital and should include relevant feelings about the patient's own body, their need for touch, interest in sexual activity, how they communicate their sexual needs to a partner, if they have one, and the ability to engage in satisfying sexual activities.

This may also be an opportunity to explore with the patient issues related to future reproduction if this is relevant to the admission. Below are a few examples of questions that can be used.

- Are you currently in a relationship?
- Has your condition had an impact on the way you and your partner feel about each other?
- Has your condition had an impact on the physical expression of your feelings?
- Has your treatment or current problem had any effect on your interest in being intimate with your partner?

12 Values and beliefs**Religious, spiritual and cultural beliefs**

The aim is to assess the patient's spiritual, religious and cultural needs to provide culturally and spiritually specific care while concurrently providing a forum to explore spiritual strengths that might be used to prevent problems or cope with difficulties. Assessment is focused on the patient's values and beliefs, including spiritual beliefs, or on the goals that guide his or her choices or decisions. A patient's experience of their stay in hospital may be influenced by their religious beliefs or other strongly held principles, cultural background or ethnic origin. It is important for nurses to have knowledge and understanding of the diverse cultures of their patients and take their different practices into account.

- Are there any spiritual/cultural beliefs that are important to you?
- Do you have any specific dietary needs related to your religious, spiritual or cultural beliefs?
- Do you have any specific personal care needs related to your religious, spiritual or cultural beliefs (i.e. washing rituals, dress)?

13 Health perception and management**Relevant medical conditions, side-effects/complications of treatment**

Assessment of the patient's perceived pattern of health and well-being and how health is managed should be documented here. Any relevant history of previous health problems, including side-effects of medication, should be noted. Examples of other useful information that should be documented are compliance with medication regimen, use of health promotion activities such as regular exercise and if the patient has annual check-ups.

- What does the patient know about their condition and planned treatment?
- How would they describe their own current overall level of fitness?
- What do they do to keep well: exercise, diet, annual check-ups or screening?

Post-procedural considerations

Decision making and nursing diagnosis

The purpose of collecting information through the process of assessment is to enable the nurse to make a series of clinical judgements, which are known in some circumstances as nursing diagnoses, and subsequently decisions about the nursing care each individual needs. The decision-making process is based upon the clues observed, analysed and interpreted and it has been suggested that expert nurses assess the situation as a whole and make judgements and decisions intuitively (Hedberg and Satterlund Larsson 2003, King and Clark 2002, Peden-McAlpine and Clark 2002), reflecting Benner's (1984) renowned novice-to-expert theory. However, others argue that all nurses use a logical process of clinical reasoning in order to identify patients' needs for nursing care and that, while this becomes more automatic with experience, it should always be possible for a nurse to explain how they arrive at a decision about an individual within their care (Gordon 1994, Putzier and Padrick 1984, Rolfe 1999). A further notion is that of a continuum, where our ability to make clinical judgements about our patients lies on a spectrum, with intuition at one end and linear, logical decisions (based on clinical trials, for example) at the other (Cader et al. 2005, Thompson 1999). Factors that may influence the process of decision making include time, complexity of the judgement or decision to be made, as well as the knowledge, experience and attitude of the individual nurse.

Nursing diagnosis is a term which describes both a clinical judgement that is made about an individual's response to health or illness, and the process of decision making that leads to that judgement. The importance of thorough assessment within this process cannot be overestimated. The gathering of comprehensive and appropriate data from patients, including the meanings attributed to events by the patient, is associated with greater diagnostic accuracy and thus more timely and effective intervention (Alfaro-LeFevre 2014, Gordon 1994, Hunter 1998).

The concept of a 'nursing diagnosis' has historically generated much debate within the nursing literature. It is therefore important to clarify the difference between a nursing diagnosis and a patient problem or care need. 'Patient problems' or 'needs' are common terms used within nursing to facilitate communication about nursing care (Hogston 1997). As patient problems/needs may involve solutions or treatments from disciplines other than nursing, the concept of a 'patient problem' is similar to but broader than a nursing diagnosis. Nursing diagnoses describe problems that may be dealt with by nursing expertise (Leih and Salentijn 1994).

The term 'nursing diagnosis' also refers to a standardized nursing language, to describe patients' needs for nursing care, that originated in America over 30 years ago and has now been developed, adapted and translated for use in numerous other countries. The language of nursing diagnosis provides a classification of over 200 terms (NANDA-I 2008), representing judgements that are commonly made with patients/clients about phenomena of concern to nurses, enabling more consistent communication and documentation of nursing care.

Most significantly, the use of common language enables nurses to clearly and consistently express what they do for patients and why, making the contribution of different nursing roles clearly visible within the multidisciplinary care pathway (Delaney 2001, Elfrink et al. 2001, Grobe 1996, Moen et al. 1999). Secondly, an increasingly important reason for trying to structure nursing terms in a systematic way has been the need to create and analyse nursing information in a meaningful way for electronic care records (Clark 1999, Westbrook 2000). The term 'nursing diagnosis' is not commonly used within the UK as no definitive classifications or common languages are in general use; however, for the aforementioned reasons, the adaptation and implementation of standard nursing languages within clinical practice in

the UK are being explored (Chambers 1998, Lyte and Jones 2001, Westbrook 2000).

Planning and implementing care

Nursing diagnoses provide a focus for planning and implementing effective and evidence-based care. This process consists of identifying nursing-sensitive patient outcomes and determining appropriate interventions (Alfaro-LeFevre 2014, Shaw 1998, White 2003).

- To determine the immediate priorities and recognize whether patient problems require nursing care or whether a referral should be made to someone else.
- To identify the anticipated outcome for the patient, noting what the patient will be able to do and within what time frame. The use of 'measurable' verbs that describe patient behaviour or what the patient says facilitates the evaluation of patient outcomes (Box 2.6).
- To determine the nursing interventions, that is, what nursing actions will prevent or manage the patient's problems so that the patient's outcomes may be achieved.
- To record the care plan for the patient which may be written or individualized from a standardized/core care plan or a computerized care plan.

Outcomes should be patient focused and realistic, stating how the outcomes or goals are to be achieved and when the outcomes should be evaluated. Patient-focused outcomes centre on the desired results of nursing care, that is, the impact of care on the patient, rather than on what the nurse does. Outcomes may be short, intermediate or long term, enabling the nurse to identify the patient's health status and progress (stability, improvement or deterioration) over time. Setting realistic outcomes and interventions requires the nurse to distinguish between nursing diagnoses that are life-threatening or an immediate risk to the patient's safety and those that may be dealt with at a later stage. Identifying which nursing diagnoses/problems contribute to other problems (for example, difficulty breathing will contribute to the patient's ability to mobilize) will make the problem a higher priority. By dealing with the breathing difficulties, the patient's ability to mobilize will be improved.

The formulation of nursing interventions is dependent on adequate information collection and accurate clinical judgement during patient assessment. As a result, specific patient outcomes may be derived and appropriate nursing interventions undertaken to assist the patient to achieve those outcomes (Hardwick 1998). Nursing interventions should be specific to help the patient achieve the outcome and should be evidence based. When determining what interventions may be appropriate in relation to a

Box 2.6 Examples of measurable and non-measurable verbs for use in outcome statements

Measurable verbs (use these to be specific)

- State; verbalize; communicate; list; describe; identify
- Demonstrate; perform
- Will lose; will gain; has an absence of
- Walk; stand; sit

Non-measurable verbs (do not use)

- Know
- Understand
- Think
- Feel

Source: Alfaro-LeFevre (2014). Reproduced with permission from Lippincott Williams & Wilkins.

patient's problem, it may be helpful to clarify the potential benefit to the patient after an intervention has been performed, as this will help to ensure its appropriateness.

It is important to continue to assess the patient on an ongoing basis whilst implementing the care planned. Assessing the patient's current status prior to implementing care will enable the nurse to check whether the patient has developed any new problems that require immediate action. During and after providing any nursing action, the nurse should assess and reassess the patient's response to care. The nurse will then be able to determine whether changes to the patient's care plan should be made immediately or at a later stage. If there are any patient care needs that require immediate action, for example consultation or referral to a doctor, recording the actions taken is essential. Involving the patient and their family or friends will promote the patient's well-being and self-care abilities. The use of clinical documentation in nurse handover will help to ensure that the care plans are up to date and relevant (Alfaro-LeFevre 2014, White 2003).

Evaluating care

Effective evaluation of care requires the nurse to critically analyse the patient's health status to determine whether the patient's condition is stable, has deteriorated or improved. Seeking the patient's and family's views in the evaluation process will facilitate decision making. By evaluating the patient's outcomes, the nurse is able to decide whether changes need to be made to the care planned. Evaluation of care should take place

in a structured manner and on a regular basis by a Registered Nurse. The frequency of evaluation depends on the clinical environment within which the individual is being cared for as well as the nature of the nursing diagnosis (problem) to which the care relates.

- What are the patient's self-care abilities?
- Is the patient able to do what you expected?
- If not, why not?
- Has something changed?
- Are you missing something?
- Are there new care priorities?

These questions will help to clarify the patient's progress (Alfaro-LeFevre 2014, White 2003). It is helpful to consider what is observed and measurable to indicate that the patient has achieved the outcome.

Documenting

Nurses have a professional responsibility to ensure that health-care records provide an accurate account of treatment, care planning and delivery, and are viewed as a tool of communication within the team. There should be 'clear evidence of the care planned, the decisions made, the care delivered and the information shared' (NMC 2010, p. 8) (Box 2.7). The content and quality of record keeping are a measure of standards of practice relating to the skills and judgement of the nurse (NMC 2010).

Box 2.7 The Royal Marsden Hospital Guidelines for Nursing Documentation (2011) (adopted in line with NMC (2010) Record keeping)

General principles

- 1 Records should be written legibly in black ink in such a way that they cannot be erased and are readable when photocopied.
- 2 Entries should be factual, consistent, accurate and not contain jargon, abbreviations or meaningless phrases (e.g. 'observations fine').
- 3 Each entry must include the date and time (using the 24-hour clock).
- 4 Each entry must be followed by a signature and the name printed as well as:
 - the job role (e.g. staff nurse or clinical nurse specialist)
 - if a nurse is a temporary employee (i.e. an agency nurse), the name of the agency must be included under the signature.
- 5 If an error is made, this should be scored out with a single line and the correction written alongside with date, time and initials. Correction fluid should not be used at any time.
- 6 All assessments and entries made by student nurses must be countersigned by a Registered Nurse.
- 7 Healthcare assistants:
 - can write on fluid balance and food intake charts
 - must not write on prescription charts, assessment sheets or care plans.

Assessment and care planning

- 1 The first written assessment and the identification of the patient's immediate needs must begin within 4 hours of admission. This must include any allergies or infection risks of the patient and the contact details of the next of kin.
- 2 The following must be completed within 24 hours of admission and updated as appropriate:
 - completion of nutritional, oral, pressure sore and manual handling risk assessments
 - other relevant assessment tools, for example pain and wound assessment.
- 3 All sections of the nursing admission assessment must be completed at some point during the patient's hospital stay with the identification of the patient's care needs. If it is not relevant or if it is inappropriate to assess certain functional health patterns, for example the patient is unconscious, then indicate the reasons accordingly.

The ongoing nursing assessment should identify whether the patient's condition is stable, has deteriorated or improved.
- 4 Care plans should be written wherever possible with the involvement of the patient, in terms that they can understand, and include:
 - patient-focused, measurable, realistic and achievable goals
 - nursing interventions reflecting best practice
 - relevant core care plans that are individualized, signed, dated and timed.
- 5 Update the care plan with altered or additional interventions as appropriate.
- 6 The nursing documentation must be referred to at shift handover so it needs to be kept up to date.

Principles of assessment

- 1 Assessment should be a systematic, deliberate and interactive process that underpins every aspect of nursing care (Heaven and Maguire, 1996).
- 2 Assessment should be seen as a continuous process (Cancer Action Team 2007).

Structure of assessment

- 1 The structure of a patient assessment should take into consideration the specialty and care setting and also the purpose of the assessment.
- 2 When caring for individuals with cancer, assessment should be carried out at key points during the cancer pathway and dimensions of assessment should include background information and assessment preferences, physical needs, social and occupational needs, psychological well-being and spiritual well-being (Cancer Action Team 2007).
- 3 Functional health patterns provide a comprehensive framework for assessment, which can be adapted for use within a variety of clinical specialties and care settings (Gordon 1994).

Methods of assessment

- 1 Methods of assessment should elicit both subjective and objective assessment data.
- 2 An assessment interview must be well structured and progress logically in order to facilitate the nurse's thinking and to make the patient feel comfortable in telling their story.
- 3 Specific assessment tools should be used, where appropriate, to enable nurses to monitor particular aspects of care, such as symptom management (e.g. pain, fatigue), over time. This will help to evaluate the effectiveness of nursing interventions while often providing an opportunity for patients to become more involved in their care (O'Connor and Eggert 1994).

Decision making and nursing diagnosis

- 1 Nurses should be encouraged to provide a rationale for their clinical judgements and decision making within their clinical practice (NMC 2015).
- 2 The language of nursing diagnosis is a tool that can be used to make clinical judgements more explicit and enable more consistent communication and documentation of nursing care (Clark 1999, Westbrook 2000).

Planning and implementing care

- 1 When planning care, it is vital that nurses recognize whether patient problems require nursing care or whether a referral should be made to someone else.
- 2 When a nursing diagnosis has been made, the anticipated outcome for the patient must be identified in a manner which is specific, achievable and measurable (NMC 2015).
- 3 Nursing interventions should be determined in order to address the nursing diagnosis and achieve the desired outcomes (Gordon 1994).

Evaluating care

- 1 Nursing care should be evaluated using measurable outcomes on a regular basis and interventions adjusted accordingly (see Box 2.8).
- 2 Progress towards achieving outcomes should be recorded in a concise and precise manner. Using a method such as charting by exception can facilitate this (Murphy 2003).

Documenting and communicating care

- 1 The content and quality of record keeping are a measure of standards of practice relating to the skills and judgement of the nurse (NMC 2010).
- 2 In addition to the written record of care, the important role that the nursing shift report, or 'handover', plays in the communication and continuation of patient care should be considered, particularly when considering the role of electronic records.

Observation

Definition

Observation is the conscious, deliberate use of the physical senses to gather data from the patient and the environment. It occurs whenever the nurse is in contact with the patient. At each patient contact, it is important to try and develop a sequence of observations. These might include the following.

- 1 As you enter the room, observe the patient for signs of distress, e.g. pallor, laboured breathing, and behaviours indicating pain or emotional distress.
- 2 Scan for safety hazards, e.g. are there spills on the floor?
- 3 Look at the equipment, e.g. urinary catheter, intravenous pumps, oxygen, monitors.
- 4 Scan the room – who is there and how do these people interact with the patient?
- 5 Observe the patient more closely for data such as skin temperature, breath sounds, drainage/dressing odours, condition of dressings, drains, need for repositioning (Wilkinson 2007).

Accurate measurements of your patient's vital signs provide crucial information about body functions (see Chapter 11: Observations).

Physical assessment/examination

Definition

Physical examination is a systematic assessment of all body systems and is concerned with identifying strengths and deficits in the patient's functional abilities. Physical assessment provides objective data that can be used to validate the subjective data gained when taking the patient's history (Wilkinson 2007). The patient's history will be the guide to the nature of the physical assessment that needs to be carried out.

During the physical assessment, a systematic approach is taken to build on the patient's history, using the key assessment skills of inspection, palpation, percussion and auscultation.

Physical assessment serves a number of purposes (Crouch and Meurier 2005).

- To obtain information on the patient's overall health status.
- To enable additional information to be obtained about any symptoms reported by the patient.
- To detect changes in a patient's condition.
- To evaluate how the patient is responding to interventions.

Anatomy and physiology

When examining an area of the body, it is essential to understand the basic anatomy of that area. This will ensure that the appropriate system is examined and that findings of the examination are understood. It will also help the formation of differential diagnoses and to ensure that appropriate investigations are ordered.

Related theory

Alongside thorough history taking and investigations, physical assessment is key to helping a patient from their presenting complaint to diagnosis and treatment. Successful assessment requires critical thinking skills and a good knowledge base to decide which assessments to make, how much information is needed and how to get the information (Wilkinson 2007). Critical thinking is an attitude and a reasoning process involving several intellectual skills. It is 'the art of thinking about your thinking while you're thinking so as to make your thinking more clear, precise, accurate, relevant, consistent, and fair' (Paul 1988, cited in Wilkinson 2007).

Before commencing a physical assessment, a detailed health history should be taken. The systems that this section will cover are abdominal, cardiovascular and respiratory. Neurological examination is covered in Chapter 11: Observations.

Evidence-based approaches

Rationale

The patient's health history and the nurse's knowledge of anatomy and physiology will help guide when it is appropriate to do a physical examination and which system to examine. From the history, a list of differential diagnoses will have been generated and the examination should seek to confirm, refute or further establish that a differential diagnosis is a possibility (Douglas and Bevan 2013).

There are four aspects of physical examination:

- inspection
- palpation
- percussion
- auscultation.

Inspection

Inspection is simply observing the patient. The practitioner should use all senses, taking note of any deviation from normal (Douglas and Bevan 2013).

If you haven't already taken a history, first introduce yourself to the patient. The patient may be particularly worried that you'll find a serious problem. When introducing yourself to the patient and initiating the examination, continue to observe their behaviour, general demeanour and appearance.

Having the opportunity to take the patient's history often allows subtle clues about their health to be raised. The precise points to consider will be informed to some extent by the history, but inspection starts as soon as you see the patient; this is sometimes called the global view of the patient, general survey or first impression (Cox 2004, Douglas and Bevan 2013, Rushforth 2009). Typically this first impression includes looking at the patient as a whole, examining the nails, skin, eyes and assessing vital signs (Douglas and Bevan 2013, Rushforth 2009). Observe the following.

- General appearance – are they well kept? Are they wearing appropriate clothing?

- Do they look well nourished?
- Do they appear to be in any pain?
- Are they retching?
- How do they get into the room? Walk? Limp? Wheelchair?
- Are they orientated to time and place? (see Chapter 11: Observations)
- What is their level of consciousness? (see Chapter 11: Observations)
- Are they breathless?

Once this initial part of the examination, inspection, is over, practitioners should move on to the system/s of concern and inspect that area closely.

Palpation

Palpation requires the use of the whole hand including the palm and the full length of the fingers to feel and assess (Bickley et al. 2013, Rushforth 2009):

- texture
- tenderness
- temperature
- contours
- pulses
- lymph nodes
- moisture
- mobility.

There are two variations on palpation: light palpation and deep palpation.

Light palpation requires a gentle touch, depressing the skin with one hand to a maximum of 2 cm (Rushforth 2009). When lightly palpating, temperature, tenderness, texture, moisture, elasticity, pulsation and any superficial organs or masses should be assessed (Rushforth 2009). Deep palpation uses the same technique as light palpation but often two hands are used, one on top of the other at a depth of around 4 cm (Rushforth 2009). When palpating deeply, internal organs and masses should be assessed. As the practitioner palpates, they should watch the patient's face assessing for any discomfort or tenderness. The order of palpation is not important unless there is an area of pain or tenderness, in which case always examine that area last.

Percussion

Percussion helps to identify organs, allowing assessment of size and shape. The technique is done by laying the tip and first joint of the middle finger flat on the patient, ensuring that no other part of the finger or hand is touching the patient (Bickley et al. 2013). Then using the middle finger of the other hand, strike the joint in a quick fluid movement with the finger tip (Bickley et al. 2013). The sound that is produced can also help identify if the structures are solid or filled with liquid or air. It takes experience and practice to be able to hear and identify the different sounds (Table 2.1).

Auscultation

Auscultation involves listening to various sounds in the body using a stethoscope (Bickley et al. 2013, Rushforth 2009). A stethoscope has a bell which should be used to hear low-pitched sounds, for example murmurs, and a diaphragm that should be used when listening to high-pitched sounds, for example bowel sounds (Figure 2.1).

Legal and professional issues

As in all aspects of care, nurses must be aware of their ethical and legal responsibilities when assessing patients. Issues of honesty and confidentiality are frequently encountered during assessment (Wilkinson 2007).

Physical assessment is an advanced skill and while practitioners may be able to practise skills through reading and work-based

Table 2.1 Different sounds heard on percussion

Sound	Quality	Example of source
Flat	Soft, high pitched, dull sound	Thigh
Dull	A medium level, thud like sound	Liver, spleen
Resonant	Loud, low pitched, hollow sound	Lung
Hyper-resonant	Very loud, low, booming, hollow sound	No normal organ
Tympanic	Loud, high pitched, drum-like sound	Gastric air bubble

Source: Adapted from Bickley et al. (2013), Rushforth (2009).

learning, many courses are available in order to learn in a structured fashion. A solid understanding of anatomy and physiology, interpretation of findings and knowledge of appropriate action to take are essential.

This chapter gives a basic overview of the techniques used when physically assessing patients. In order to perform physical assessment safely, practitioners would require further education and supervised clinical experience to ensure competence. The Nursing and Midwifery Council (NMC 2015) states that practitioners must be accountable for their actions and omissions and must practise within their sphere of competence at all times.

Patient consent

The NMC (2015) clearly states that patient consent must be gained before any procedure has begun. Before gaining consent, information about the procedure should be given to the patient in a clear, honest and jargon-free manner.

Pre-procedural considerations

Equipment

Good preparation is essential for any competent physical assessment (Crouch and Meurier 2005). The following equipment may be used as part of a physical examination.

- Pen torch.
- Stethoscope – this is a medical device which is often used to listen to internal sounds of the human body. A good-quality stethoscope will aid diagnosis as more subtle sounds will be heard clearly (see Figure 2.1).
- Examination couch.
- Tongue depressor.
- Ruler – this must measure in centimetres and be at least 10 cm long.

Patient preparation

During the physical assessment, the use of sheets, blankets and gowns will help to minimally expose the area to be examined, maximizing privacy and dignity. Whatever system(s) you plan to examine, try to organize your steps to minimize the number of times the patient needs to change position (Rushforth 2009).

Respiratory examination

Anatomy and physiology

The respiratory system consists of an upper and lower airway (Figure 2.2). The upper airway starts with the nasopharynx and the oropharynx then continues to the laryngopharynx and the larynx (Rushforth 2009). The lower airway starts at the trachea which then divides into two bronchi, then lobar bronchi, then secondary bronchi, tertiary bronchi, terminal bronchioles, respiratory bronchioles and alveolar ducts (Rushforth 2009).

The right lung is larger than the left lung due to the presence of the heart on the left side (Devereux and Douglas 2009). The right lung is made up of three lobes, upper, middle and lower,

Figure 2.1 Labelled diagram of stethoscope illustrating bell and diaphragm.

Figure 2.2 Structures of the respiratory system. Source: Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Figure 2.3 Lung, fissures and lobes.

Figure 2.4 Bony structures of the chest and thorax.

and the left only has two: upper and lower (Figure 2.3). The lungs are not stationary but expand and contract during inhalation and exhalation (Bickley et al. 2013). In order for this to happen smoothly, they are covered in two serous membranes: the visceral pleura and the parietal pleura (Bickley et al. 2013). The space between these two membranes can occasionally become filled with substances like air, blood and fluid (Rushforth 2009).

The lungs are protected by the thorax and ribcage which surrounds them; when examining the chest, the thorax can be helpful to describe the location of findings (Figure 2.4). See Chapter 9: Respiratory care.

Related theory

The order of examination for the respiratory system is:

- inspection
- palpation
- percussion
- auscultation.

Both the anterior (front) and the posterior (back) chest must be examined and the same techniques are used for both sides.

Inspection

Chest deformities

Some examples of chest deformities are barrel chest, pigeon chest, funnel chest and flail chest (Table 2.2).

Palpation

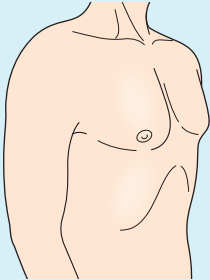

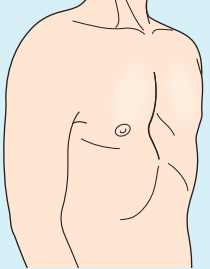

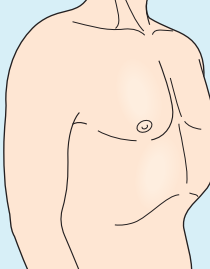

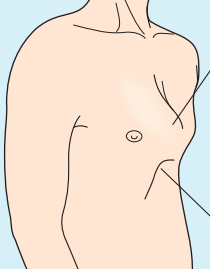

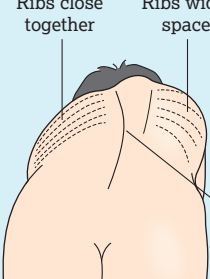

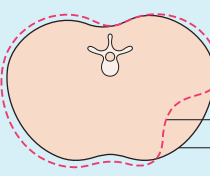

Lymph nodes

Part of palpation when examining the respiratory system is to examine the lymph nodes in the neck. Enlarged lymph nodes can be an important sign of infection or malignancy (Devereux and Douglas 2009). To do this, stand behind the patient and examine both sides of the neck at the same time. Use your middle and index fingers to softly palpate in circular movements the lymph nodes in the positions illustrated in Figure 2.5.

Chest expansion

To assess for chest expansion and symmetry, adopt the position seen in Figure 2.6 and ask the patient to take a deep breath in. You should be able to see your thumbs move an equal distance apart.

Table 2.2 Deformities of the chest

	<p>Normal adult</p> <p>The thorax in the normal adult is wider than it is deep. Its lateral diameter is larger than its anteroposterior diameter</p>
	<p>Funnel chest</p> <p>Note depression in the lower portion of the sternum. Compression of the heart and great vessels may cause murmurs</p>
	<p>Barrel chest</p> <p>There is an increased anteroposterior diameter. This shape is normal during infancy, and often accompanies aging and chronic obstructive pulmonary disease</p>
	<p>Pigeon chest</p> <p>The sternum is displaced anteriorly, increasing the anteroposterior diameter. The costal cartilages adjacent to the protruding sternum are depressed</p>
	<p>Thoracic kyphoscoliosis</p> <p>Abnormal spinal curvatures and vertebral rotation deform the chest. Distortion of the underlying lungs may make interpretation of lung findings very difficult</p>
	<p>Traumatic flail chest</p> <p>Multiple rib fractures may result in paradoxical movements of the thorax. As descent of the diaphragm decreases intrathoracic pressure, on inspiration the injured area caves inward; on expiration, it moves outward</p>

**Figure 2.5** The lymph nodes of the head and neck.**Figure 2.6** Position of hands to assess for chest expansion.

Figure 2.7 Locations for feeling fremitus: back.

Tactile fremitus

Fremitus is the palpable vibrations of the patient's voice through the chest wall (Bickley et al. 2013). See Figure 2.7 and Figure 2.8 for locations for feeling fremitus. Compare both sides of the chest, using the ball or ulnar surface of your hand (Bickley et al. 2013). The vibrations felt should be symmetrical and will decrease as you work down the chest wall. Fremitus is usually decreased or absent over the precordium. Asymmetry could indicate:

- consolidation
- emphysema
- pneumothorax
- plural effusion (Rushforth 2009).

Faint or absent fremitus in the upper thorax could indicate:

- obstruction of the bronchial tree
- fluid
- obesity (Rushforth 2009).

Figure 2.8 Locations for feeling fremitus: front.

Figure 2.9 'Ladder' pattern for percussion and auscultation of the chest.

Percussion

When percussing and auscultating, each side of the chest should be compared. To do this, percuss and auscultate in a ladder-like pattern in the positions shown in Figure 2.9.

Breath sounds

Normal breath sounds are also known as vesicular breath sounds; they are soft and are louder and longer on breathing in (inspiration) compared with breathing out (expiration) (Talley and O'Connor 2006). Bronchial breaths sound different, they have a hollow quality and are audible throughout expiration (Talley and O'Connor 2006). There is often a short silent gap between inspiration and expiration (Bickley et al. 2013).

Adventitious sounds are added sounds on top of breath sounds. Some examples include the following.

- Wheeze – a continuous, high-pitched, hissing sound.
- Crackle – an intermittent high-pitched crackle. If crackles are heard, note:
 - volume, pitch and duration
 - number
 - timing, on inspiration or expiration?
 - location
 - persistence
 - alteration on patient's position change.
- Rhonchi – a continuous, low-pitched, snoring noise (Bickley et al. 2013).

Evidence-based approaches

Rationale

The patient's health history and the nurse's knowledge of anatomy and physiology will help guide when it is appropriate to do a respiratory physical examination. Here are some examples of the presentations that would lead to a respiratory examination.

- Dyspnoea
- Cough
- Chest pain
- Wheezing

Procedure guideline 2.1 Respiratory examination

Essential equipment

- Stethoscope
- Examination couch

Pre-procedure

Action

- 1 Explain the procedure and why you are doing it to the patient.
- 2 Gain patient's verbal consent.
- 3 Make sure the patient is warm and comfortable and sitting on the edge of the bed or on a chair.
- 4 Expose the patient from head to waist.

Rationale

- The patient must be involved in the planning of care and have clear, jargon-free information before any procedure takes place (NMC 2010, **C**).
- Consent must be gained before any procedure takes place (NMC 2015, **C**).
- To ensure that both the anterior (front) and posterior (back) thorax and lungs can be examined (Bickley et al. 2013, **E**).
- To allow a thorough examination (Talley and O'Connor 2006, **E**).

Procedure

- 5 Wash and dry hands.

To prevent the spread of infection (Douglas and Bevan 2013, **E**).

General inspection

- 6 Take a global view of the patient.
- 7 Look at the patient's skin and nails. Feel the texture, temperature and turgor of the skin.
- 8 Press the patient's fingernail firmly between your finger and thumb for 5 seconds and then let go. Count how many seconds it takes for the colour to return to the nail.
- 9 Ask the patient to hold out their arms with the wrists flexed and their palms facing forwards for 1 minute.
- 10 Look at the patient's eyes.
- 11 Look at and in the patient's mouth.
- 12 Look at and in the patient's nose.
- 13 Listen to the patient's breathing.
- 14 Look at the patient's neck.
- 15 Palpate the trachea gently with your index finger and thumb.
- 16 Palpate the head and neck nodes. See Figure 2.5.

See 'Inspection', above.

Abnormalities of the skin and nails can be an indication of a variety of different conditions, for example heart disease, lung disease, cyanosis and/or anaemia (Bickley et al. 2013, Rushforth 2009). Also look for tobacco staining (Talley and O'Connor 2006). **E**

To assess the capillary refill; this can give an indication of the status of circulation (Rushforth 2009). Normal return is 2 seconds. **E**

To assess for flapping tremor; this can be seen in carbon dioxide retention and severe ventilator failure (Devereux and Douglas 2009, **E**).

To assess for any abnormalities, particularly looking for any signs of hypercholesterolaemia and anaemia (Talley and O'Connor 2006, **E**).

The mouth can give a snapshot of the patient's general state of health. Look for signs of malnutrition, infection, central cyanosis and any sores (Bickley et al. 2013, Rushforth 2009). Look for signs of mouth breathing and upper respiratory tract infection (Talley and O'Connor 2006). **E**

To assess for nasal flare, deviated septum and nasal polyps (Talley and O'Connor 2006, **E**).

To assess for any audible wheeze or stridor (Bickley et al. 2013, Devereux and Douglas 2009, **E**).

To assess if accessory muscles are being used and if the trachea is midline (Bickley et al. 2013, **E**).

To ensure it is midline with no deviation (Talley and O'Connor 2006, **E**).

To assess for enlarged nodes; this can be a sign of malignancy or infection (Devereux and Douglas 2009, **E**).

Posterior chest

- 17 Inspect the patient's chest.

To assess for any scars, masses, deformities and asymmetry (Bickley et al. 2013, **E**).

Palpation

- 18 Lightly palpate the chest.
- 19 Place your thumbs at the level of the 10th rib either side of the spine with your fingers fanned out towards the lateral (side) chest. Ask the patient to take a deep breath in. See Figure 2.6.

To assess for any signs of tenderness, pain or masses (Bickley et al. 2013, Rushforth 2009, **E**).

To assess chest expansion (Bickley et al. 2013, Devereux and Douglas 2009, Rushforth 2009, Talley and O'Connor 2006, **E**).

(continued)

Procedure guideline 2.1 Respiratory examination (continued)

Action	Rationale
20 Place the edge of your palm and little finger on the patient's chest at the points seen in Figures 2.7 and 2.8 and ask the patient to say 99. Assess both sides of the chest together using both hands.	To assess for tactile fremitus (Bickley et al. 2013, Devereux and Douglas 2009, Rushforth 2009, Talley and O'Connor 2006, E).
Percussion	
21 Percuss the chest (see Figure 2.9).	To assess for a normal resonant lung and identifying any abnormalities (Bickley et al. 2013, E).
Auscultation	
22 Auscultate the lung using the diaphragm of the stethoscope (see Figure 2.9).	To assess for vesicular breath sounds and any adventitious sounds (Bickley et al. 2013, E).
Anterior chest	
23 Inspect the patient's chest.	To assess for any scars, masses, deformities and asymmetry (Bickley et al. 2013, E).
Palpation	
24 Lightly palpate the chest	To assess for any signs of tenderness, pain or masses (Bickley et al. 2013, Rushforth 2009, E).
25 Place your thumbs along each costal margin at about the 5th/6th rib with your fingers fanned out towards the lateral chest. Ask the patient to take a deep breath in. See Figure 2.6.	To assess chest expansion (Bickley et al. 2013, Devereux and Douglas 2009, Rushforth 2009, Talley and O'Connor 2006, E).
26 Place the edge of your palm and little finger on the patient's chest at the points seen in Figures 2.7 and 2.8 and ask the patient to say 99. Assess both sides of the chest together using both hands.	To assess for tactile fremitus (Bickley et al. 2013, Devereux and Douglas 2009, Rushforth 2009, Talley and O'Connor 2006, E).
Percussion	
27 Percuss the chest (see Figure 2.9).	To assess for a normal resonant lung and identifying any abnormalities (Bickley et al. 2013, E).
Auscultation	
28 Auscultate the lung using the bell of the stethoscope for the apex of the lung; above the clavicle and the diaphragm of the stethoscope for the rest of the chest (see Figure 2.9).	To assess for vesicular breath sounds and any adventitious sounds (Bickley et al. 2013, E).
Post-procedure	
29 Document fully.	Accurate records should be kept of all discussions and/or assessments made (NMC 2010, C).
30 Report any abnormal findings to a senior nurse or to medical staff.	Patients should be cared for as part of a multidisciplinary team and, where appropriate, patient care should be referred to another more experienced practitioner (NMC 2015, C).
31 Clean the equipment used and wash hands.	To prevent the spread of infection (Douglas et al. 2013, E).
32 Explain findings to the patient.	The patient should be told, in a way they can understand, the information they want or need to know about their health (NMC 2015, C).
33 Discuss plan of care with the patient.	Where possible, patients should be involved in planning their care (NMC 2015, C).

Cardiovascular examination**Anatomy and physiology**

The heart is a muscular organ that delivers blood to the pulmonary and systemic systems (Grubb et al. 2013) (Figure 2.10). A good understanding of the vascular system of the heart is important.

Related theory

When carrying out a cardiovascular assessment, the order of examination is:

- inspection
- palpation
- auscultation.

Note that percussion is not part of a cardiovascular assessment.

Inspection

As with all systems, the examination should commence with a global view of the patient followed by inspection of the nails, skin, eyes and mouth. However, many symptoms that would lead to a cardiovascular assessment can be life-threatening so first take a

moment to assess whether the patient is well enough for a full examination or whether they need immediate treatment in order to be stabilized first (Rushforth 2009).

Part of inspection is measuring the jugular venous pressure (JVP) (Figure 2.11). This reflects the pressure in the right atrium and is a good indicator of cardiac function (Powell 2006). To do this, the location of the right internal jugular vein is paramount. The vein runs deep within the sternomastoid muscle so it is not directly visible (Bickley et al. 2013) (Figure 2.12). Instead, practitioners can locate it by looking for its pulsation within the sternomastoid muscle (Bickley et al. 2013).

Closely examine the precordium (the area of the chest that sits over the heart) as scars can be a sign of past trauma or surgery (Grubb et al. 2013, Powell 2006, Talley and O'Connor 2006). Inspection may also reveal the apical impulse, also known as the point of maximum impulse, which is normally located at the fourth or fifth intercostal space (Bickley et al. 2013). Less

Figure 2.11 Measuring a JVP.

commonly, left ventricular movements, known as heaves and lifts, may be visible (Bickley et al. 2013). It is important to note any chest deformities (see 'Respiratory examination', above).

It is important to assess for signs of vascular disease, examining the feet and legs for:

- pain
- swelling
- discoloration
- ulceration
- temperature (Grubb et al. 2013).

Palpation

Arterial pulses should be palpated and checked to assess for cardiac output and peripheral vascular resistance (Rushforth 2009), noting the following qualities: rate, rhythm, amplitude and character. Arterial pulses include:

- radial
- brachial
- carotid
- femoral
- popliteal
- posterior tibial
- dorsalis pedis.

A weak pulse can be a sign of various conditions, including decreased cardiac output (Rushforth 2009). A bounding pulse can indicate an increased cardiac output which can be present in hypertension and anaemia (Rushforth 2009). Pulses on each side of the body should be compared simultaneously if possible. There are two exceptions to this: the practitioner will need to use both hands to assess each popliteal pulse and the carotid pulses are palpated separately as doing both together may make the patient feel faint.

When palpating the chest, heaves, lifts and thrills should be assessed. Heaves and lifts are sustained impulses and if present will be felt through the flat of your hand being lifted rhythmically during palpation (Bickley et al. 2013). They can be a sign of an enlarged ventricle or atrium or sometimes a ventricular aneurysm (Bickley et al. 2013). Thrills are sometimes present if the patient has a heart murmur. They will be felt most clearly using the ball of the hand palpating firmly in the area of the murmur and feel like a buzzing or vibration (Bickley et al. 2013).

Auscultation

When auscultating, normal heart sounds should be identified plus any adventitious sounds (Rushforth 2009). The sound of the beating heart is often described as ‘lub dub’ and is caused by closure of valves (Powell 2006). The ‘lub’ sound, which is also referred to as S1, is heard at the beginning of systole when the mitral and tricuspid valves are closing; ‘dub’ or S2 is heard at the end of systole when the aortic and pulmonary valves close (Powell 2006). There are some extra sounds that can sometimes be heard called S3 and S4. S3 is occasionally heard immediately after S2 and is caused by the vibration of rapid ventricular filling (Rushforth 2009). S4 can rarely be heard immediately before S1 and marks atrial contraction. Both of these sounds can indicate a change in ventricular compliance (Bickley et al. 2013).

Murmurs can be heard in a number of different conditions; they are caused by turbulent blood flow and, whilst they are sometimes harmless, they can indicate valvular heart disease (Bickley et al. 2013). Heart sounds and murmurs that originate in the four valves radiate widely; see Figure 2.13 for an illustration of auscultation points.

Assessment of carotid bruits is an important component of cardiovascular assessment. Bruits are often described as a whooshing sound and can indicate atherosclerotic arterial disease (Bickley et al. 2013).

Evidence-based approaches

Rationale

The patient’s health history and the nurse’s knowledge of anatomy and physiology will help guide when it is appropriate to do a cardiovascular physical examination. The list of presentations that may lead to a cardiovascular examination is vast; some examples include:

- chest pain
- palpitation
- leg ulcer
- breathlessness
- oedema
- dizziness.

Figure 2.13 Auscultation points and location of the heart valves.

Procedure guideline 2.2 Cardiovascular examination	
Essential equipment <ul style="list-style-type: none">• Stethoscope• Examination couch• Pen torch• Tongue depressor• Ruler	
Pre-procedure	
Action	Rationale
1 Explain the procedure and why you are doing it to the patient.	The patient must be involved in the planning of care and have clear, jargon-free information before any procedure takes place (NMC 2015, C).
2 Gain patient’s consent.	Consent must be gained before any procedure takes place (NMC 2015, C).
3 Check that the patient has an empty bladder.	A full bladder will interfere with the examination (Walsh 2006b, E).
4 Make sure the patient is warm and comfortable and ideally have them in the supine position, with their head at 30–45° and their arms by their sides.	This is the optimum position from which to assess the JVP (Talley and O’Connor 2006, E).
5 Expose the patient from head to waist. You will also need access to their legs.	To allow a thorough examination (Talley and O’Connor 2006, E).

Procedure

6 Wash and dry hands.	To prevent the spread of infection (Douglas et al. 2013, E).
General inspection	
7 Take a global view of the patient.	See 'Inspection', above.
8 Look at the patient's skin and nails. Feel the texture, temperature and turgor of the skin.	Abnormalities of the skin and nails can be an indication of a variety of different conditions, for example heart disease, endocarditis, hypercholesterolaemia and/or anaemia (Bickley et al. 2013, Gawkrödger 2009, Rushforth 2009). Also look for tobacco staining. E
9 Press the patient's fingernail firmly between your finger and thumb for 5 seconds and then let go. Count how many seconds it takes for the colour to return to the nail.	To assess the capillary refill; this can give an indication of the status of circulation (Rushforth 2009). Normal return is 2 seconds. E
10 Look at the patient's eyes.	Assessing for any abnormalities, particularly looking for any signs of hypercholesterolaemia and anaemia (Talley and O'Connor 2006, E).
11 Look at and in the patient's mouth.	The mouth can give a snapshot of the patient's general state of health. Look for signs of malnutrition, infection, central cyanosis and any sores (Douglas and Bevan 2013, Rushforth 2009, E).
12 Ask the patient to turn their head to the left, use tangential lighting and locate the highest pulsation point of the internal jugular vein (see Figure 2.11). Place a ruler vertically from the sternal angle, then use a tongue depressor placed horizontally to make a right angle from the pulsation to the ruler. The jugular venous pressure is measured in cms and the measurement is where the tongue depressor meets the ruler.	To assess the jugular venous pressure (Bickley et al. 2013, E).
13 Inspect the precordium.	To assess for scars, deformities, heaves, lifts and the apical impulse (Bickley et al. 2013, E).
14 Inspect the legs.	To assess for signs of venous disease and ischaemic changes (Grubb et al. 2013, E).
Palpation	
15 Palpate the pulses (see Figure 2.12).	To assess cardiac output (Rushforth 2009, E).
16 Palpate the chest.	To assess for tenderness, heaves, lifts and thrills (Bickley et al. 2013, Rushforth 2009, E).
17 Palpate with the finger tips the 5th intercostal space midclavicular line.	To assess the apical impulse (Bickley et al. 2013, Rushforth 2009, E).
Auscultation	
18 Listen with the bell of the stethoscope to the carotid pulse.	To assess for bruits (Bickley et al. 2013, E).
19 Auscultate at the aortic, pulmonary, tricuspid and mitral valves (see Figure 2.13) with the diaphragm of the stethoscope.	To assess S1 and S2 (Bickley et al. 2013, E).
20 Auscultate at the aortic, pulmonary, tricuspid and mitral valves (see Figure 2.13) with the bell of the stethoscope.	To assess for S3, S4 and murmurs (Bickley et al. 2013, E).
21 Ask the patient to roll partially onto their left side and listen with the bell of the stethoscope to the apical impulse.	To assess for a mitral murmur (Bickley et al. 2013, E).
22 Ask the patient to sit up and lean forward, exhale completely and hold their breath. Listen with the diaphragm of the stethoscope to the apical impulse and along the left sternal border. Make sure to tell the patient to start breathing normally again.	To assess for an aortic murmur and pericardial friction rubs (Bickley et al. 2013, Rushforth 2009, E).
23 Ask the patient to sit up and listen to the lung bases with the diaphragm of the stethoscope.	To assess for lung congestion that can be caused by heart failure (Rushforth 2009, E).

(continued)

Procedure guideline 2.2 Cardiovascular examination (continued)

30	Post-procedure
Action	Rationale
24 Document fully.	Accurate records should be kept of all discussions and/or assessments made (NMC 2010, C).
25 Report any abnormal findings to a senior nurse or to medical staff.	Patients should be cared for as part of a multidisciplinary team and where appropriate, patient care should be referred to another more experienced practitioner (NMC 2015, C).
26 Clean the equipment used and wash your hands.	To prevent the spread of infection (Douglas et al. 2013, E).
27 Explain findings to the patient.	The patient should be told, in a way they can understand, the information they want or need to know about their health (NMC 2015, C).
28 Discuss plan of care with the patient.	Where possible patients should be involved in planning their care (NMC 2015, C).

Abdominal examination

Anatomy and physiology

The abdominal cavity houses large parts of the gastrointestinal system, the renal system and the reproductive system. It is therefore important to have an understanding of the anatomy and physiology of all three systems.

The gastrointestinal (GI) system includes the entire GI tract as well as the accessory organs (Figure 2.14). When examining the abdominal area, it is important to be able to visualize which organs are in which quadrant. This will help to form possible differential diagnoses.

The physiology of the gastrointestinal system is covered in Chapter 5: Elimination and Chapter 7: Nutrition, fluid balance and blood transfusion

Related theory

A full abdominal examination combines the following techniques:

- inspection
- auscultation
- percussion
- palpation.

Figure 2.14 Organs of the gastrointestinal system. *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Table 2.3 Causes attributable to different umbilicus positions

Umbilicus position	Cause
Not visible	Fat
Shallow, pointing downwards	Fluid
Pushed upwards	Pregnancy

The order of examination is altered when examining the abdomen; auscultation should be done before palpation and percussion to avoid alteration of bowel sounds (Walsh 2006a).

Inspection

Externally the abdomen should appear flat and symmetrical (MacGilchrist et al. 2013). Reasons for any deviations from normal may be:

- fat
- fluid
- flatus
- foetus
- faeces
- fibroid
- full bladder
- false pregnancy
- tumour
- hernia (Talley and O'Connor 2006).

The umbilicus position can sometimes help to identify why there is distension (Talley and O'Connor 2006) (Table 2.3).

The skin should be examined for signs of abnormality. Scars should be noted as a sign of past injury or surgery; striae, rashes and bruising should also be noted (MacGilchrist et al. 2013).

Auscultation

Bowel sounds should be listened for in all four quadrants of the abdomen (Figure 2.15). Bowel sounds are often described as clicks or gurgles and you should be able to hear 5–30 clicks

**Figure 2.15** The four quadrants of the abdomen.**Figure 2.16** Stethoscope positioning for auscultating bruits.

in 1 minute (Walsh 2006a). Bowel sounds are often described as active, i.e. normal, absent or hyperactive. Absence of bowel sounds may indicate bowel obstruction and hyperactive bowel sounds may be present if patients are having altered bowel function (Rushforth 2009).

Assessment of bruits is an important component of physical assessment. Bruits are often described as a whooshing sound and can indicate atherosclerotic arterial disease (Bickley et al. 2013). If the bruits are over the renal artery it can be a sign of renal artery stenosis (Bickley et al. 2013). See Figure 2.16 for stethoscope positioning.

Percussion

Percussion is used to detect air, fluid, faeces, organs and masses (Walsh 2006a). Predominantly the abdomen should have a distribution of tympany and dullness – tympany where there is gas in the gastrointestinal tract and dullness where other organs and faeces lie (Bickley et al. 2013). Large areas of dullness may indicate organomegaly (enlarged organs), tumour or ascites (Bickley et al. 2013). Percussion is also used to locate and measure the size of the liver (Walsh 2006a). A normal liver is normally 6–12 cm (Talley and O'Connor 2006).

Palpation

Palpation is used to assess tenderness, rebound tenderness, organs and masses (Talley and O'Connor 2006). If an organ or mass is found, palpation should be used to gather more information about it. Talley and O'Connor (2006) suggest that the following information should be included when describing a mass.

- Site
- Tenderness
- Size
- Surface
- Edge
- Consistency
- Mobility
- Whether it has a pulse or not

Likewise, if an organ is found it should be described. The spleen and kidneys are not normally palpable if they are not enlarged but a normal liver edge can sometimes be felt

(Talley and O'Connor 2006). If palpable, it should feel soft, regular and smooth with a well-defined border (Talley and O'Connor 2006).

Evidence-based approaches

Rationale

The patient's health history and the nurse's knowledge of anatomy and physiology will help guide when it is appropriate to do an abdominal physical examination. The list of presentations that may lead to an abdominal examination is vast, and as discussed in the anatomy and physiology section, it could involve

the gastrointestinal, renal and/or reproductive systems. Some examples include:

- abdominal pain
- nausea and/or vomiting
- change in bowel habit
- weight change
- jaundice
- bleeding
- dysuria/urgency or frequency
- flank pain
- suprapubic pain.

Procedure guideline 2.3 Abdominal examination

Essential equipment

- Stethoscope
- Examination couch
- Pen torch
- Tongue depressor

Pre-procedure

Action

- 1 Explain the procedure and why you are doing it to the patient.
- 2 Gain patient's consent.
- 3 Check that the patient has an empty bladder.
- 4 Make sure the patient is warm and comfortable and ideally have them in the supine position, with their arms by their sides.
- 5 Expose the patient from nipple to pubis, maintaining patient dignity at all times.

Rationale

The patient must be involved in the planning of care and have clear, jargon-free information before any procedure takes place (NMC 2015, **C**).

Consent must be gained before any procedure takes place (NMC 2015, **C**).

A full bladder will interfere with the examination (Walsh 2006a, **P**).

If the patient is uncomfortable or cold the abdominal muscles will be tense (Rushforth 2009). The supine position helps relax the abdominal muscles and is the optimum position for abdominal palpation (Talley and O'Connor 2006). **E**

To ensure a thorough examination (Cox 2004, **E**).

Procedure

- 6 Wash and dry hands.

To prevent the spread of infection (Gawkrodger 2009, **E**).

General inspection

- 7 Take a global view of the patient. See 'Inspection', above.
- 8 Look at the patient's skin and nails. Feel the texture and turgor of the skin. Abnormalities of the skin and nails can be an indication of a variety of different conditions, for example bowel disease, malnutrition, liver disease, dehydration and/or anaemia (Bickley et al. 2013, Gawkrodger 2009, Rushforth 2009, **E**).
- 9 Ask the patient to extend their arms, flex their wrists and part their fingers. Ask them to stay in this position for 15 seconds. To assess for liver flap; this can be a sign of liver and/or renal failure (Talley and O'Connor 2006, **E**).
- 10 Look at the patient's eyes. To assess for any abnormalities, particularly looking for any signs of jaundice, hypercholesterolaemia and anaemia (Talley and O'Connor 2006, **E**).
- 11 Look at the patient's nose. To assess for signs of telangiectasia which can indicate liver disease (Bickley et al. 2013, **E**).
- 12 Look at and in the patient's mouth. The mouth can give a snapshot of the patient's general state of health. Look for signs of malnutrition, infection and any sores (Rushforth 2009, **E**).
- 13 Smell the patient's breath. To assess for signs of fetor (unpleasant smelling breath) (Talley and O'Connor 2006). A sweet-smelling breath can be a sign of ketoacidosis. **E**
- 14 Ask the patient to shrug their shoulders and lightly palpate, using the finger tips, directly above the clavicle. To assess for a raised supraclavicular lymph node which can indicate gastrointestinal malignancy (Talley and O'Connor 2006, **E**).
- 15 Move to the foot of the bed to inspect the abdomen. Assessing the abdomen from different angles will help to identify any abnormalities (Walsh 2006a, **E**).

16 Observe the contour of the abdomen and position of the umbilicus.	To assess for asymmetry or distension, peristalsis and/or pulsations (Bickley et al. 2013, Walsh 2006a, E).
17 Move to the side of the bed and observe the contour of the abdomen tangentially.	This will allow any subtle changes in contour to be observed (Cox 2004).
18 Look at the patient's skin.	To assess for any signs of spider naevi, striae, scars, caput medusa, bruising and rashes (MacGilchrist et al. 2013, E).
Auscultation	
19 Using the diaphragm of the stethoscope, listen in all four quadrants for 1 minute.	To assess for bowel sounds (Bickley et al. 2013, E).
20 Using the bell of the stethoscope, listen over the aortic, renal, iliac and femoral arteries (see Figure 2.16).	To assess for bruits (Bickley et al. 2013, E).
Percussion	
21 Percuss in 9 areas of the abdomen.	To listen for a normal distribution of tympany and dullness (see Table 2.1) (Bickley et al. 2013, E).
22 Percuss for liver span. To do this, percuss upwards, starting in the right lower quadrant, midclavicular line. Stop when you hear the dullness of the liver. Next percuss down, starting from the nipple line, midclavicular; stop when the sound changes from the resonant lung to the dull liver. Measure between those two points.	To assess the size and location of the liver (Walsh 2006a, E).
23 The above technique can be employed to percuss the spleen, bladder and kidneys.	Not routinely done but may be useful if abnormality, in particular organomegaly, is suspected.
Palpation	
24 Lightly palpate the abdomen using one hand. Look at the patient's face at all times, to ensure they are not in discomfort.	To assess for tenderness, rebound tenderness, superficial organs or masses (Talley and O'Connor 2006, E).
25 Deeply palpate the abdomen.	To assess organs, deeper masses and to define masses that have already been discovered (Talley and O'Connor 2006, E).
26 Palpate for the liver. To do this, place your left hand in the small of the patient's back and your right in the right lower quadrant pointing towards the upper left quadrant. Ask the patient to take a deep breath and palpate up. If nothing is felt, move up towards the liver and repeat until you reach the ribcage.	To assess for hepatomegaly and gallbladder tenderness; this is known as Murphy's sign (MacGilchrist et al. 2013, E).
27 Palpate for the spleen. Ask the patient to tip slightly onto their right side. Start from the umbilicus region and mimic the technique above, moving towards the spleen.	To assess for splenomegaly (MacGilchrist et al. 2013, E).
28 Palpate for the kidneys. Do each kidney separately. Right side – stand on the right side of the patient, place left hand just below the 12th rib and lift up. Place the other on the right upper quadrant of the abdomen. Ask the patient to take a deep breath and press the right hand deeply into the abdomen, trying to feel the kidney between your hands. Repeat for the left side.	To assess for kidney enlargement; if the kidney is normal it is not usually palpable (MacGilchrist et al. 2013, E).
29 Lightly palpate each costovertebral angle (the area directly overlaying the kidneys) for tenderness; if none is felt, place one hand flat over the costovertebral angle and strike the hand firmly with the other fist.	Pain can indicate pyelonephritis (Bickley et al. 2013, E).
Post-procedure	
30 Document fully.	Accurate records should be kept of all discussions and/or assessments made (NMC 2015, C).
31 Report any abnormal findings to a senior nurse or to medical staff.	Patients should be cared for as part of a multidisciplinary team and, where appropriate, patient care should be referred to another more experienced practitioner (NMC 2015, C).
32 Clean the equipment used and wash your hands.	To prevent the spread of infection (Douglas et al. 2013, E).
33 Explain the findings to the patient.	The patient should be told, in a way they can understand, the information they want or need to know about their health (NMC 2015, C).
34 Explain the plan of care to the patient.	Where possible patients should be involved in planning their care (NMC 2015, C).

Post-procedural considerations

34

Documentation

Practitioners should ensure that the following components are documented.

- Rationale for examination.
- Patient's consent to examination.
- Type of examination performed.
- Findings from the examination.
- Plan of care.

As with all record keeping, documentation regarding physical examinations should be clear, concise, accurate and without jargon or abbreviations (NMC 2015).

Communication and discharge planning

Definition

Discharge planning is defined by Rorden and Taft (1990) as 'a process made up of several steps or phases whose immediate goal is to anticipate changes in patient care needs and whose long-term goal is to ensure continuity of health care'. Discharge planning should involve the development and implementation of a plan to facilitate the transfer of an individual from hospital to an appropriate setting and include the multidisciplinary team, the patient and their carers. Furthermore, it involves building on, or adding to, any assessments undertaken prior to admission (DH 2003).

Introduction

Discharge planning is a routine feature of health systems in many countries (Shepperd et al. 2013). The evidence suggests that a structured discharge plan tailored to the individual is best practice (Shepperd et al. 2013); therefore, effective, safe discharge planning needs to be patient and carer focused. There is consistent evidence to suggest that best practice in hospital discharge involves multidisciplinary teamwork throughout the process (Borrill et al. 2000). The multidisciplinary approach, where all staff have a clear understanding of their roles and responsibilities, will also help to prevent inappropriate readmissions and delayed discharges (Stewart 2000). This approach also promotes the highest possible level of independence for the patient, their partner and family by encouraging appropriate self-care activities.

Ineffective discharge planning has been shown to have detrimental effects on a patient's psychological and physical well-being and their illness experience (Cook 2001, Kissane and Zaider 2010, Lees 2013). Planning care, providing adequate information and involving patients, families and healthcare professionals will keep disruption to a minimum.

To achieve the best quality of life for patients and carers, there needs to be effective co-ordination in terms of care planning and delivery of that care over time (Day et al. 2009, NMC 2009, Øvretveit 1993). Discharge co-ordinators are, in

general, health or social care professionals who have both hospital and community experience. Their role is to advise, help with planning, and assist the co-ordination of the differing care providers that the patient may need when leaving hospital, particularly when the nursing and care needs are complex. For complex discharges, it is helpful if a key worker, for example the discharge co-ordinator, is appointed to manage the discharge and, where appropriate, for family meetings/case conferences to take place and include the patient/carer, multidisciplinary team and primary healthcare team (PHCT) and representatives (Department of Evaluation in Healthcare Organisations 2001).

Patients with additional needs

There are groups of patients who may have additional needs on discharge and the approach taken may have to be tailored to meet these additional needs. If, for example, the patient has dementia or a learning disability, the approach to their discharge plan may need to be adjusted. If, for example, the patient has been assessed as lacking capacity to make a decision about where they live then the principles of the Mental Capacity Act (2005) must be employed to ensure the family and carers are involved. Where the patient is assessed as lacking capacity and has no relatives or friends and so is 'unbefriended' as defined by the Mental Capacity Act (2005), a referral should be made to the local Independent Mental Capacity Advocacy Service (Mental Capacity Act 2005). There is a concern that where a person has a degree of cognitive impairment, there will be an assumption that they cannot return home or that they need care. These assumptions should be challenged and decisions made on the basis of an assessment, including a mental capacity assessment. The assessment should evidence that the principles of the Mental Capacity Act (2005) have been applied.

For patients who may have additional needs on discharge, it is worth exploring what support services may be available and to identify what services were in place prior to admission. For example, if the person has a learning disability they may have a learning disability nurse in the community; involving them in the patient's discharge would ensure a safer transition for the patient and enable access to a professional who has knowledge and expertise in the field of learning disabilities but also in the needs of the patient.

Discharge processes (DH 2004b) endorse the value of co-ordination in a climate of shorter hospital stays and timely patient discharge. Poor discharge planning may result in patients remaining in hospital for longer than is necessary. Research has demonstrated that a high level of communication between the professionals planning the discharge and the providers of services outside the hospital setting is an effective mode of preventing readmission (Shepperd et al. 2013). McKenna et al. (2000) suggest that an indicator of poor discharge practice is poor communication amongst the multidisciplinary team (MDT), and between the hospital and community. For patients with complex needs, see Box 2.8 for additional support and guidance for decision making and planning. This should be used in conjunction with the discharge checklist (Figure 2.17).

Box 2.8 Guide to arranging a complex discharge home

NB: This is not an exhaustive list and MUST BE DISCUSSED with the complex discharge co-ordinator/specialist sister, discharge planning, palliative care

Complex discharge definition

- A large package of care involving different agencies.
- The patient's needs have changed since admission, with different services requiring co-ordination.
- The family/carer requires intensive input into discharge planning considerations (e.g. psychological interventions):
 - patients who are entitled to NHS Continuing Healthcare and who require a package of care on discharge
 - patients for repatriation.

1 Comprehensive assessment by nurse on admission and document care accordingly

- | | |
|---|--|
| (a) Provisional discharge date set. | <ul style="list-style-type: none"> • This will only be an approximate date, depending on care needs, equipment, and so on. • It should be reviewed regularly with multidisciplinary team. • Discharge should not be arranged for a Friday or weekend. |
| (b) Referrals to relevant members of multidisciplinary team. | For example, occupational therapist, physiotherapist, social services. |
| (c) Referral to community health services (in liaison with multidisciplinary team). | For example, community nurse (who may be able to arrange for night sitters), community palliative care team. |
| (d) Request equipment from community nurse and discuss with family. | For example, hoist, hospital bed, pressure-relieving mattress/cushion, commode, nebulizer. |
- If oxygen is required**, medical team to complete Home Oxygen Ordering Form (HOOF) and Home Oxygen Consent Form (HOCF) for oxygen cylinders and concentrators at home. Fax to relevant oxygen supplier.

2 Discuss at ward multidisciplinary meeting, arrange family meeting/case conference as required, and invite all appropriate healthcare professionals, including community staff

- | | |
|--|---|
| (a) Appoint discharge co-ordinator at the multidisciplinary meeting. | <ul style="list-style-type: none"> • To act as co-ordinator for referrals and point of contact for any discharge concerns. • To plan and prepare the family meeting/case conference and to arrange a chairperson and minute-taker for the meeting. • Patient's named nurse to liaise with discharge co-ordinator. |
| (b) Formulate a discharge plan at meeting. | <ul style="list-style-type: none"> • At the meeting, formulate a discharge plan in conjunction with patient, carers, and all hospital and community personnel involved and agree a discharge date; an occupational therapist home visit may be required. |
| (c) Ascertain discharge address. | <ul style="list-style-type: none"> • Liaise with services accordingly. • It is important to agree who will care for patient/where the patient will be cared for, for example ground/first floor. • Ascertain type of accommodation patient lives in so that the equipment ordered will fit in appropriately. • NB: If not returning to own home, a GP will be required to take patient on as a temporary resident. |
| (d) Confirm PROVISIONAL discharge date. | <ul style="list-style-type: none"> • This will depend on when community services and equipment can be arranged. • This must be agreed with the patient and family/informal carer/s. |

3 Ascertain whether community nurse is able to undertake any necessary clinical procedures in accordance with their local trust policy, for example care of skin-tunnelled catheters. Consider alternative arrangements if necessary

- | | |
|--|---|
| (a) Confirm equipment agreed and delivery date. | <ul style="list-style-type: none"> • NB: Family must be informed of delivery date and also requested to contact ward to inform that this has been received. |
| (b) Confirm start date for care. | <ul style="list-style-type: none"> • For example, social services/community nurse/community palliative care. |
| (c) Confirm with patient/family agreed discharge date. | <ul style="list-style-type: none"> • Liaise with complex discharge co-ordinator for Community Services Arrangements Form. • Check community services are able to enter patient's home as necessary. |

4 Forty-eight hours prior to discharge, fax and telephone community nurse with Community Care Referral Form and discuss any special needs of patient, for example syringe driver, oxygen, wound care, intravenous therapy, methicillin-resistant *Staphylococcus aureus* or other infection status. Give written information and instructions

- | | |
|--|--|
| a. Arrange transport and assess need for escort/oxygen during transport. | <ul style="list-style-type: none"> • Should be in place for any change in patient's condition/treatment plan. |
| b. Ongoing review. | <ul style="list-style-type: none"> • If there is a change, notify/liaise with multidisciplinary team and community services. |
| c. If NO change within 24 hours of discharge, confirm that: <ul style="list-style-type: none"> – patient is medically fit for discharge – all community services are in place as agreed – patient has drugs to take out (TTO) and next appointment – access to home, heating and food are checked. | <ul style="list-style-type: none"> • Ensure patient has drugs TTO with written and verbal instructions. • Next in/outpatient appointment as required. • Check arrangements for patient to get into home (front door key), heating, food and someone there to welcome them home, as appropriate. |

5 Hospital equipment, for example syringe drivers: ensure clearly marked and arrangements made for return

6 After discharge, follow-up phone call to patient by ward nurse/complex discharge co-ordinator as agreed to ensure all is well

The ten steps to discharge planning

The DH has identified ten steps to discharge planning to assist with the planning of discharge and transfer from hospital and intermediate care (DH 2010).

- 1 Start planning for discharge or transfer before or on admission.
- 2 Identify whether the patient has simple or complex discharge and transfer needs, involving the patient or carer in your decision.
- 3 Develop a clinical management plan for every patient within 24 hours of admission.
- 4 Co-ordinate the discharge or transfer of care process through effective leadership and handover of responsibilities at ward level.
- 5 Set an expected date of discharge or transfer within 24–48 hours of admission and discuss with the patient and carer.
- 6 Review the clinical management plan with the patient each day, take necessary action and update progress towards the discharge or transfer date.
- 7 Involve patients and carers so that they can make informed decisions and choices that deliver a personalized care pathway and maximize their independence.
- 8 Plan discharges and transfers to take place over 7 days to deliver continuity of care for the patients.
- 9 Use a discharge checklist 24–48 hours before transfer.
- 10 Make decisions to discharge and transfer patients each day.

Evidence-based approaches

38

Single Assessment Process

The Single Assessment Process (SAP) is a key part of the *National Service Framework for Older People* (DH 2001), but is not used comprehensively in the UK. The SAP is designed to replace fragmented assessments carried out by different agencies with one seamless procedure (Hunter 1998). It is based on the recognition that many older people have wide-ranging welfare needs and that agencies need to work together to ensure that assessment and subsequent care planning are effective and co-ordinated, and that care is holistic and centres on the whole person (Lymbery 2005). This standard aims to ensure that the NHS and social care services treat older people as individuals and enable them to make choices about their own care, by producing a comprehensive 'individualized care plan' that will set out their full needs and entitlements (Taylor 2012). The SAP aims to make sure older people's needs are assessed thoroughly and accurately, but without procedures being needlessly duplicated by different agencies, and that information is shared appropriately between health and social care agencies.

Legal and professional issues

There is a requirement in discharge planning for nurses to share information about patients with health and social care providers in the community and, in doing so, there needs to be consideration regarding consent to share information and using safe procedures to ensure information is only shared with those who require it. Failing to apply good information governance processes could result in information being shared inappropriately and the breaching of a patient's right to confidentiality. Patients need to consent to their information being shared and, where the patient lacks capacity to share information, then sharing needs to be considered in the patient's 'best interest' based on a mental capacity best interest assessment (Mental Capacity Act 2005, p.3).

Pre-procedural considerations

It is essential that nurses are aware of their organization's discharge procedures, policies and protocols. If a patient is to be admitted for an elective procedure and has attended pre-assessment, discharge needs should be identified at this point to allow effective planning and potential services notified in advance of any admission. This is even more pertinent where patients are being admitted for a short length of stay. These discussions with patients and their families can also help them to determine what they may need on discharge and to plan accordingly.

The role of informal carers

Engaging and involving patients and informal carers, family member or friends who provide care in an unpaid capacity as equal partners is central to successful discharge planning (DH 2003, Holzhausen et al. 2001). The Picker Report, an independent patient survey, identified that 16% of patients questioned reported that they did not feel involved in their discharge (Garrett and Boyd 2008). The hospital discharge process is also a critical time for informal carers, placing an increasing burden of care on them (Bauer et al. 2009, Higginson and Costantini 2008), yet Holzhausen et al. (2001) suggest they do not feel involved in the discharge process. It may be the first time they have been confronted with the reality of their role, the effect it may have on their relationship with the person needing care, their family and their employment (Hill et al. 2001). Research suggests that if carers are unsupported, this can result in early readmission of the patient (Holzhausen et al. 2001). It is therefore important to involve carers as partners in the discharge planning process.

The Carers (Equal Opportunities) Act 2004 was implemented to support carers in a practical way by providing information, helping carers to remain at work and to care for themselves.

Under the Act, carers are entitled to their own assessment and many support services can be provided, including respite, at no charge. Carers are often unaware that they are entitled to an assessment and may be able to access care and support as a carer. It is important that carers are made aware of this and part of this might be as simple as letting them know that the role they play with their family member is that of a carer: many people would see themselves as a wife, husband or daughter rather than a carer.

It is important to recognize that in some families, children may take on a caring role and their needs may go unrecognized (Naked Flame Research 2004). Informing community health and social care providers that there are young carers involved, with prior consent from the parents, may enable the young carers to access additional support services (CarersUK 2012, Naked Flame Research 2004). Young carers may struggle with the responsibilities of providing care to parents and their function can frequently go unrecognized, making the young carer feel isolated and distressed.

Throughout discharge planning, carers' needs should be recognized and acknowledged. Carers may have different needs from patients and there may be conflicting opinions about how the patient's care needs can be met. It is not uncommon for patients to report that their informal carer is willing to provide all care but the carer is not in agreement with this. Healthcare professionals should allow carers sufficient time and provide appropriate information to enable them to make decisions. They should also provide written information on the discharge plan and ensure adequate support is in place before discharge takes place (DH 2010). This will promote a successful and seamless transfer from hospital to home.

The discharge planning process and the primary/secondary care interface

The discharge planning process can be initiated by any member of the PHCT or social services staff in the patient's home, prior to admission, in pre-admission clinics or on hospital admission (Huber and McClelland 2003). Importance is attached to developing a primary care-led NHS, reinforced by the government's White Paper *The New NHS: Modern, Dependable* (DH 1998). The focus on quality, patient-centred care and services closer to where people live will be dependent on primary, secondary and tertiary professionals working together (Davis 1998).

However, it is important to note that the Community Care (Delayed Discharges) Act (DH 2003) introduced a system of reimbursement to NHS bodies from social services departments for delays caused by the failure of social services departments to provide timely assessment and/or services for a patient being discharged from an acute hospital bed. An awareness of the process and required timescales is essential to ensure that a patient's discharge is not delayed because social services have had insufficient time to respond to a request for an assessment.

The discharge planning process takes into account a patient's physical, psychological, social, cultural, economic and environmental needs. It involves not only patients but also families, friends, informal carers, the hospital multidisciplinary team and the community health/social services teams (Maramba et al. 2004, Salantera et al. 2003), with the emphasis on health and social services departments working jointly. However, a new emphasis is being placed on personalized care in the community, with patients purchasing and managing their own care package (Darzi 2008). Giving patients greater control and choice over the services they need requires the professionals to ensure that they have provided information regarding all the possible alternatives for care open to the patient and their carers (Darzi 2008).

As well as patient experience, discharge planning is considered a factor in reducing the length of hospital stay, which has a financial impact for the NHS (DH 2004a,b, Bull and Roberts

Box 2.9 Discharge against medical advice form

Name:

Hospital No:

Address:

I wish to discharge myself against medical advice and accept full responsibility for my actions.

Signed:

Date:

Time:

Statement to be signed by the Doctor

I have discussed with the patient the medical reasons why he/she should remain in the hospital.

Signed:

This form should be filed with the patient's medical records

NB: If concerned about support in the community for the patient, contact social services, the complex discharge co-ordinator or the on-call sister in charge out of hours for advice.

2001, Mardis and Brownson 2003, Nazarko 1998). Given the huge cost of inpatient care, it is important to ensure that procedures are in place, and complied with, to facilitate patients being discharged at the earliest opportunity. However, the notion of a seamless service may be idealistic because of increasing time constraints and the complex care needs of high-dependency patients (Smith 1996).

A significant proportion of patients, 3–11%, return to hospital within 28 days because of complications that have arisen as a consequence of their health. Readmission rates can be reduced through the health assessments and planning that take place in hospital (NHS Institute for Innovation and Improvement 2014). This reinforces the fact that good discharge planning can not only support a better experience for the patient and their carers on discharge but could in fact prevent further unnecessary admissions to hospital.

Occasionally the discharge process may not proceed as planned; a discharge may be delayed for a number of reasons and a system should be in place to record this. Patients may take their own discharge against medical advice and this should be documented accordingly (Box 2.9). When patients are assessed as requiring care or equipment but decline these, this does not negate the nurse's duty to ensure a discharge is safe. A discussion should take place with the patient and carer to assess how they intend to manage without the required care/equipment in place. It is crucial that the community services are aware of assessed needs that are not being met through patient choice or lack of resources. It is critical that the community teams who will be supporting the patient when they return home are notified and where possible this should be in writing, such as sending them a copy of the 'Discharge against medical advice' form (see Box 2.9, Box 2.10).

When patients are informed by their medical teams that there are no further treatment options and advised that their prognosis may be poor, they may decide they want to go home urgently and plans would need to be set up at short notice.

Box 2.10 Patients taking discharge against medical advice**Nursing staff responsibility**

If a patient wishes to take their own discharge, the ward sister/co-ordinator should contact:

- a member of the medical team
- the manager on call
- the complex discharge co-ordinator.

The complex discharge co-ordinator will inform social services if appropriate. Out of hours, following a risk assessment, the manager on call will contact the local social services department, if appropriate, and inform the hospital social services department the following day.

Medical staff responsibility

The doctor, following consultation with the patient, should complete the appropriate form prior to the patient leaving the hospital. The form must be signed by the patient and the doctor and filed in the medical notes. The doctor must immediately contact the patient's GP.

Voluntary services

In many areas voluntary sector providers have begun to forge ways to deliver efficient, high-quality, patient-centred care. Evidence suggests that partnerships between the NHS and voluntary sectors have the potential to address a number of priorities, including prevention and shifting treatment, care and support into the community (Addicott 2013). Therefore, it is worth exploring what voluntary services are available locally that could support patients in the return to the community, ranging from practical support such as small home improvements to befriending services.

Reablement and intermediate care

The provision of reablement or enablement and intermediate care packages constitutes what are known as 'supported discharges'. The aim is to support the patient in making the transfer from hospital to community, thereby avoiding lengthy stays for rehabilitation in an acute hospital bed (DH 2010). This may be a short stay in a residential rehabilitation unit or community hospital. This can also be provided in the patient's own home with additional services such as occupational therapy and physiotherapy being provided to support a personal care package. These services are normally short term and are likely to be reviewed within 6 weeks of discharge.

Reablement or enablement has been defined as 'services for people with poor physical or mental health to help them accommodate their illness by learning or re-learning the skills necessary for daily living. The focus is on restoring independent functioning rather than resolving health care issues, and on helping people to do things for themselves rather than the traditional home care approach of doing things for people that they cannot do for themselves' (DH 2010). Reablement or enablement focuses on dressing, using the stairs, washing and preparing meals. In some areas reablement or enablement may include social reintegration to support social activities. Although reablement overlaps with intermediate care, its focus on assisting people to regain their abilities is distinctive.

The *National Service Framework for Older People* (DH 2001) signalled the development of intermediate care as one of the major initiatives for services in the future. It is recognized that, if at all possible, older people are best cared for at home. To aid the transition period from hospital to home, intermediate care teams may provide a period of intensive care/rehabilitation following a hospital stay, which may take place in a care home or in the individual's own home. It is likely to be limited to a maximum of 6 weeks but there are local variations in practice. Intermediate care needs to have a person-centred approach, involving patients and carers in all aspects of assessment, goal setting and discharge planning. Its success depends on local knowledge of the service and inter-agency collaboration (Hancock 2003). There is growing evidence suggesting that intermediate care initiatives reduce admissions to acute hospitals and residential/nursing home placements (DH 2010, Foundation Trust Network 2012).

Social services care – Sections 2 and 5

If a patient does not meet the criteria for reablement, enablement or intermediate care, they may still receive assistance with personal care and domestic tasks through social services. However, it must be made clear to the patient and/or their family that they will be financially assessed and as a result may be charged for the service. In some local authorities, if the patient is assessed as 'self-funding', social services may only then offer a signposting service to private care providers. Where a patient is assessed as requiring care from social services to enable them to return home, then the trust should notify the local authority using the Community Care and Delayed Discharge Act processes.

The local authority will require a Section 2 no later than 72 hours prior to discharge but this should be done at the earliest opportunity. When the patient has been assessed and is ready for discharge, a Section 5 notification should be sent to the local authority at least 24 hours before discharge. How the local authority responds to the Section 2 may depend on what local arrangements are in place. Many local authorities have a social worker or social work department within the trust to facilitate the setting up of care packages for discharge. Other authorities may require additional assessments such as occupational therapy or medical reports to enable them to set up the care. It is not uncommon for local authorities to request an NHS Continuing Healthcare checklist to be completed as part of the process to assess if the patient might be entitled to NHS Continuing Healthcare funding.

NHS Continuing Healthcare

NHS Continuing Healthcare funding exists to support people with complex healthcare needs. It is provided to support the care that people need over an extended period of time as a result of disability, accident or illness, to address both physical and mental health needs. It may require services from the NHS and/or social care. It can be provided in a range of settings, for example, from a care home to care in people's own homes. NHS Continuing Healthcare is a package of care arranged and funded solely by the NHS. It should be awarded when it is established (through a comprehensive multidisciplinary assessment) that an individual's primary care need is a health need. There has been inconsistency in applying the criteria nationally (House of Commons Health Committee 2005), resulting in the Department of Health producing a *National Framework for NHS Continuing Healthcare* (DH 2009).

In November 2012 new national tools for NHS Continuing Healthcare were launched. These replace any previous tools, including the fast-track assessment for patients who have a rapidly deteriorating condition and a checklist to identify if a patient should be assessed using the full assessment. There is a legal obligation to inform patients of their right to be assessed for NHS Continuing Healthcare funding. There is an online resource booklet (www.gov.uk/government/publications/nhs-continuing-healthcare-and-nhs-funded-nursing-care-public-information-leaflet) informing patients of their rights and outlining the process (DH 2012). Patients who may be entitled to funding through this process could be paying unnecessarily for their care through social services as they will have been financially assessed or could be funding their own care. An important element of the new tools is the requirement for a signed consent rather than presumed consent (DH 2012).

Discharge to a care or nursing home

Discharging a patient to a care or nursing home requires careful thought as giving up their own home is one of the most traumatic events that a person has to consider. The impact on a patient and their carer may be significant, particularly where the person lives with a partner or family member and this would be a loss for both of them. A thorough multidisciplinary assessment is essential, taking into account the individual needs of the patient and their family or carer and exploring all the options before deciding on a care/nursing home. It is really important that carers are supported throughout this process. In most cases the family or carer will be the person who is looking for a care home placement. This can be quite a daunting process and it is worth providing a list of questions and things to look for when assessing a care or nursing home (Table 2.4).

Nursing and care home placements can be delayed while waiting for funding to be approved or waiting for a suitable bed to become available and it may therefore be necessary to consider an interim placement (DH 2003). It is important that the patient and carers are aware that there may be time limits on the stay in hospital so they will be required to find a suitable placement within an agreed timescale. Many hospitals have a policy to support staff where patients and their carers are delaying the process of arranging a nursing home placement.

In 2007 there were important changes in the funding arrangements for adults requiring registered nursing care in nursing homes in England (DH 2013). All adults needing the skills and knowledge of a Registered Nurse to meet all or certain elements of their care needs have that care paid for by the NHS. The amount of funding, paid directly to the nursing home, is dependent on a comprehensive assessment of the patient's care needs by a Registered Nurse, who will usually be employed by the local Clinical Commissioning Group. NHS-funded nursing care was originally provided via payment 'bands', which relate to the level of nursing care required. However, the National Framework (DH 2006b), which came into effect in October 2007, replaced the banding system with a weekly rate for NHS-funded nursing care.

Table 2.4 Questions and things to look for when assessing a care or nursing home

Questions	
First impressions	<ul style="list-style-type: none"> • Is the home easy for family and friends to visit, particularly those who have to rely on public transport? • Does the home have its own transport? • Is the main area accessible for disabilities, e.g. wheelchairs, poor sighted, hard of hearing? • Do the staff answer the door promptly? • Do the staff appear friendly and welcoming? • Does there appear to be a number of staff on duty? • Do the residents look well cared for and clean? • Is there an up-to-date registration certificate on display? • It is usual to sign a visitors' book on arrival.
The accommodation	<ul style="list-style-type: none"> • Is the home/room clean and fresh? • Are the rooms single or shared? • Do the rooms have ensuite facilities? • Can you bring your own furniture and personal belongings? • Where are the nearest toilets, are they accessible? • Is there a telephone in the room and/or mobile phone reception? • Is there a wifi connection/is there a charge for this? • Are there quiet areas to sit in? • What are the meal times? • Is there a choice of meals/diets? • Is there a laundry service on site?
Personal needs	<ul style="list-style-type: none"> • How often do the hairdresser, dentist, chiropody, religious support, GP visit? • Does a resident change GP if they move from the local area? • Where are medications stored? • Can I get a newspaper? • What activities can I join in or hobbies to continue? • Does the home arrange outings? • Are there quiet areas for family/friends to visit? • Can they stay for meals? • Is there an overnight room where they can stay?
Finances and contracts	<ul style="list-style-type: none"> • What are the fees? • What services do the fees include, e.g. chiropody, hairdresser, etc.? • What are the terms and conditions? • Is there a reduction if the patient is admitted to hospital or goes on holiday? • What is the notice period/terminating contract? • When is the room available from?
Nursing needs	<ul style="list-style-type: none"> • How many qualified nursing staff are on duty day and night (in a nursing home)? • How often do qualified nursing staff review a resident (in a nursing home)? • How often does the community nursing team visit and review residents in the care home? • What is the daily care routine? • If the patient has very specific nursing needs, how will they be managed? Refer to the list given by the ward staff on the patient's specific health care needs. • How often do the community palliative care team visit the home? • How often is the GP or doctor in the home? • Although a difficult thing to consider, are they able to support patients to remain in the home for end-of-life care?

Equipment to facilitate a patient's discharge

Patients will frequently require equipment to enable them to return home. The equipment needs of each patient should be assessed at pre-admission and throughout their stay. From a nursing perspective, patients may require additional equipment such as oxygen, which should be prescribed using the appropriate national Home Oxygen Order Forms part A and B. However, in some hospitals this task is completed by a specialist respiratory nurse. It is useful to know how the local procedures work and how to access oxygen for patients at home. Consideration also needs to be given to the monitoring and reviewing of the patient on oxygen once at home.

Specialist ongoing care provisions for patients at home

Patients may require additional provisions to be put in place to facilitate a safe and timely discharge. Patients may be returning home having had interventions that mean they need specialist

nursing input. There will be locally agreed policies and procedures in the community about what can be provided, therefore it is important to confirm that the individual patient's nursing needs can be met before discharge.

Nutritional needs on discharge

In some cases, patients may be receiving nutritional supplements via feeding tubes, known as enteral feeding. The common routes for enteral feeding in the community are:

- radiologically inserted gastrostomy (RIG)
- percutaneous endoscopically placed gastrostomy (PEG)
- jejunostomy
- nasogastric.

Community nurses and dieticians should be contacted in advance of a patient returning home with supportive feeding *in situ* to

Pumps and drains

For wound healing, in some cases patients may be discharged with drains or pumps *in situ*. It is important to confirm that the Clinical Commissioning Group will fund the equipment before discharge. The patient should be supplied with at least 1 week's supply of dressings, allowing the community nurse time to order additional supplies. This timescale may vary depending on local agreements between acute trust and community health providers.

Medication

Before a patient is discharged, the nurse needs to ensure that the patient and, where appropriate, the carer are competent to self-administer medication at home. In some areas tablet dispensers are provided, particularly for those who have difficulty opening containers. If carers/community nurses are involved, local policies need to be adhered to. A medicines administration record (MAR chart) should be given on discharge, clearly stating the name of the drug, dose and frequency and any other special instructions. Special considerations are required for medications prescribed for pumps and drivers, e.g. for patients who require end-of-life care of symptom management.

Patients with particular care needs on discharge

It is important to recognize that some patients may have additional needs that they have not considered themselves whilst in hospital (Box 2.11). If, for example, the patient lives alone or is very frail, simple tasks such as shopping for basic provisions may be very difficult. Consequently, some shopping may need to be done prior to discharge. The patient may have a family member, friend or neighbour who can do this but the patient may assume this task is going to be done when it has not been, thus leaving the patient at home with no basic provisions and no means of getting them. It is therefore really important to talk to the patient about how they might manage these tasks on discharge and consider other means of support such as Age UK or a local voluntary service.

For patients who are frail and at risk of falls, ensuring that they know that the community pendant alarm systems can be installed may provide the patient and family with some reassurance. Further information regarding these alarms and the local providers is usually held by the local authority.

Housing and impact on discharge

On discharge, consideration may need to be given to patient accommodation, such as the suitability of the accommodation and equipment needs, for example, if the patient's property is in a poor state or there are issues in relation to hoarding. A domiciliary visit may be required to ensure the property is habitable; this may need to be done by or with social services. It is also possible that prior to admission patients were homeless or they have become homeless during the admission. The patient may need to be supported to access accommodation through the local authority homelessness team. As part of the process, the patient will need to provide evidence of eligibility for social housing.

Issues of access to patient accommodation may impact on discharge plans. For example, the patient was mobile prior to admission and lives in third-floor accommodation with no lift, but is no longer mobile. However, the patient may still be discharged back to their property whilst the housing department reviews the accommodation and provides suitable alternative accommodation at a later date. Where the patient is a home owner, the housing department may be less likely to intervene and it may be down to the patient and their family to address this.

Prior to discharge

It is important to continue to review the discharge needs of a patient up until the day of their discharge. There are certain

Box 2.11 Patients with particular care needs on discharge

- Live alone.
- Are frail and/or elderly.
- Have care needs which place a high demand on carers.
- Have a limited prognosis.
- Have serious illnesses and will be returning to hospital for further treatments.
- Have continuing disability.
- Have learning difficulties.
- Have mental illness or dementia.
- Have dependants.
- Have limited financial resources.
- Are homeless or live in poor housing.
- Do not have English as their first language.
- Have been in hospital for an 'extended stay'.
- Require aids/equipment at home.

issues that need to be addressed for all patients, such as transport to enable them to return home and that medications to take home have been ordered and are ready for discharge. For patients with more complex needs, it may be useful to use a discharge checklist; this can be commenced on the patient's admission and monitored throughout the patient's hospital stay (see Figure 2.17).

Discharge at the end of life

The *End of Life Care Strategy* (DH 2008) requires that an assessment is made of the patient's preferred place of care and how and where they wish to be cared for at the end of life. Some patients may already have an advance care plan, within which will be recorded these wishes as well as any advance decision they have made about their end-of-life care. For some patients, these conversations may need to take place to ensure that they and their families are given the opportunity to make informed decisions about their wishes. It is important that these conversations are realistic and that patients and their families are aware of the services and potential gaps that might arise once the person is at home. For instance, if the patient believes that community nurses can be with them at any time day or night when a crisis occurs, this may set up the patient, family and community healthcare providers to fail.

The condition of a person nearing the end of life may change rapidly, so it is essential that choices are made and community services are accessed without delay. There may be occasions when a patient is reaching the end of life and the decision is made that their preferred place of care/death is home. Then every effort must be made to ensure that all practicable steps are taken to allow that to happen (Vaartio et al. 2006). Such discharges are often complex and multifactorial and require a multidisciplinary team to be flexible and responsive. It is important in the first instance to contact relevant community teams to highlight the need for a rapid response to any referrals being made. Community nursing, the community palliative care team and, where available, the community matron should be notified at the earliest opportunity. A fast-track NHS Continuing Healthcare funding application may need to be submitted to access funding for the care provision. The patient may also require essential equipment to enable them to return home, such as a profiling bed, commode or hoist; again, these should be ordered at the first opportunity.

Once care and equipment are in place and discharge is proceeding, ensure that a medical review takes place and that the GP, community nurses and community palliative care team are provided with a copy of the discharge summary (Figure 2.18). Telephone contact with the GP prior to discharge is essential to ensure they visit the patient at home.

Name:

Hospital No:

Patients Being Discharged Home for Urgent Palliative Care Checklist for Discharge

This form should be used to assist with planning an urgent discharge home for a patient with terminal care needs. It should be used in conjunction with the Discharge Policy.

Sign and date to confirm when arranged and equipment given. Document relevant information in the discharge planning section of the nursing documentation. Document if item or care is not applicable.

Appoint a designated discharge lead:

Name:..... **Designation:**..... **Contact No:**.....

	Date & Time	Signature, Print Name & Job Title
Patient / Family Issues		
Meeting with patient/family to discuss:- patient's condition and prognosis		
Plan agreed and discussed with patient and carers. Explain the level of care that will be provided in the community. Ensure an understanding that there will not be 24 hour nursing presence.		
Communication with Community Nurse and Community Palliative Care Team		
Discuss with patient/family: <ul style="list-style-type: none"> • Patient and family needs • The role of each service and the timing and frequency of visits • Community Service cover at night (to support family) e.g. Marie Curie or other local services • The need to complete the Continuing Care Application Form, if necessary. • Liaise with complex discharge co-ordinator if advice or fast tracking needed. 		
Agreed planned date and time of community nurses first visit.....		
Agreed planned date and time of community palliative care team first visit.....		
Night nursing service Start date.....		
Communication with GP and Community Palliative Care Medical Team- Medical Responsibilities (Hospital medical team to organize – the nurse to confirm when arranged)		
Registrar to discuss patient's condition with GP and request home visit on day of discharge for death certification purposes. Agreed date and time of visit.....		
Oxygen: HOOF and HOCF completed and faxed to relevant company. Company to arrange delivery date and time with family. [Fax copies to GP for information only]		
Medical summary faxed to GP <input type="checkbox"/> copy with patient <input type="checkbox"/>		
Registrar or Specialist Nurse to discuss with the Community Palliative Care team the patient's needs and proposed plan of care		
Adequate supply of drugs prescribed for discharge (TTOs) including crisis drugs e.g. s/c morphine, midazolam.		
Authorization for drugs to be administered by community nurses. Please refer to Subcutaneous Drugs policy and		

Figure 2.18 Checklist for patients being discharged home for urgent palliative care.

(continued)

complete the discharge checklist for the McKinley T34 syringe pump.		
Prescription sheet of authorisation for drugs to be administered by community nurses. Faxed to Community Nurse and GP		
'Do Not Attempt Resuscitation' letter for Ambulance Crew		

Equipment - confirm delivery of equipment

Electric, profiling hospital bed		
Pressure relieving equipment		
Commode/urinal/bed-pan		
Hoist/ slings/ sliding sheets		
Other, please state e.g. McKinley T34.....		

Provide 4 days supply of:

Dressings		
Sharps bin		
Continence aids		

Transport (confirm by ticking appropriate boxes) CHECK OTHER DISCHARGE DOCUMENTATION

Escort (family/nurse)		
Family informed and aware that the patient may not survive the transfer journey and that the ambulance crew will not attempt resuscitation		

Written information and documentation

Community Care Referral form completed and faxed for the attention of.....		
Community Care Referral form and medical summary given to patient or relative (specify)		
Community Palliative Care Team form completed and faxed for the attention of.....		
Patient/carer given list of contact numbers of community services (including night service)		
Medication list, stating reasons for drugs, given and explained to patient/ relative		
Confirm with the Hospital Consultant/Complex Discharge-Co-ordinator whether a bed should be held for this patient for 24hrs only (unless in exceptional circumstances following discussion with the Complex Discharge Co-ordinator)		

Signature/print name of designated ward based discharge lead:.....

Date/Time.....

File this form in the patient's records on discharge.

Figure 2.18 *Continued*

The patient should be reviewed just prior to discharge by the medical team and any changes in their clinical condition or needs should be shared with the community healthcare providers. It may even be necessary to review the decision and to have open and honest conversations with the patient and their family about what to expect in the coming hours, days or weeks.

Post-procedural considerations

A discharge delay is when a patient remains in hospital beyond the date agreed between the multidisciplinary team and beyond the time when they are medically fit to be discharged (DH 2003). For every patient who is 'delayed', NHS trusts are required to report the delay to their commissioners. It is the responsibility of the health authorities, in collaboration with local authorities, to monitor and address any issues that result in delays in the transfer of patients from an acute bed to their home or community bed, such as care home or rehabilitation bed. Trusts closely monitor bed activity and reporting varies from weekly to daily in winter months.

Chapter 3

Infection prevention and control

Procedure guidelines

- 3.1** Hand washing 61
- 3.2** Hand decontamination using alcohol handrub 63
- 3.3** Putting on and removing non-sterile gloves 64
- 3.4** Putting on and removing a disposable apron 66
- 3.5** Putting on and removing a disposable mask or respirator 67
- 3.6** Putting on or removing goggles or a face shield 68
- 3.7** Surgical scrub technique 69
- 3.8** Donning sterile gloves: open technique 71
- 3.9** Donning a sterile gown and gloves: closed technique 73
- 3.10** Aseptic technique example: changing a wound dressing 78
- 3.11** Source isolation: preparing an isolation room 83
- 3.12** Source isolation: entering the isolation room 84
- 3.13** Source isolation: leaving the isolation room 85
- 3.14** Source isolation: transporting infected patients outside the source isolation area 86
- 3.15** Protective isolation: preparing the room 87
- 3.16** Protective isolation: entering the isolation room 88
- 3.17** Safe disposal of foul, infected or infested linen 92

Overview

This chapter describes the steps to be taken to minimize the risk of individuals acquiring infections during the course of care or treatment. Patients are most at risk but healthcare staff are also legally obliged to take reasonable and practicable precautions to protect themselves, other staff and anyone else who may be at risk in their workplace (Health and Safety at Work etc. Act 1974). The chapter describes the *standard precautions* that must be taken with all patients at all times regardless of their known infection status, and the additional precautions that need to be taken with some patients. Additional precautions can be required either:

- because the patient is colonized or infected with micro-organisms that may pose a particular risk to others, or
- because they are particularly vulnerable to infection themselves.

Note that it is quite possible for additional precautions to be required for both these reasons with one patient – someone who is more vulnerable to infection may well acquire an infection that poses a risk to others.

The chapter also describes the specific precautions that must be taken during invasive procedures, in particular aseptic technique.

Related issues such as the safe management of healthcare waste are also considered briefly.

Infection prevention and control

Definitions

'Infection prevention and control' has been defined as the clinical application of microbiology in practice (RCN 2010). More simply, it is a collective term for those activities intended to protect people from infections. Such activities are carried out as part of daily life by most individuals; for example, people wash their hands before eating to protect themselves from infection. The term is most often used in relation to healthcare, in particular with reference to preventing patients acquiring those infections most often associated with healthcare (such as wound infection) and preventing the transmission of micro-organisms from one patient to another (sometimes referred to as cross-infection).

Defined in Box 3.1 are some other terms used when discussing infection prevention and control. Confusion may sometimes arise because some of these terms are synonymous or have meanings which overlap, or are used in different ways by different people or organizations. This has been highlighted wherever possible.

Box 3.1 Terms used when discussing infection prevention and control

Infectious agent

Anything that may be transmitted from one person to another, or from the environment to a person, and subsequently cause an infection or parasitic infestation. Infectious agents are most often micro-organisms such as bacteria or viruses.

Pathogen

A micro-organism that is capable of causing infection. Many micro-organisms are opportunistic pathogens; that is, they will cause infection in vulnerable individuals but not, normally, in healthy adults.

Colonization

When micro-organisms are present on or in a person but not currently causing any harm, that person is said to be colonized with those organisms. For example, human beings are normally colonized with huge numbers of several different species of bacteria.

Healthcare-associated infection (HCAI)

Any infection acquired as a result of a healthcare-related intervention or an infection acquired during the course of healthcare that the patient may reasonably expect to be protected from. For example, a person may acquire viral gastroenteritis in many circumstances but, if they acquire it in hospital from another patient, it should be regarded as healthcare associated. This has replaced the term 'hospital-acquired infection'.

Cross-infection

Cross-infection is one term given to the transmission of infectious agents between patients within the healthcare setting. It may be direct transmission from one person to another, or indirect, for example via an incorrectly cleaned piece of equipment.

Universal precautions

Correctly called universal blood and body fluid precautions, these are the precautions that are taken with all blood and 'high-risk' body fluids. They are based on the principle that any individual may be infected with a bloodborne virus, such as HIV or hepatitis B, and so pose a risk of infection; no individual can be regarded as completely 'risk free'. They are incorporated within standard precautions.

Standard precautions

The phrase 'standard precautions' is sometimes used interchangeably with 'universal precautions' (see above) but is used in this chapter and elsewhere (e.g. Health Protection Scotland 2009, Siegel et al. 2007) to describe the actions that should be taken in every care situation to protect patients and others from infection, regardless of what is known of the patient's status with respect to infection. Standard precautions include:

- hand hygiene at the '5 moments' described by the WHO (2009a), including before and after each patient contact
- care in the use and disposal of sharps
- the correct use of personal protective equipment for contact with all blood, body fluids, secretions and excretions (except sweat)
- providing care in a suitably clean environment with adequately decontaminated equipment
- the safe disposal of waste
- the safe management of used linen.

Transmission-based precautions

Additional infection control precautions taken with patients known or strongly suspected to be infected or colonized with organisms that pose a significant risk to other patients. The precautions will vary depending on the route by which the organism travels from one individual to another, but there will be common elements. Transmission-based precautions can be divided into:

- contact
- enteric
- droplet
- airborne.

Contact precautions

Additional infection control precautions to be taken with patients known or strongly suspected to be infected or colonized with pathogenic micro-organisms that are mainly transmitted through touch or physical contact. Contact precautions normally consist of isolation of the patient in a single room, where possible, and use of gloves and apron for any procedure involving contact with the patient or their immediate environment (Siegel et al. 2007).

Enteric precautions

Additional infection control precautions to be taken with patients suffering symptoms of infectious gastroenteritis, that is diarrhoea or vomiting that does not have an obvious mechanical or non-infectious cause. Enteric precautions should be taken from the first instance of diarrhoea or vomiting, regardless of whether a causative organism has been identified, until there is a definitive diagnosis that the symptoms do not have an infectious cause. Enteric precautions consist of prompt isolation of the patient in a single room with the door closed and use of gloves and apron for any procedure involving contact with the patient or their immediate environment (Chadwick et al. 2000, DH/HPA 2008).

Droplet precautions

Additional infection control precautions taken with patients known or strongly suspected to be infected or colonized with pathogenic micro-organisms that are mainly transmitted via droplets of body fluid expelled by an infected person. These are most often respiratory secretions expelled during coughing and sneezing but can include droplets from other sources such as projectile vomiting or explosive diarrhoea. The droplets are relatively large ($>5 \mu\text{m}$ diameter) and do not remain suspended in the air for long so special ventilation is not normally required. Droplet precautions consist of isolation of the patient in a single room with the door closed and use of gloves and apron for any procedure involving contact with the patient or their immediate environment. Staff entering the room should wear a mask (Siegel et al. 2007).

Airborne precautions

Additional infection control precautions taken with patients known or strongly suspected to be infected or colonized with pathogenic micro-organisms that are mainly transmitted through the airborne route. These organisms are present in smaller droplets expelled by an infected person and so remain suspended in the air. Droplet precautions consist of prompt isolation of the patient in a single room, if possible with negative pressure ventilation or a positive pressure lobby, with the door closed, and use of gloves and apron for any procedure involving contact with the patient or their immediate environment. Staff entering the room should wear a fitted respirator (Siegel et al. 2007).

Some guidelines merge droplet and airborne precautions in order to provide a single set of instructions for staff caring for patients with any respiratory or airborne infection.

Isolation

Isolation is the practice of nursing a patient in a single-occupancy room to reduce the risk of spread of pathogens and to reinforce and facilitate additional infection control precautions.

Source isolation

The practice of isolating a patient for the main purpose of preventing the spread of organisms from that patient.

Protective isolation

The practice of isolating a patient for the main purpose of preventing the spread of organisms to that patient, normally used for patients with impaired immune systems.

Cohorting

When the number of patients with a particular infection or carrying a particular organism exceeds the single room capacity of a healthcare provider, they may be nursed together in a cohort. This is most often done for highly infectious conditions such as norovirus. Patients who require isolation but have different infections cannot be cohort nursed together because of the risk of cross-infection between them.

Barrier nursing

The practice of nursing a patient who is carrying an infectious agent that may be a risk to others in such a way as to minimize the risk of transmission of that agent to others.

Reverse barrier nursing

The practice of nursing an individual who is regarded as being particularly vulnerable to infection in such a way as to minimize the transmission of potential pathogens to that person.

Related theory

People who are receiving healthcare, whether in hospital or elsewhere, are at risk of infection (Loveday et al. 2014). There are many reasons for this; for example, people who are already ill may be less able to resist infection, and the invasive devices and procedures that are often used in healthcare often bypass some of the body's normal defences. If they are in hospital, this puts them in close proximity to other people who may also be more vulnerable to infection (Breathnach 2005, Gillespie and Bamford 2012). However, many infections acquired by patients receiving healthcare are preventable, as has been amply demonstrated by the 50% reduction in MRSA bacteraemia (bloodstream infections caused by meticillin-resistant *Staphylococcus aureus*) in English NHS hospitals between 2005 and 2008 (Health Protection Agency 2010a) and dramatic falls in the number of cases of *Clostridium difficile* infection in England (Health Protection Agency 2010b). These reductions were achieved by the systematic application and monitoring of established practices for the prevention and control of infection, including diligent hand hygiene and correct aseptic technique.

Common healthcare-associated infections

The 2011 national prevalence survey of patients in hospital in England with infections identified that 64 out of every 1000 patients in hospital at the time of the survey had an infection, a prevalence rate of 6.4%. Incidentally, this is another illustration of the fact that many healthcare-associated infections are preventable – the previous survey in 2006 showed a prevalence of 8.2% (Smythe et al. 2008). The most common types of infection were respiratory tract, urinary tract and surgical site infections (Health Protection Agency 2012). Less common types of infection, for example bacteraemia (bacteria infecting the bloodstream), may be more severe, so *all* procedures must be carried out in such a way as to minimize the risk of any infection.

Causes of infection

Infections are normally caused by micro-organisms. These are life forms too small to see with the naked eye. In some cases, for example prion diseases such as Creutzfeldt-Jakob disease (CJD), it can be unclear if the causative agent is actually living or not, while at the other extreme, infection control precautions will be applied to prevent the transmission of visible parasites such as scabies mites or enteric worms that may be metres in length (although their eggs are microscopic). The term 'infectious agent' is therefore often used to describe anything that may be transmitted from one person to another, or from the environment to a person, and subsequently cause an infection or parasitic infestation.

The major groups of micro-organisms are described below. Which group an infectious agent belongs to will have significant implications for the treatment of an infected individual – for example, antibiotics target bacteria but have no effect on viral infections – but for infection prevention and control it is more important to understand the *route of transmission* as this will dictate if any additional, transmission-based, precautions need to be in place (Siegel et al. 2007).

Types and classification of micro-organisms

Historically, the classification of micro-organisms was based on physical characteristics such as their size, shape or ability to retain a particular stain to make them visible under the microscope. Some of these distinctions are still useful, but classification is increasingly based on genetic characteristics, as analysis reveals the actual relationships between organisms. This can lead to confusion as new discoveries lead to species being reclassified and renamed. It should be noted that there can also be a wide variety of characteristics within each species, leading to significant variations in the severity of infection caused by different strains of the same organism. A good example of this is *Escherichia coli*. Every human being carries millions of these bacteria with no ill

effects but infection with the toxin-producing O157 strain can cause serious illness.

This section describes the different types of organisms that may be encountered in a healthcare environment as well as the differences between and within the different types (Gillespie and Bamford 2012, Goering et al. 2012).

Bacteria

Bacteria are probably the most important group of micro-organisms in terms of infection prevention and control because they are responsible for many opportunistic infections in healthcare. A healthy human being will typically be host to one *quadrillion* (1000 trillion or 10^{15}) bacteria – around ten times as many organisms as there are cells in the human body. In normal circumstances the relationship between these bacteria and their host is commensal (i.e. their presence does not cause the host any problems) and may be mutually beneficial. For example, *E. coli* present in the gut can be an aid to digestion. However, when circumstances change, these commensal organisms can cause infections. If the *E. coli* in the example above are transferred from the gut to the urinary tract, a urinary tract infection can result.

Whether or not any particular situation will result in an infection depends on a wide range of factors and is not always predictable. What is certain is that bacterial infections cannot occur when bacteria are not present, hence the importance of measures designed to minimize the risk of transmission. However, the presence of bacteria does not necessarily indicate an infection – as noted above, many millions of bacteria live on and in the human body without causing harm – so the diagnosis of a bacterial infection and any decision about treatment must be made by considering a combination of the patient's symptoms and laboratory results that may indicate the presence of any particular bacteria (Gillespie and Bamford 2012).

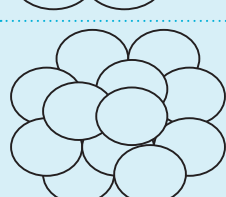

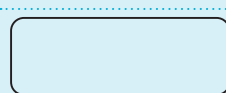

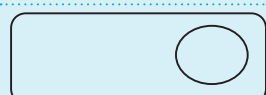

Bacteria are what are known as *prokaryotes*, as opposed to *eukaryotes*, the term used for more complex organisms such as humans. This means that bacterial cells are much smaller and simpler than human cells, typically about the size of some of the structures such as mitochondria that exist within a mammalian cell. This small size means that bacteria do not have separate structures (such as a nucleus) within their cells. What bacteria do have and mammalian cells do not is a cell wall that contains the rest of the cell and gives it a distinctive shape (Goering et al. 2012). Some of these shapes are illustrated in Table 3.1. In terms of healthcare-associated infections, the most important bacteria are generally rod shaped or spherical.

The structure of the cell wall determines another important distinction in medically significant bacteria: whether they are Gram positive or Gram negative. The 'Gram' in these terms refers to Gram staining, named after its Dutch inventor, Hans Christian Gram (1853–1938), who devised the stain in 1884. Put simply, the structure of the cell wall determines whether or not the bacteria are able to retain a particular stain in the presence of an organic solvent such as acetone. The structure of the cell wall determines other characteristics of the bacteria, including their susceptibility to particular antibiotics, so knowing whether the cause of a bacterial infection is Gram positive or negative can help to determine appropriate treatment (Goering et al. 2012). The structure of the two different types of cell wall is shown in Figure 3.1.

Other structures visible outside the cell wall may include pili, which are rigid tubes that help the bacteria attach to host cells (or, in some cases, other bacteria for the exchange of genetic material), flagellae, which are longer, mobile projections that can help bacteria to move around, and capsules, that can provide protection or help the bacteria to adhere to surfaces. These are illustrated in Figure 3.2. The presence or absence of different structures will play a part in determining an organism's pathogenicity – its ability to cause an infection and the severity of that infection (Goering et al. 2012).

A final bacterial structure to consider is the spore. Bacteria normally reproduce by a process called binary fission – they create

Table 3.1 Bacterial shapes and arrangements

Shape/arrangements	Notes/example
	Coccus (sphere) Different species divide in one plane to make pairs and chains or in multiple planes to make clusters
	Chain <i>Streptococcus</i>
	Pair (diplococci) <i>Neisseria</i>
	Cluster <i>Staphylococcus</i>
	Straight rod <i>Escherichia coli</i>
	Spore-forming rod <i>Clostridium difficile</i>
	Comma-shaped <i>Vibrio cholerae</i>
	Spiral-shaped <i>Treponema pallidum</i> , which causes syphilis

a copy of their genetic material and split themselves in two, with each 'daughter' cell being an almost exact copy of the parent (there are mechanisms by which bacteria can transfer genetic material between cells and so acquire characteristics such as antibiotic resistance, but they are beyond the scope of this chapter). However, some bacteria, notably *Clostridium difficile*,

have the capacity, in adverse conditions, to surround a copy of their genetic material with a tough coat. Because this structure is created within the bacterial cell, it is sometimes referred to as an endospore, but is more often simply called a *spore*. Once the spore is formed, the parent cell dies and disintegrates, leaving the spore to survive until conditions are suitable for it to

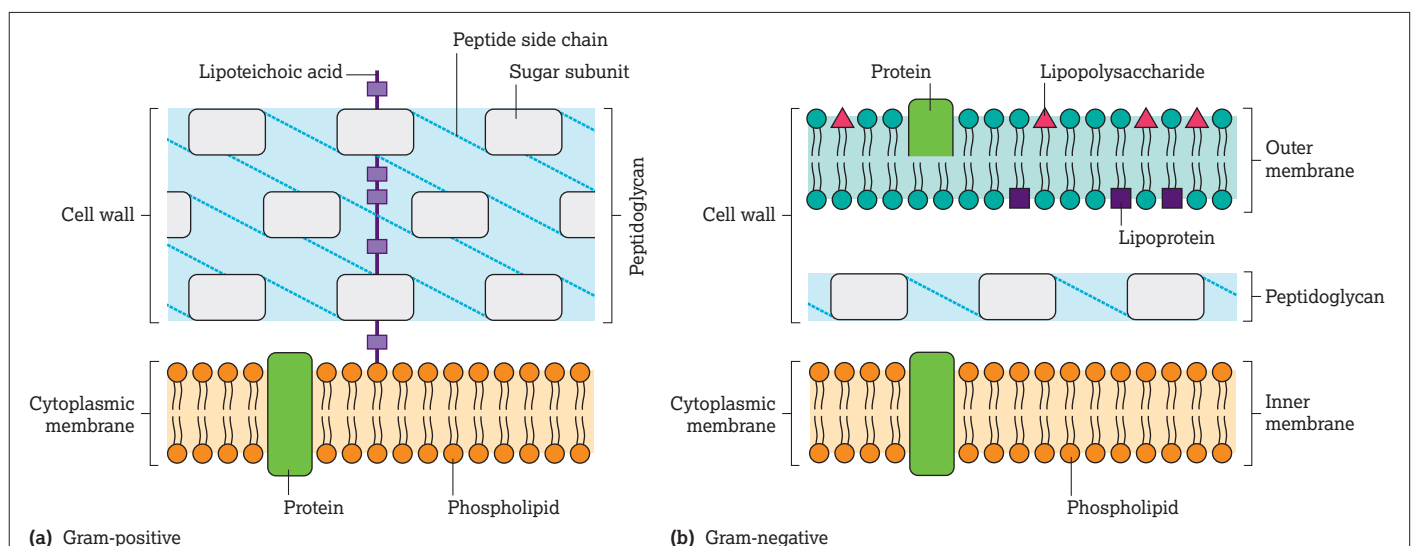

Figure 3.1 Gram-positive (a) and Gram-negative (b) bacterial cell walls. *Source:* Adapted from Elliot et al. (2007). Reproduced with permission from John Wiley & Sons.

Figure 3.2 Bacterial structures.

germinate into a normal, ‘vegetative’ bacterial cell that can then reproduce (Goering et al. 2012). Spores are extremely tough and durable. They are not destroyed by boiling (hence the need for high-temperature steam under pressure in sterilizing autoclaves) or by the alcohol handrubs widely used for hand hygiene – hence the need to physically remove them from the hands by washing with soap and water when caring for a patient with *Clostridium difficile* infection (DH/HPA 2008).

Some medically significant bacteria are listed in Table 3.2. A few bacteria do not easily fit into the Gram-positive/negative dichotomy. The most medically significant of these are the Mycobacteria, which are responsible for diseases including tuberculosis and leprosy (Goering et al. 2012).

Viruses

Viruses are much smaller, and even simpler, than bacteria. They are often little more than a protein capsule containing some genetic material. They do not have cells, and some people do not even consider them to be alive. They have genes and will evolve through natural selection, but have no metabolism of their own. The most significant characteristic of viruses is that they can only reproduce within a host cell, by using the cell’s own mechanisms

to reproduce the viral genetic material and to manufacture the other elements required to produce more virus particles. This often causes the death of the cell concerned (Goering et al. 2012).

The small size of viruses (poliovirus, for example, is only 30 nanometres (nm) across) means that most are smaller than the wavelengths of visible light. They can only be ‘seen’ with a specialist instrument such as an electron microscope, which will only be available in a very few hospital microbiology laboratories. Diagnosis of viral infections is normally by the patient’s symptoms, with confirmation by laboratory tests designed to detect either the virus itself or antibodies produced by the patient’s immune system as a response to infection (Goering et al. 2012).

There are viruses that specifically infect humans, or other animals, or plants, or even bacteria. This is one characteristic that can be used in classifying them. However, the main basis for classification is by the type of genetic material they contain. This can be DNA or RNA, and may be in a double strand, as seen in other organisms’ DNA, or in a single strand. Other characteristics include the shape of the viral particle and the sort of disease caused by infection (Gillespie and Bamford 2012).

The life cycle of all viruses is similar and can be summarized as follows (Goering et al. 2012).

- 1 **Attachment:** a virus particle attaches to the outside of a host cell. Viruses are generally very limited in the types of cell that they can attach to, and normally infect only a single species or a limited range of related host organisms. Even a wide-ranging virus such as rabies is restricted to infecting mammals.
- 2 **Penetration:** the virus particle enters the host cell. The exact mechanism of this depends on the virus and the type of host.
- 3 **Uncoating:** the virus particle breaks down and exposes the viral genetic material.
- 4 **Replication:** the instructions contained in the viral genes cause the host cell mechanisms to create more viral particles.
- 5 **Release:** the new viral particles are released from the cell. Some viruses may ‘bud’ from the surface of the cell, acquiring their enclosing membranes in the process, but often release occurs due to cell rupture and destruction.

This process is illustrated in Figure 3.3.

A final point to consider in relation to viral structure and infection prevention and control is the presence or absence of a lipid envelope enclosing the viral particle. Those viruses that have a lipid envelope, such as herpes zoster virus (responsible for chickenpox and shingles), are much more susceptible to destruction by alcohol than those without, for example norovirus, which is a common cause of viral gastroenteritis (WHO 2009a).

Fungi

Like bacteria, fungi exist in many environments on Earth, including occasionally as commensal organisms on human beings. Unlike bacteria, they are eukaryotic, so their cells share some characteristics with other eukaryotes such as humans, but they are distinct from both animals and plants. Fungi are familiar to us as mushrooms and toadstools and the yeast that is used in brewing and baking. They also have many uses in the pharmaceutical industry, particularly in the production of antibiotics. Fungi produce spores, both for survival in adverse conditions, as bacteria do, and to provide a mechanism for dispersal in the same way as plants (Goering et al. 2012).

A few varieties of fungi are able to cause opportunistic infections in humans. These are usually found in one of two forms: either as single-celled yeast-like forms that reproduce in a similar fashion to bacteria, by dividing or budding, or as plant-like filaments called *hyphae*. A mass of hyphae together forms a *mycelium*. Some fungi may appear in either form, depending on environmental conditions. Fungal infections are referred to as *mycoses*. Superficial mycoses such as ringworm and thrush usually involve only the skin or mucous membranes and are normally mild, if unpleasant,

Table 3.2 Medically significant bacteria

	Spherical	Rod-shaped
Gram positive	<i>Staphylococcus aureus</i> <i>Streptococcus</i> spp	<i>Clostridium difficile</i> <i>Clostridium tetani</i> <i>Bacillus</i> spp
Gram negative	<i>Neisseria meningitides</i> <i>Neisseria gonorrhoeae</i>	<i>Pseudomonas aeruginosa</i> <i>Escherichia coli</i> <i>Legionella pneumophila</i> <i>Acinetobacter baumannii</i> <i>Salmonella</i>

Figure 3.3 The viral life cycle. *Source:* Adapted from Perry (2007). Reproduced with permission from John Wiley & Sons.

but deeper mycoses involving major organs can be life-threatening. These most frequently occur in patients who have severely impaired immune systems and may be an indicator of such impairment; for example, pneumonia caused by *Pneumocystis jirovecii* (previously *carinii*) is considered a clinical indication of AIDS. Superficial infections are generally transmitted by physical contact, whereas deeper infections can result, for example, from spores being inhaled. This is why it is important to ensure that patients with impaired immunity are protected from situations where the spores of potentially pathogenic fungi are likely to be released, for example during building work (Goering et al. 2012).

Protozoa

Protozoa are single-celled animals, some species of which are medically important parasites of human beings, particularly in tropical and subtropical parts of the world where diseases such as malaria are a major public health issue. Unlike bacteria, their relationship with humans is almost always parasitic – that is, their presence has an adverse effect on the host. The life cycles of protozoa can be complex, and may involve stages in different hosts.

Medically important protozoa include *Plasmodium*, the cause of malaria, *Giardia* and *Cryptosporidium*, which can cause gastroenteritis, and *Trichomonas*, which is a sexually transmitted cause of vaginitis (Gillespie and Bamford 2012).

The most common routes of infection with protozoa are by consuming them in food or water or via an insect vector such as a mosquito (Goering et al. 2012). Cross-infection in the course of healthcare is uncommon but not unknown.

Helminths

'Helminths' is a generic term for parasitic worms. A number of worms from three different groups affect humans: tapeworms, roundworms (nematodes) and flukes. Transmission is generally

by ingestion of eggs or larvae, or of infected animals or fish, but some are transmitted via an insect vector and some, notably the nematode *Strongyloides*, have a larval stage that is capable of penetrating the skin (Gillespie and Bamford 2012).

Helminth infections can affect almost every part of the body, and the effects can be severe. For example, the *Ascaris* worm can cause bowel obstruction if there are large numbers present; *Brugia* and *Wuchereria* obstruct the lymphatic system and eventually cause elephantiasis as a result; and infection with *Toxocara* (often after contact with dog faeces) can result in epilepsy or blindness (Goering et al. 2012). However, cross-infection in healthcare is not normally considered a significant risk.

Arthropods

Arthropods (insects) are most significant in infectious disease in terms of their function as vectors of many viral, bacterial, protozoan and helminth-caused diseases. Some flies lay eggs in the skin of mammals, including humans, and the larvae feed and develop in the skin before pupating into the adult form, and some, such as lice and mites, are associated with humans for the whole of their life cycle. Such arthropod infestations can be uncomfortable, and there is often significant social stigma attached to them, possibly because the creatures are often visible to the naked eye. The activity of the insects and the presence of their saliva and faeces can result in quite severe skin conditions that are then vulnerable to secondary fungal or bacterial infection (Goering et al. 2012).

Lice

Species of *Pediculus* infest the hair and body of humans, feeding by sucking blood from their host. The adult animal is around 3 mm long and wingless, moving by means of claws. It cannot jump or fly, and dies within 24 hours if away from its host, so cross-infection is normally by direct contact or transfer of eggs or adults through sharing personal items (Wilson 2006).

Scabies

Scabies is caused by the mite *Sarcoptes scabiei*, an insect less than 1 mm long, which burrows into the top layers of skin. Infestation usually starts around the wrists and in between the fingers because acquisition is normally by close contact with an infected individual. The female mites lay eggs in these burrows and the offspring can spread to other areas of skin elsewhere on the body. The burrows are visible as a characteristic rash in the areas affected. In immunocompromised hosts or in those unable to practise normal levels of personal hygiene, very high levels of infestation can occur, often with thickening of the skin and the formation of thick crusts. This is known as 'Norwegian scabies' and is associated with a much higher risk of cross-infection than the normal presentation. Scabies is most often associated with long-stay care settings, but there have been reported outbreaks associated with more acute healthcare facilities (Wilson 2006).

Prions

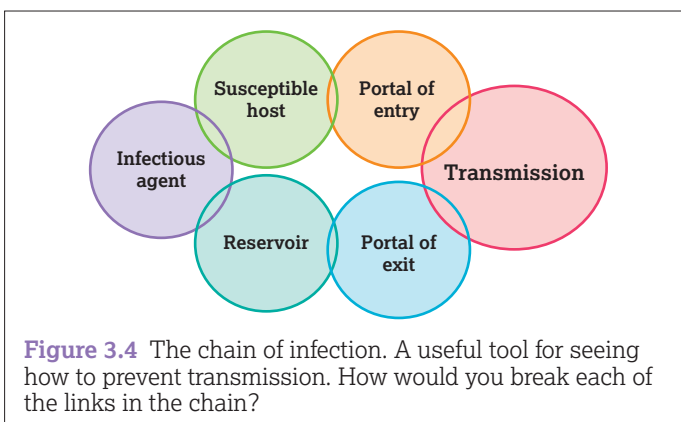

Prions are thought to be the causative agents of a group of diseases called transmissible spongiform encephalopathies (TSEs), the most well known of which are Creutzfeldt-Jakob disease (CJD) and its variant (vCJD). vCJD has been associated with the bovine spongiform encephalopathy (BSE) outbreak in Great Britain in the late 1980s and early 1990s. TSEs cause serious, irreversible damage to the central nervous system and are fatal. They are characterized by 'plaques' in the brain that are surrounded by holes that give the appearance of a sponge, hence the name. It used to be thought that this group of diseases was caused by so-called 'slow' viruses but they are now widely thought to be caused by prions, although this theory is not universally accepted. The theory is described below (Weaving 2007).

The prion protein (PrP) is a normally occurring protein found on the surface of some cells (PrPC). The disease-causing form of the protein (PrP^{CJD}) appears to have an identical amino acid

sequence but has a different three-dimensional shape. When the normal protein PrPC is exposed to the disease-causing form PrPC^{JD}, it changes its conformation to that of PrPC^{JD}. PrPC^{JD} appears to progressively accumulate and be deposited in the brain, resulting in the characteristic 'plaques'. This process is slow compared to the replication of most micro-organisms and 'classic' CJD normally appears in older people.

One of the characteristics of vCJD is that it affects a much younger age group, although the incubation period still appears to be a number of years. There are currently no reliable tests to identify infection before the onset of symptoms, which has led to the worry that there could be a large pool of asymptomatic carriers of the vCJD infectious agent who may act as a reservoir for onward transmission via healthcare procedures. Routes of transmission already confirmed for CJD and vCJD include dura mater and corneal grafts, treatment with human-derived growth hormone, blood transfusion and surgical instruments. The infectious agent does not appear to be affected by decontamination processes such as autoclaving and chemical disinfection to the same extent as more familiar micro-organisms such as bacteria or viruses. This has led to extensive reviews of decontamination procedures in the UK and has resulted in an increased emphasis on effective washing to remove any residual organic material that may harbour the infectious agent, and on the tracking of instruments to individual patients to facilitate any look-back exercise should any patient be identified as suffering from CJD or vCJD at a later date (Weaving 2007).

Creutzfeldt-Jakob disease is a sporadic illness that affects around one person in every million and probably arises from a spontaneous genetic mutation. It should also be noted that only a very small number of people have developed vCJD. It appears that a combination of exposure to the infectious agent and genetic susceptibility is necessary for progression to the disease (related TSEs have a very strong genetic component), and there are numerous measures in place to prevent both the infectious agent entering the food chain and onward transmission through healthcare interventions. These appear to be the only routes of infection – there is no evidence of transmission via any other route. However, there is much that is unclear about the disease and the causative agent.

Mechanisms of infection

Whether or not a particular infectious agent will cause an infection in any given circumstance is dependent on many different factors, including how easily that agent can be transmitted, its *pathogenicity* (which is its ability to cause disease) and its *virulence* (which determines the severity of the infection produced) (Gillespie and Bamford 2012). It is generally accepted that for infection to occur, certain linked requirements need to be met; these links are often referred to as the *chain of infection* (Damani 2011). While the chain of infection will not be strictly accurate in every case – some 'links' may be missing or will overlap – it is an extremely useful model to use when considering how infection can be prevented, by breaking the 'links' in this chain. Some links are easier to break than others – for example, it is often easier to prevent an infectious agent entering a susceptible person than it is to prevent it leaving an infected one.

The chain of infection is illustrated in Figure 3.4 and the links are listed, with examples of how infection can be prevented at each link, in Table 3.3.

Table 3.3 Links in the chain of infection

Link	Definition	Example	Examples of breaking the chain
Infectious agent	A potentially pathogenic micro-organism or other agent	Any potential pathogen	Removal of infectious agents through cleaning; destruction of micro-organisms through sterilization of equipment; treatment of patient with bacterial infection with antibiotics
Reservoir	Any location where micro-organisms or other agents may exist or reproduce	Human beings; the healthcare environment; stagnant water	Cleaning equipment and the environment; removing stagnant water by flushing low-use taps and showers and changing flower water regularly; minimizing the number of people present in high-risk situations such as surgery
Portal of exit	The route by which the infectious agent leaves the reservoir	Diarrhoea or vomit may carry norovirus; droplets expelled during coughing or sneezing may contain respiratory pathogens	Asking a patient with active tuberculosis infection to wear a mask in communal areas of the hospital
Mode of transmission	See 'Modes of transmission'		
Portal of entry	The route by which the infectious agent enters a new host	Organisms introduced into a normally sterile part of the body through use of an invasive device, for example urinary catheter; inhalation of airborne pathogens	Avoiding unnecessary invasive devices; using strict aseptic technique; staff members wearing masks when dealing with infectious agents that may be inhaled
Susceptible host	The person that the infectious agent enters has to be susceptible to infection	The very old and very young are more susceptible, as are people with underlying chronic illnesses	Ensuring adequate nutrition and personal hygiene; providing vaccination to healthcare workers

Modes of transmission

The mode of transmission is the method by which an infectious agent passes from one person or place to another. Considering the mode of transmission allows the practitioner to implement the measures required to prevent it.

Direct contact

This is person-to-person spread of infectious agents through physical contact between people. It occurs through normal nursing activities and can happen during aseptic procedures if technique is poor. It can be prevented through good hand hygiene, the use of barriers such as aprons and gloves and non-touch technique for aseptic procedures (Loveday et al. 2014).

Indirect contact

This occurs when someone comes into contact with a contaminated object. Many items in the healthcare environment can become contaminated, but the most likely routes of spread are inadequately decontaminated items of equipment used for diagnosis or treatment. Transmission is prevented by effective cleaning, decontamination and good hand hygiene (DH/HPA 2008).

Droplet transmission

When people cough, sneeze or even talk, they expel droplets of respiratory secretions and saliva. These droplets will travel about a metre from the person expelling them, and may contain the agents responsible for respiratory infections such as influenza or tuberculosis. Transmission is prevented through isolating the affected patient and using masks, aprons and gloves to provide a barrier. Transmission of these infectious agents may also be reduced through good hand hygiene as transmission by indirect contact via contaminated surfaces is also possible (Crabtree and Henry 2011).

Airborne transmission

Airborne transmission also involves droplets or particles containing infectious agents, but on a small enough scale that the particles can remain suspended in the air for long periods of time. Infections spread via this route include measles and chickenpox. Prevention is as for droplet transmission.

Parenteral transmission

This is a form of contact transmission, where blood or body fluids containing infectious agents come into contact with mucous membranes or exposed tissue. In healthcare, this can occur through transplantation or infusion (which is why blood and organs for transplantation are screened for bloodborne viruses such as HIV) or through an inoculation injury where blood splashes into the eyes or a used item of sharp equipment penetrates the skin. This last type of incident is often referred to as a 'needlestick' injury. Transmission is prevented by good practice in handling and disposing of sharps and the appropriate use of protective equipment, including eye protection (UK Health Departments 1998). A European Union directive recently incorporated into UK legislation requires the use of 'safe' or needle-free devices wherever possible in order to reduce the risk of inoculation injury (Health and Safety Executive 2013).

Faecal–oral transmission

This occurs when an infectious agent present in the faeces of an infected person is subsequently ingested by someone else and enters their gastrointestinal tract. It is the route of much gastrointestinal illness and water- and foodborne disease. There are often several steps involved. As an example, someone with infectious diarrhoea whose hand hygiene is poor is likely to contaminate any food they prepare; this exposes anyone who eats that food to infection. Transmission is prevented through isolating any patient with symptoms of gastroenteritis; effective hand hygiene by both staff and patients with soap and water (as many of these organisms are less susceptible to alcohol); appropriate use of gloves and aprons; and good food hygiene (DH/HPA 2008).

Vector transmission

Many diseases are spread through the action of a vector, most often an insect that travels from one person to another to feed. This route is not currently a concern in healthcare in England, but in some areas of the world, for example where malaria is endemic, protecting patients from vectors such as mosquitoes is an important element of nursing care.

These definitions are useful for considering the different routes by which infectious agents can spread but there is also overlap between the different categories: droplet and airborne spread, for example, or indirect contact and faecal–oral. Many agents will be spread by more than one route or there may be a combination of routes involved. In norovirus infection, for example, the overall mode of spread is faecal–oral but if someone is infected with norovirus, they may vomit and create an aerosol of droplets that contain the virus. Those droplets may be ingested directly from the atmosphere or they may settle on food, surfaces or equipment in the immediate vicinity. Anyone touching those surfaces will pick up the virus on their hands (indirect contact) and transmit it to their mouth either directly or via food.

Sources of infection

An individual may become infected with organisms already present on their body (endogenous infection) or introduced from elsewhere (exogenous infection). The majority of healthcare-associated infections (HCAIs) are endogenous, hence the importance of procedures such as effective skin decontamination prior to invasive procedures (Loveday et al. 2014).

Indicators and effects of infection

Generally, infection is said to have occurred when infectious agents enter a normally sterile area of the body and cause symptoms as a result. There are obvious exceptions to this (for example, the digestive tract is not sterile, being home to trillions of micro-organisms, but many types of infectious gastroenteritis are caused by particular organisms entering this area) but it is a useful working definition. The symptoms of infection are listed below. Not all symptoms will be present in all cases, and it should be noted that many symptoms are due to the body's response to infection and so may not be present in severely immunocompromised patients (Fishman 2011).

Symptoms of infection

- **Heat:** the site of the infection may feel warm to the touch, and the patient may have a raised temperature.
- **Pain:** at the site of the infection.
- **Swelling:** at the site of the infection.
- **Redness:** at the site of the infection.
- Pus.
- Feeling of general malaise.
- In *gastrointestinal infection*: abdominal pain and tenderness; nausea; diarrhoea and/or vomiting (Goering et al. 2012).
- In *urinary tract infection*: frequency of micturition; often confusion in the elderly; loin pain and/or abdominal discomfort (Goering et al. 2012).

Evidence-based approaches

Rationale

The principle of all infection prevention and control is preventing the transmission of infectious agents. However, the measures taken to reduce the risk of transmission must be reasonable, practicable and proportionate to the risk of transmission and the effects of infection with any particular agent. For example, while *Staphylococcus aureus* can cause severe infections, it is carried by around a third of the population and so isolating every patient carrying it would not be practicable. MRSA can cause equally serious infections, is resistant to many of the antibiotics that would normally be

used to treat these infections and is carried by far fewer people, so it is both reasonable and practicable to take additional precautions to prevent its spread in healthcare. These may include isolation in an acute hospital but it would not be reasonable to segregate a colonized individual in a mental health unit where social interaction may form part of their care and the risk to other individuals is less.

The management of any individual who is infected or colonized with an organism that may pose a risk to other individuals must be based on a risk assessment that takes into account the following factors:

- how easily the infectious agent can be passed to other people
- the susceptibility to infection of other people being cared for in the same area and the likely consequences of their becoming infected
- the practicality of implementing particular infection prevention and control precautions within that area or institution (the number of single rooms available, for example)
- the individual's other nursing needs (Wilson 2006).

The infection prevention and control policies of health and social care providers are based on generic risk assessments of their usual client or patient group and should be adhered to unless there are strong reasons to alter procedures for a particular individual's care. In such circumstances, the advice of the infection prevention and control team (IPCT) should be sought first. Nurses working in organizations without an IPCT should identify the most appropriate source from which to seek advice, preferably before it is needed.

Indications

Infection prevention and control precautions must be taken with all patients, regardless of whether or not they are known to be carrying any particular infectious agent that may cause a hazard to others. This is because it is impossible to guarantee whether or not any given individual is free of any particular infectious agent and because many common micro-organisms may cause infections in some circumstances. Additional infection control precautions are indicated when:

- an individual is particularly vulnerable to infection because of some deficiency in their normal defence mechanisms; or
- they are known to be infected or colonized with an infectious agent that may pose a particular risk to others.

Contraindications

As mentioned previously, precautions to prevent the spread of infection must be based on a risk assessment that takes in all the relevant factors. In some cases precautions will need to be modified because of a patient's physical or psychological needs. Isolation, for example, has been demonstrated to have an adverse psychological effect on some individuals (Morgan et al. 2009).

Anticipated patient outcomes

The anticipated outcome is that no patient will acquire micro-organisms from any other individual during the course of healthcare or suffer an avoidable infection.

Legal and professional issues

In England, the Health and Safety at Work etc. Act 1974 is the primary piece of legislation relating to the safety of people in the workplace. It applies to all employees and employers, and requires them to do everything that is reasonable and practicable to prevent harm coming to anyone in the workplace. It requires employers to provide training and appropriate protective equipment and employees to follow the training that they have received, use the protective equipment provided, and report any situations where they believe inadequate precautions are putting anyone's health and safety at serious risk. This dovetails with the requirements of the Nursing and Midwifery Council (NMC 2015) for nurses to promote and protect the well-being of those in their care and to

report their concerns in writing if problems in the environment of care are putting people at risk.

The requirement to protect individuals from healthcare-associated infections is further emphasized in England by the Health and Social Care Act 2008. This legislation is monitored and enforced by the Care Quality Commission, which assesses care providers against the requirements of the Code of Practice on the prevention and control of infections and related guidance (DH 2010a). Often referred to as the Hygiene Code, this has been applied to NHS hospitals in England, in one form or another, for some years and now applies to all providers of health or adult social care. Each provider must be registered with the Care Quality Commission and declare compliance with the ten criteria of the Hygiene Code. These criteria are summarized in Table 3.4. They also provide a useful guide for healthcare providers in other countries as to the elements an organization should have in place to facilitate effective infection prevention processes. For example, they could be used as the basis for a checklist for healthcare practitioners and organizations to assess the processes, policies and procedures that they have in place or may wish to have to help minimize the risk of infection to patients.

In England, nurses need to be aware of the measures that are in place in their workplace to ensure compliance with the Code of Practice. For example, many hospital trusts have a programme of regular visits to clinical areas by senior staff who will carry out an inspection against the criteria of the Code as if they were an external assessor. This programme ensures that senior staff are familiar with the Code and that everyone is familiar with the inspection process. In addition, nurses may need to carry out activities to promote compliance and provide evidence of assurance, such as audits of hand hygiene performance or compliance with aseptic technique. One such set of audits in place in many hospitals in England is the package produced by the Department of Health (2007a) and known collectively as *Saving Lives*. These are discussed in more detail later.

In addition to healthcare-specific requirements, items of legislation and regulation have also been devised with the objective of reducing the risk of infection in any situation that apply to healthcare as much as they do to any other business or workplace. These include legislation and regulation relating to food hygiene (Food Safety Act 1990), water quality (Health and Safety Commission 2001), waste management (Hazardous Waste Regulations 2005) and other issues that are peripheral to healthcare but must be taken into account when developing policies and procedures for an NHS trust or other healthcare provider.

Competencies

The NMC Code (NMC 2015) states that all nurses must work within the limits of their competence. This means, for example, not carrying out aseptic procedures without being competent and confident that they can be carried out without increasing the risk of introducing infection through lack of knowledge or technique. However, there are some procedures for infection prevention and control that must be carried out as part of every care activity, and so all nurses must be competent in these if they are to provide any level of physical care at all. These are the *standard precautions* for infection prevention and control (Wilson 2006) and include:

- hand hygiene
- use of personal protective equipment such as gloves and aprons
- appropriate segregation and disposal of waste, in particular used sharps items and other equipment designated as single use
- appropriate decontamination of reusable equipment after use.

Pre-procedural considerations

Equipment

All infection prevention and control measures have the objective of preventing the transmission of infectious agents, whether by removing such agents from items that may be contaminated (hand hygiene and cleaning) or establishing a barrier (personal

Table 3.4 Criteria of the 2010 Hygiene Code of Practice

Compliance criterion	What the registered provider will need to demonstrate
1	Systems to manage and monitor the prevention and control of infection. These systems use risk assessments and consider how susceptible service users are and any risks that their environment and other users may pose to them
2	Provide and maintain a clean and appropriate environment in managed premises that facilitates the prevention and control of infections
3	Provide suitable accurate information on infections to service users and their visitors
4	Provide suitable accurate information on infections to any person concerned with providing further support or nursing/medical care in a timely fashion
5	Ensure that people who have or develop an infection are identified promptly and receive the appropriate treatment and care to reduce the risk of passing on the infection to other people
6	Ensure that all staff and those employed to provide care in all settings are fully involved in the process of preventing and controlling infection
7	Provide or secure adequate isolation facilities
8	Secure adequate access to laboratory support as appropriate
9	Have and adhere to policies designed for the individual's care and provider organizations that will help to prevent and control infections
10	Ensure, so far as is reasonably practicable, that care workers are free of and are protected from exposure to infections that can be caught at work and that all staff are suitably educated in the prevention and control of infection associated with the provision of health and social care

protective equipment and isolation). There are therefore some items that should be available for effective infection prevention and control in any situation where healthcare is provided. It is worth noting that it is a legal requirement in the UK for employers to provide suitable personal protective equipment when risks cannot be controlled in other ways, and for employees to use the equipment provided (Health and Safety Executive 2005).

Equipment for hand hygiene

It is essential that wherever care is provided, there are facilities for hand hygiene (WHO 2009a). Hand wash basins in clinical areas should have taps that can be turned on and off without using the hands; that is, they should be non-touch or lever operated (DH 2006). Basins used solely by clinical staff for hand hygiene should not have plugs (to encourage hand washing under running water) or overflows (because they are difficult to clean effectively and can be a reservoir for organisms such as *Pseudomonas* that may cause infection in vulnerable individuals) (DH 2013a). Basins that are also used by patients may require plugs, which will require careful management with some client groups to reduce the risk of flooding. In all cases, the taps should be positioned so that water does not fall directly into the outflow as this may lead to splashes containing organisms from within the drain. Taps should be of a mixer type that allows the temperature to be set before hand washing starts. Access to basins must be unobstructed by any furniture or equipment to ensure that they can easily be used whenever required (WHO 2009a).

Liquid soap dispensers should be positioned close to hand wash basins and care should be taken to ensure that soap cannot drip onto the floor from the dispenser and cause a slip hazard. Soap should be simple and unscented to minimize the risk of adverse reactions from frequent use. There is no advantage to using soap or detergents combined with or containing antimicrobial agents for routine hand washing. These preparations carry a higher risk of adverse reactions and should not be used routinely. Bar soap should not be used. For surgical scrub, the most commonly used preparations contain either chlorhexidine or povidone-iodine; both reduce bacterial counts significantly but chlorhexidine has a residual effect that prevents rapid regrowth. A paper towel dispenser should be fixed to the wall close to the hand wash basin.

Hand towels should be of adequate quality to ensure that hands are completely dried by the proper use of one or two towels. To conveniently dispose of these towels, a suitable bin with a pedal-operated lid should be positioned close to the basin, but not so that it obstructs access to the basin (WHO 2009a).

Alcohol-based handrub should be available at the point of care in every clinical area for use immediately before care and between different care activities on the same patient (NPSA 2008). Dispensers may be attached to the patient's bed or bedside locker, and free-standing pump-top bottles can be used where appropriate, such as on the desk in a room used for outpatient clinics. Dispensers should not be sited close to sinks unless this is unavoidable because of the risk of confusion with soap, particularly if the dispensers are similar. Smaller sized personal issue bottles are appropriate where there is a risk that handrub may be accidentally or deliberately drunk, such as in paediatric areas or when caring for a patient with alcohol dependency (NPSA 2008). *Note:* Antiseptic handrubs based on non-alcoholic antiseptics are available but evidence suggests that alcohol is the most useful agent in terms of range and speed of antimicrobial activity (WHO 2009a).

Equipment for waste disposal

Also available should be disposal bags for domestic and clinical waste and a sharps bin if the procedure is to involve the use of any sharp single-use items (DH 2013b). The sharps bin should always be taken to the point of use (Loveday et al. 2014); do not transport used sharps in any other way or in any other container (UK Health Departments 1998). Bags and containers used for hazardous waste should be coloured according to their final disposal method (DH 2013b).

Personal protective equipment (PPE)

Other equipment required for infection prevention and control will depend on the activity being carried out, but basic PPE to provide a barrier to body fluids and micro-organisms – non-latex disposable gloves, disposable aprons and eye protection as a minimum – should be readily available in the clinical area (Loveday et al. 2014), and particularly where regular use is anticipated. For example, it is appropriate to have dispensers for gloves and aprons situated outside isolation rooms. All PPE sold in the UK

must comply with the relevant regulations and standards, including being 'CE' marked to demonstrate that they meet these standards (Department of Trade and Industry 2002).

60 Disposable gloves

Gloves will be necessary in some circumstances but should be worn only when required (WHO 2009b). Non-sterile disposable gloves are most usefully available packaged in boxes of 100 ambidextrous gloves, in small, medium and large sizes. These boxes should be located close to the point of use, ideally in a fixed dispenser to make removing the gloves from the box as easy as possible. In the past, natural rubber latex was commonly used for these gloves but concerns about latex sensitivity mean that many healthcare organizations have adopted gloves made of alternative materials such as vinyl (RCN 2012). There is some evidence that vinyl may be a less effective barrier than latex (Kerr et al. 2004), but all gloves carry a risk of failure, often not visible to the naked eye (Kerr et al. 2004, Korniewicz et al. 2002), hence the need for hand hygiene regardless of whether or not gloves are worn. Whatever the material, these gloves are single use – they should be used for the task for which they are required and then removed and disposed of. They cannot be cleaned and reused for another task (MHRA 2006, Loveday et al. 2014).

Disposable aprons

Single-use disposable aprons may be obtained either in a box or linked together on a roll. Presentation is not important as long as it is compatible with the dispensers in use and the product meets the requisite standards (i.e. is 'CE' marked). Aprons are normally made of thin polythene and are available in a range of colours. Different coloured aprons can be used to designate staff doing different tasks or working in different areas to give a visible reminder of the risk of cross-infection. As with disposable gloves, disposable aprons should be used for the task for which they are required and then removed and disposed of (MHRA 2006, Loveday et al. 2014).

Sterile gloves

Single-use sterile gloves, both latex and latex free, should be available in any area where their use is anticipated. Sterile gloves are packed as a left-and-right pair and are manufactured in a wide range of full and half sizes (similar to shoe sizes) so as to fit closely and provide the best possible compromise between acting as a barrier and allowing the wearer to work normally. Natural rubber latex is still one of the best materials for this, so sterile gloves are more often made of this than of alternative materials. Care must be taken to ensure alternatives are available for patients and staff with sensitivity to latex (RCN 2012).

Sterile gowns

To provide 'maximal barrier precautions' during surgery or other invasive procedures carrying a high risk of infection, or where infection would have serious consequences to the patient such as insertion of a central venous catheter, a sterile gown will be required in addition to sterile gloves. Modern sterile gowns are most often single-use disposable products made of water-repellent material as multiple-use fabric gowns may, over time, lose their effectiveness as a barrier (Leonas 1998).

Eye protection

Eye protection will be required in any situation where the mucous membranes of the eyes may be exposed to body fluid droplets created during aerosol-generating procedures or surgery with power tools. Both single-use and multiple-use options are available. Goggles are normally sufficient as long as they are worn in conjunction with a fluid-repellent mask. If greater protection is required, or a mask is not worn for any reason, a face shield should be used. Face shields may also be more appropriate for people who wear glasses. Prescription glasses will often not provide sufficient protection and should not be relied upon (UK Health Departments 1998).

Masks and respirators

If dealing with organisms spread by the airborne or droplet route, a facemask or respirator will be required. When using a respirator (usually used to prevent the transmission of respiratory viruses), a good fit is essential to ensure that there is no leakage around the sides. Staff who are likely to need to use respirators should be 'fit tested' using a taste test to ensure that they have the correct size. A taste test consists of wearing the respirator while being exposed to a strong-tasting vapour (normally inside a hood to contain the vapour); if the subject can taste the vapour then the respirator is not properly fitted. Fit testing is normally carried out by the infection prevention and control team or occupational health department. Note that facial hair under the edge of the respirator will prevent a proper seal; staff with beards that prevent a proper seal will not be able to work safely if a respirator is required (Stobbe et al. 1988).

Single-use masks and respirators are normally the best option (and should be strictly single use). Multiple-use respirators are sometimes required for people whose face shape does not allow a good seal with disposable products (DH 2010b).

Assessment and recording tools

Assessment for infection prevention and control should take place at every level in an organization providing healthcare, from completing an assessment of infection risks (both to and from the patient) as part of the care planning process to the audit of compliance in a team, unit or hospital (DH 2010a). As mentioned previously, the Care Quality Commission assesses care providers in England against the requirements of the Hygiene Code. Other external assessors may also require evidence that procedures are in place to reduce the risk of healthcare-associated infection. Such evidence may include audits of compliance with hand hygiene against the WHO '5 moments' when hand hygiene should be performed at the point of care (WHO 2009a) or audits to demonstrate that all the elements of a procedure that carries a particular risk of infection have been carried out. Such procedures are sometimes referred to as 'high-impact interventions' because the risk of infection is such that improving adherence to good practice when they are carried out can have a significant impact on an organization's infection rates. The English Department of Health's *Saving Lives* toolkit (DH 2007a) is a collection of guidelines for high-impact interventions in the form of care bundles, and audits of those care bundles that can be used both for practice improvement and as evidence of good practice for internal and external assessment. All nurses should know which of these tools are being used in their workplace and actively participate in their completion.

At the level of individual patients, all additional precautions for infection prevention should be documented within the patient's individual plan of care. This should include regular reassessment and changes as necessary as the patient's condition alters. For example, a patient given antibiotics for a chest infection will be at increased risk of developing *Clostridium difficile* infection; if they develop diarrhoea, they must be isolated immediately. If the diarrhoea settles following treatment, they will no longer require isolation once they have been free of symptoms for 48 hours (DH/HPA 2008). When a procedure is carried out that requires additional precautions, for example aseptic technique, it should be documented in the record of that procedure that those precautions were adhered to or, if not, the reasons why they could not be implemented.

Specific patient preparation

Education

All patients should be informed about the risks of healthcare-associated infection and the measures that are known to reduce the risk of infection. In particular, patient education programmes that encourage the patient to ask healthcare workers 'Did you wash your hands?' have been demonstrated to increase compliance with hand hygiene (McGuckin et al. 2011). In addition, patients who are infected or colonized with infectious agents that

require additional precautions to be implemented to reduce the risk of infection to other patients must be clearly told the nature of the infectious agent and its mode of spread, the risk to others, the details of the precautions required and the rationale behind them. Patients are likely to suffer anxiety if they are infected or colonized

by such agents and this may be alleviated if they are provided with clear information. Similarly, there are adverse psychological effects of isolation and other precautions (Gammon 1998) and these are more likely to be mitigated if the patient has a clear understanding of why they are being implemented (Ward 2000).

Procedure guideline 3.1 Hand washing

Essential equipment

- Hand wash basin
- Liquid soap
- Paper towels
- Domestic waste bin

Pre-procedure

Action

- 1 Remove any rings, bracelets and wristwatch still worn and roll up sleeves. (*Note:* It is good practice to remove all hand and wrist jewellery and roll up sleeves before entering any clinical area and the English Department of Health has instructed NHS trusts to implement a 'bare below the elbows' dress code.)
- 2 Cover cuts and abrasions on hands with waterproof dressing.
- 3 Remove nail varnish and artificial nails (most uniform policies and dress codes prohibit these). Nails must also be short and clean.

Rationale

Jewellery inhibits good hand washing. Dirt and bacteria can remain beneath jewellery after hand washing. Long sleeves prevent washing of wrists and will easily become contaminated and so a route of transmission of micro-organisms (DH 2010c, **C**; WHO 2009a, **C**). Note that many organizations' dress codes allow staff to wear wedding rings while providing care. Although it can be argued that a smooth ring is less likely to retain dirt and bacteria than one with a stone or engraving, there is no evidence to suggest that wedding rings inhibit hand decontamination any less than other rings. **E**

Cuts and abrasions can become contaminated with bacteria and cannot be easily cleaned. Repeated hand washing can worsen an injury (WHO 2009a, **C**). Breaks in the skin will allow the entry of potential pathogens. **E**

Long and false nails and imperfections in nail polish harbour dirt and bacteria that are not effectively removed by hand washing (WHO 2009a, **C**).

Procedure

- 4 Turn on the taps and where possible direct the water flow away from the plughole. Run the water at a flow rate that prevents splashing.
- 5 Run the water until hand hot.
- 6 Wet the surface of hands and wrists.
- 7 Apply liquid soap and water to all surfaces of the hands.
- 8 Rub hands together for a minimum of 10–15 seconds, paying particular attention to between the fingers and the tips of fingers and thumbs (**Action figure 8a**). The areas that are most frequently missed through poor hand hygiene technique are shown in **Action figure 8b**.
- 9 Rinse soap thoroughly off hands.
- 10 Turn off the taps using your wrist or elbow. If the taps are not lever-type, turn them off using a paper hand towel to prevent contact.

Plugholes are often contaminated with micro-organisms that could be transferred to the environment or the user if splashing occurs (NHS Estates 2001, **C**).

Warm water is more pleasant to wash with than cold so hand washing is more likely to be carried out effectively. **E**

Water that is too hot could cause scalding. Soap is more effective in breaking down dirt and organic matter when used with hand-hot water (DH 2001, **C**).

Soap applied directly onto dry hands may damage the skin. **E**

The water will also quickly mix with the soap to speed up hand washing. **E**

Liquid soap is very effective in removing dirt, organic material and any loosely adherent transient flora. Tablets of soap can become contaminated, potentially transferring micro-organisms from one user to another, but may be used if liquid soap is unavailable (DH 2001, **C**). To ensure all surfaces of the hands are cleaned. **E**

To ensure all surfaces of the hands are cleaned. Areas that are missed can be a source of cross-infection (Fraise and Bradley 2009, **E**).

Soap residue can lead to irritation and damage to the skin. Damaged skin does not provide a barrier to infection for the healthcare worker and can become colonized with potentially pathogenic bacteria, leading to cross-infection (DH 2001, **C**).

To avoid recontaminating the hands. **E**

(continued)

Procedure guideline 3.1 Hand washing (continued)

Post-procedure	
Action	Rationale
11 Dry hands thoroughly with a disposable paper towel from a towel dispenser.	Damp hands encourage the multiplication of bacteria and can potentially become sore (DH 2001, C).
12 Dispose of used paper towels in a black bag in a foot-operated waste bin.	Paper towels used to dry the hands are normally non-hazardous and can be disposed of via the domestic waste stream (DH 2013b, C). Using a foot-operated waste bin prevents contamination of the hands. E

Action Figure 8a 1. Rub hands palm to palm. 2. Rub back of each hand with palm of other hand with fingers interlaced. 3. Rub palm to palm with fingers interlaced. Rub with back of fingers to opposing palms with fingers interlocked. Rub tips of fingers. Rub tips of fingers in opposite palm in a circular motion. 4. Rub each thumb clasped in opposite hand using a rotational movement. 5. Rub each wrist with opposite hand. 6. Rinse hands with water.

Action Figure 8b Areas most commonly missed following hand washing. *Source:* Nursing Times (1978). Reproduced with permission from EMAP Publishing Ltd.

Procedure guideline 3.2 Hand decontamination using alcohol handrub

Essential equipment

- Alcohol-based handrub

Procedure

Action

- 1 Dispense the amount of handrub indicated in the manufacturer's instructions into the palm of one hand.
- 2 Rub the alcohol handrub into all areas of the hands, until the hands are dry, using the illustrated actions in **Action figure 2**.

Rationale

Too much handrub will take longer to dry and may consequently cause delays; too little will not decontaminate hands adequately. **E**

To ensure all areas of the hands are decontaminated. Alcohol is a rapid-acting disinfectant, with the added advantage that it evaporates, leaving the hands dry. This prevents contamination of equipment, whilst facilitating the application of gloves (WHO 2009a, **C**).

Procedure guideline 3.3 Putting on and removing non-sterile gloves

Essential equipment

- Non-sterile gloves

Pre-procedure

Action

- 1 Clean hands before putting on gloves.

Rationale

Hands must be cleansed before and after every patient contact or contact with patient's equipment (Loveday et al. 2014, **C**).

Procedure

- 2 Remove gloves from the box singly (**Action figure 2**), to prevent contamination of the gloves lower down. If it is likely that more than two gloves will be required (i.e. if the procedure requires gloves to be changed part-way through), consider removing all the gloves needed before starting the procedure.
- 3 Holding the cuff of the glove, pull it into position, taking care not to contaminate the glove from the wearer's skin (**Action figure 3**). This is particularly important when the second glove is being put on, as the gloved hand of the first glove can touch the skin of the ungloved second hand if care is not taken.
- 4 During the procedure or when undertaking two procedures with the same patient, it may be necessary to change gloves. Gloves are single-use items and must not be cleansed and reused.
- 5 If gloves become damaged during use, they must be replaced.
- 6 Remove the gloves when the procedure is completed, taking care not to contaminate the hands or the environment from the outside of the gloves.
- 7 Remove the first glove by firmly holding the outside of the glove wrist and pulling off the glove in such a way as to turn it inside out (**Action figure 7**).
- 8 Remove the second glove by slipping the fingers of the ungloved hand inside the wrist of the glove and pulling it off whilst at the same time turning it inside out (**Action figure 8**).

To prevent cross-contamination. **E**

To prevent cross-contamination (WHO 2009b, **C**).

Disposable gloves are single-use items. They cannot be cleaned and reused for the same or another patient (MHRA 2006, **C**).

Damaged gloves are not an effective barrier (WHO 2009b, **C**).

The outside of the glove may be contaminated. **E**

Whilst removing the first glove, the second gloved hand continues to be protected. By turning the glove inside out during removal, any contamination is contained inside the glove. **E**

By putting the fingers inside the glove, they will not be in contact with the potentially contaminated outer surface of the glove. **E**

Post-procedure

- 9 Dispose of used gloves as 'hazardous infectious waste' (**Action figure 9**), that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team.

All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, **C**).

- 10 After removing the gloves, decontaminate your hands.

Hands may have become contaminated (Loveday et al. 2014, **C**; WHO 2009b, **C**).

Action Figure 2 Remove gloves from the box.

Action Figure 3 Holding the cuff of the glove, pull it into position.

Action Figure 7 Remove the first glove by firmly holding the outside of the glove wrist, then pull off the glove in such a way as to turn it inside out.

Action Figure 8 Remove the second glove by slipping the thumb of the ungloved hand inside the wrist of the glove and pulling it off while turning it inside out.

Action Figure 9 Dispose of used gloves into an orange waste bag.

Procedure guideline 3.4 Putting on and removing a disposable apron

<i>Essential equipment</i> <ul style="list-style-type: none">• Disposable apron	
<i>Pre-procedure</i>	
Action	Rationale
1 Remove an apron from the dispenser or roll using clean hands and open it out.	To make it easy to put on. E
<i>Procedure</i>	
2 Place the neck loop over your head and tie the ties together behind your back, positioning the apron so that as much of the front of your body is protected as possible (Action figures 2a, 2b).	To minimize the risk of contamination being transferred between your clothing and the patient, in either direction. E
3 If gloves are required, don them as described in Procedure guideline 3.3: Putting on and removing non-sterile gloves. At the end of the procedure, remove gloves first.	The gloves are more likely to be contaminated than the apron and therefore should be removed first to prevent cross-contamination (DH 2010b, C).
4 Remove the apron by breaking the ties and neck loop; grasp the inside of the apron and dispose of it (Action figure 4).	The inside of the apron should be clean. E
<i>Post-procedure</i>	
5 Dispose of used aprons as 'hazardous infectious waste', that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team.	All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, C).
6 After removing the apron, decontaminate your hands.	Hands may have become contaminated (Loveday et al. 2014, C).

Action Figure 2a Place the neck loop of the apron over your head.

Action Figure 2b Tie the ties together behind your back, positioning the apron so that as much of the front of your body is protected as possible.

Action Figure 4 Remove the apron by breaking the neck loop and ties.

Procedure guideline 3.5 Putting on and removing a disposable mask or respirator

Essential equipment

- Disposable surgical mask or respirator

Pre-procedure

Action	Rationale
1 Remove surgical-type masks singly from the box, or remove individually wrapped items from their packaging, with clean hands.	To prevent contamination of the item or others in the box or dispenser. E
2 Remove glasses, if worn.	Glasses will obstruct the correct positioning of the mask or respirator and may be dislodged and damaged. E

Procedure

3 Place the mask/respirator over nose, mouth and chin (Action figure 3).	To ensure correct positioning. E
4 Fit the flexible nose piece over the bridge of your nose if wearing a respirator.	To ensure the best fit. E
5 Secure the mask or respirator at the back of the head with ties or fitted elastic straps and adjust to fit (Action figure 5).	To ensure the mask/respirator is comfortable to wear and remains in the correct position throughout the procedure. E
6 If wearing a respirator, perform a fit check. First, breathe in – respirator should collapse or be ‘sucked in’ to the face. Then breathe out – respirator should not leak around the edges.	To ensure that there is a good seal around the edge of the respirator so that there is no route for non-filtered air to pass in either direction. Note that this check should be carried out whenever a respirator is worn and is not a substitute for prior fit testing (DH 2010b, C).
7 Replace glasses, if worn.	To restore normal vision. E
8 At the end of the procedure, or after leaving the room in which the respirator is required, remove by grasping the ties or straps at the back of the head and either break them or pull them forward over the top of the head. Do not touch the front of the mask/respirator (Action figures 8a, 8b).	To avoid contaminating the hands with material from the outside of the mask/respirator (DH 2010b, C).
9 Dispose of used disposable items as ‘hazardous infectious waste’, that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team.	All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, C).

Post-procedure

10 Clean reusable items according to the manufacturer’s instructions, usually with detergent and water or a detergent wipe.	To avoid cross-contamination and ensure the item is suitable for further use (DH 2010b, C).
---	---

(continued)

Procedure guideline 3.5 Putting on and removing a disposable mask or respirator (continued)

68

Action Figure 3 Place the mask over your nose, mouth and chin.

Action Figure 5 Secure the mask at the back of the head with ties.

Action Figure 8a After use, remove the mask by untying or breaking the ties and pulling them forward.

Action Figure 8b Do not touch the front of the mask.

Procedure guideline 3.6 Putting on or removing goggles or a face shield

Purpose

To protect the mucous membranes of the eyes, nose and mouth from body fluid droplets generated during aerosol-generating procedures or surgery with power tools.

Essential equipment

- Reusable or disposable goggles or face shield

Pre-procedure

Action	Rationale
1 Remove eye protection from any packaging with clean hands.	To prevent cross-contamination. E
2 Apply demister solution according to manufacturer's instructions, if required.	To ensure good visibility throughout the procedure. E
3 Position item over eyes/face and secure using ear pieces or headband; adjust to fit.	To ensure the item is comfortable to wear and remains in the correct position throughout the procedure. E
4 At the end of the procedure, remove by grasping the ear pieces or headband at the back or side of the head and lifting forward, away from the face. Do not touch the front of the goggles or face shield (Action figure 4).	To avoid contaminating the hands with material from the outside of the eye protection (DH 2010b, C).

Post-procedure

- 5 Dispose of used disposable items as 'hazardous infectious waste', that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team.
- 6 Clean reusable items according to the manufacturer's instructions, usually with detergent and water or a detergent wipe.

All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, **C**).

To avoid cross-contamination and ensure the item is suitable for further use. **E**

Action Figure 4 Don and remove eye protection by grasping the earpieces; do not touch the front.

Procedure guideline 3.7 Surgical scrub technique

Purpose

To reduce the release of bacteria from the hands while carrying out surgical or high-risk procedures. The difference from conventional hand washing is the reduction in the level of resident bacteria on the hands as well as removal of the majority of transient bacteria.

Essential equipment

- Hand wash basin or surgical scrub sink with sufficient space available under the outlet to allow easy rinsing of hands and forearms
- Liquid medicated soap
- Sterile towels
- Domestic waste bin

Optional equipment

Sterile scrubbing brush, nail file or other implement for cleaning beneath the nails. Note that WHO (2009a) guidelines recommend that scrubbing brushes should **not** be used as they may damage the skin and encourage the shedding of cells (including bacteria).

Pre-procedure**Action**

- 1 Remove any rings, bracelets and wristwatch still worn and roll up sleeves before entering the operating theatre or procedure area. (*Note: Most organizations will require staff entering operating theatres to change into 'scrubs'.*)

Rationale

To ensure the ability of good hand washing as jewellery inhibits good hand washing. Dirt and bacteria can remain beneath jewellery after hand washing. Long sleeves prevent washing of wrists and will easily become contaminated and so a route of transmission of micro-organisms (DH 2010c, **C**; WHO 2009a, **C**).

(continued)

Procedure guideline 3.7 Surgical scrub technique (continued)

Action	Rationale
2 Cover cuts and abrasions on hands with waterproof dressing.	Cuts and abrasions can become contaminated with bacteria and cannot be easily cleaned. Repeated hand washing can worsen an injury (WHO 2009a, C). Breaks in the skin will allow the entry of potential pathogens.
3 Remove nail varnish and artificial nails (most uniform policies and dress codes prohibit these). Nails must also be short and clean.	Long and false nails and imperfections in nail polish harbour dirt and bacteria that are not effectively removed by hand washing (WHO 2009a, C).
Procedure	
4 Turn on the taps and where possible direct the water flow away from the plughole. Run the water at a flow rate that prevents splashing.	Plugholes are often contaminated with micro-organisms that could be transferred to the environment or the user if splashing occurs (NHS Estates 2001, C).
5 Run the water until hand hot.	Warm water is more pleasant to wash with than cold so hand washing is more likely to be carried out effectively. E Water that is too hot could cause scalding. E Soap is more effective in breaking down dirt and organic matter when used with hand-hot water (DH 2001, C).
6 Wet the surface of hands, wrists and forearms.	Soap applied directly onto dry hands may damage the skin. E The water will also quickly mix with the soap to speed up hand washing. E
7 Apply medicated liquid soap and water to all surfaces of the hands.	Liquid soap is very effective in removing dirt, organic material and any loosely adherent transient flora. The bactericidal additive contributes to the reduction in numbers of bacteria. Chlorhexidine has a residual effect to prevent regrowth of bacteria for a period after hand decontamination (WHO 2009a, C).
8 Clean beneath the nails using a sterile implement (preferred) or soft scrubbing brush.	The area under the nails may harbour dirt and micro-organisms not easily removed by the other stages of the procedure (WHO 2009a, C). WHO guidelines suggest carrying out this stage before entering the operating theatre; experience indicates it is more easily incorporated into the surgical scrub procedure. E .
9 Start timing. Thoroughly wash the hands for 2 minutes, using the actions shown in Procedure guideline 3.1: Hand washing, Action figure 8a .	No advantage has been shown from scrub procedures lasting longer than 2 minutes (WHO 2009a, C).
10 Wash each arm from wrist to elbow for 1 minute, keeping the hand higher than the elbow at all times.	To avoid recontaminating the hands with water that has been used to clean the arms (WHO 2009a, C).
11 Rinse hands and arms thoroughly from fingertips to elbow, keeping the hands above the elbows at all times.	To avoid recontaminating the hands with water that has been used to clean the arms (WHO 2009a, C).
Post-procedure	
12 Dry hands thoroughly with a sterile paper or cloth towel. Dry in one direction only, from the fingertips to the elbow.	Damp hands encourage the multiplication of bacteria (DH 2001, C). Drying from hands to elbows only reduces the risk of contaminating hands with bacteria from parts of the arm that have not been washed. E .
13 Dispose of used paper towels in a black bag in an open or foot-operated waste bin.	Paper towels used to dry the hands are normally non-hazardous and can be disposed of via the domestic waste stream (DH 2013b, C). Using an open or foot-operated waste bin prevents contamination of the hands. E

WHO guidelines state that surgical procedures may be carried out one after the other without the need for further hand washing if hands are perfectly clean and dry, provided that the handrubbing technique for surgical hand preparation is followed (WHO 2009a). See Procedure guideline 3.2: Hand decontamination using alcohol handrub, **Action figure 2**.

Procedure guideline 3.8 Donning sterile gloves: open technique

Purpose

To have a barrier between the nurse's hands and the patient to prevent the transmission of infectious agents in either direction, and to prevent contamination of a vulnerable area or invasive device through contact with non-sterile gloves.

Note that in steps 4 and 5, below, either glove can be put on first. Simply exchange 'left' and 'right' in the description if you wish to put on the right-hand glove first.

Essential equipment

- Sterile disposable gloves
- All other equipment required for the procedure for which the gloves are required

Pre-procedure

Action

- 1 Clean hands using soap and water or alcohol-based handrub.
- 2 Prepare all the equipment required for the procedure, including setting up the sterile field and tipping sterile items on to it from packets if you do not have an assistant, but do not touch any sterile item before putting on gloves.

Rationale

Hands must be cleansed before and after every patient contact or contact with patient's equipment (Loveday et al. 2014, **C**).
To avoid contaminating gloves with non-sterile packets. **E**

Procedure

- 3 Open the packet containing the gloves and open out the inside packaging on a clean surface so that the fingers of the gloves are pointed away from you, taking care not to touch the gloves or allow them to come into contact with anything that is non-sterile (**Action figure 3**).
- 4 Clean hands using soap and water or alcohol-based handrub.
- 5 Hold the cuff of the left-hand glove with your right fingertips, at the uppermost edge where the cuff folds back on itself. Lift this edge away from the opposite edge to create an opening. Keeping them together, slide the fingers of the left hand into the glove, taking care not to contaminate the outside of the glove, while keeping hold of the folded edge in the other hand and pulling the glove onto the hand. Spread the fingers of the left hand slightly to help them enter the fingers of the glove (**Action figures 5a, 5b, 5c**).
- 6 Open up the right-hand glove with your left-hand fingertips by sliding them beneath the folded-back cuff. Taking care not to touch the left-hand glove or the outside of the right-hand glove, and keeping the fingers together, slide the fingers of the right hand into the right-hand glove. Again, spread your fingers slightly once inside the body of the glove to help them into the glove fingers (**Action figures 6a, 6b**).
- 7 When both gloves are on, adjust the fit by pulling on the body of the glove to get your fingers to the end of the glove fingers (**Action figures 7a, 7b**).

To prevent contamination of the gloves and to put them in the best position for putting them on. **E**

Hands must be cleansed before and after every patient contact or contact with patient's equipment (Loveday et al. 2014, **C**).

To prevent contamination of the outside of the glove. **E**

To prevent contamination of the outside of the glove. **E**

To ensure the gloves are comfortable to wear and do not interfere with the procedure. **E**

Post-procedure

- 8 Remove the gloves when the procedure is completed, taking care not to contaminate the hands or the environment from the outside of the gloves.
- 9 First, remove the first glove by firmly holding the outside of the glove wrist and pulling off the glove in such a way as to turn it inside out.
- 10 Then remove the second glove by slipping the fingers of the ungloved hand inside the wrist of the glove and pulling it off whilst at the same time turning it inside out.

The outside of the glove is likely to be contaminated. **E**

Whilst removing the first glove, the second gloved hand continues to be protected. By turning the glove inside out during removal, any contamination is contained inside the glove. **E**

By putting the fingers inside the glove, the fingers will not be in contact with the potentially contaminated outer surface of the glove. **E**

(continued)

Procedure guideline 3.8 Donning sterile gloves: open technique (continued)

Action	Rationale
11 Dispose of used gloves as 'hazardous infectious waste', that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team.	All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, C).
12 After removing the gloves, decontaminate your hands.	Hands may have become contaminated (Loveday et al. 2014, C).

Action Figure 3 Open the packet containing the gloves onto a clean surface and open out the inside packaging so that the fingers of the gloves point away from you.

Action Figure 5a Hold the cuff of the first glove with the opposite hand and slide the fingertips of the other hand (that the glove is to go on) into the opening.

Action Figure 5b Keep hold of the folded edge and pull the glove onto your hand.

Action Figure 5c Spread your fingers slightly to help them enter the fingers of the glove.

Action Figure 6a Slide the fingertips of your gloved hand beneath the folded cuff of the second glove.

Action Figure 6b Slide the fingertips of your ungloved hand into the opening of the second glove.

Action Figure 7a Pull the glove onto your hand, again spreading your fingers slightly to help them enter the fingers of the glove.

Action Figure 7b When both gloves are on, adjust the fit.

Procedure guideline 3.9 Donning a sterile gown and gloves: closed technique

Note 1: These procedures will normally require participants to also wear a mask and eye protection.

Note 2: An assistant is required to open sterile gloves and tie the back of the gown.

Essential equipment

- Sterile disposable gloves
- Sterile disposable or reusable gown

Pre-procedure

Action

- 1 Prepare the area where gowning and gloving will take place. Open the gown pack with clean hands. Do not touch the inside of the package.
- 2 Wash your hands using a surgical scrub technique with either antiseptic hand wash solution or soap. Dry using a separate sterile paper towel for each hand and forearm. If hands have been washed with soap, apply an antiseptic handrub to the hands and forearms.

Rationale

To ensure that there is adequate room to don gown and gloves and to avoid contaminating either. **E**

To both disinfect and physically remove matter and micro-organisms from the hands (WHO 2009a, **C**).

(continued)

Procedure guideline 3.9 Donning a sterile gown and gloves: closed technique (continued)**Procedure**

74

Action**Rationale**

- | | |
|--|--|
| 3 Open the inner layer of the gown pack, if present (Action figures 3a, 3b). | To allow the gown to be removed. E |
| 4 Grasp the gown on its inside surface just below the neck opening (this should be uppermost if the gown pack has been opened correctly) and lift it up, holding it away from the body and any walls or furniture. The gown should fall open with the inside facing towards you (Action figure 4). | To open out the gown while keeping its outer surface sterile. E |
| 5 Insert the free hand into the corresponding sleeve of the gown, pulling the gown towards you, until your fingers reach, but do not go beyond, the cuff of the sleeve (Action figure 5). | To pull on the gown while keeping its outer surface sterile. E |
| 6 Release the inside surface of the gown and insert that hand into the corresponding sleeve, again until your fingers reach, but do not go beyond, the cuff of the sleeve (Action figure 6). The assistant should help to pull the gown on and tie the ties, without touching any part of the gown other than the ties and rear edges. | To pull on the gown while keeping its outer surface sterile. E |
| 7 The assistant opens a pair of sterile gloves and presents the inner packaging for you to take. Place this on the sterile area of the open gown package so that the fingers of the gloves point towards you (Action figure 7). | To prepare the gloves for donning while keeping them and the gown sterile. E |
| 8 Open the inner packaging of the gloves. The fingers should be towards you, the thumbs uppermost and the cuffs folded over. Keeping your hands within the sleeves of the gown, slide the thumb of your right hand (still inside the sleeve) between the folded-over cuff and the body of the right glove. Pick up that glove. Grasp the cuff of that glove on the opposite side with the other hand (still inside its sleeve) and unfold it, pulling it over the cuff of the sleeve and the hand inside. Then push your right hand through the cuff of the sleeve into the glove. Repeat the process with the left hand. Once both hands are inside their respective gloves, there is no risk of contaminating the outside of the gloves or gown with your bare hands (Action figures 8a, 8b, 8c, 8d, 8e, 8f, 8g). | To don the gloves while keeping their outer surface sterile and ensuring that there is no risk of contaminating the outside of the gown. E |
| 9 If you need to change a glove because it is damaged or contaminated, pull the sleeve cuff down over your hand as you do so and don the replacement glove using the technique above. | To minimize the risk of contaminating the gown or the sterile field. E |
| 10 Dispose of used gloves and disposable gowns as 'hazardous infectious waste', that is, into an orange waste bag, unless instructed otherwise by the infection prevention and control team. | All waste contaminated with blood, body fluids, excretions, secretions and infectious agents thought to pose a particular risk should be disposed of as hazardous infectious waste. Orange is the recognized colour for hazardous infectious waste that does not require incineration and may be made safe by alternative treatment (DH 2013b, C). |

Post-procedure

- | | |
|--|--|
| 11 At the end of the procedure, remove gown and gloves as a single unit by pulling the gown away from you so as to turn it and the gloves inside out (Action figures 11a, 11b). | To avoid cross-contamination of hands. E |
| 12 Consign reusable gowns as infected linen according to local arrangements. | To minimize any risk to laundry workers from contaminated items (NHS Executive 1995, C). |
| 13 After removing the gloves and gown, decontaminate your hands. | Hands may have become contaminated (Loveday et al. 2014, C). |

Action Figure 3a Open the gown pack with clean hands onto a clean surface. Do not touch the inner packet until after the surgical scrub.

Action Figure 3b Open the inner layer of the pack; use sterile towels to dry hands and forearms if required.

Action Figure 4 Lift up the gown by its inner surface and hold it away from the body.

Action Figure 6 Put the other hand into the other sleeve. Again, your hand should not go beyond the cuff.

Action Figure 5 Put one hand into the corresponding sleeve and use the other hand to pull the gown towards you. Your hand should not go beyond the cuff.

(continued)

Procedure guideline 3.9 Donning a sterile gown and gloves: closed technique (*continued*)

76

Action Figure 7 The assistant opens a pair of sterile gloves and presents the inner packaging for you to take.

Action Figure 8a Take the gloves, keeping your hands inside your sleeves.

Action Figure 8b Open the inner glove packet on the sterile open gown package so that the glove fingers point towards you.

Action Figure 8c Slide the thumb of one hand (still inside the sleeve) under the folded-over cuff of the corresponding glove.

Action Figure 8d Push your hand through the cuff and into the glove.

Action Figure 8e Pull the glove into position using the other hand (still inside its sleeve).

Action Figure 8f Repeat the process with the other glove.

Action Figure 8g Adjust the fit when both gloves are on.

Action Figure 11b Turn it and the gloves inside out.

Action Figure 11a At the end of the procedure, remove gown and gloves as a single unit by pulling the gown away from you.

Aseptic technique

Evidence-based approaches

78

Rationale

Aseptic technique is the practice of carrying out a procedure in such a way that you minimize the risk of introducing contamination into a vulnerable area or contaminating an invasive device. Aseptic technique is required whenever you are carrying out a procedure that involves contact with a part of the body or an invasive device where introducing micro-organisms may increase the risk of infection. Note that the area or device on which you are working will not necessarily be sterile – wounds, for example, will be colonized with micro-organisms – but your aim must be to avoid introducing additional contamination.

Aseptic non-touch technique (ANTT) is the practice of avoiding contamination by not touching key elements such as the tip of a needle, the seal of an intravenous connector after it has been decontaminated, or the inside surface of a sterile dressing where it will be in contact with the wound (Rowley and Clare 2011). An example of non-touch technique is illustrated in Figure 3.5. Gloves are normally worn for ANTT but they are mainly for the practitioner’s, rather than the patient’s, protection. Non-sterile gloves are therefore perfectly acceptable.

As with other infection prevention and control measures, the actions taken to reduce the risk of contamination will depend on the procedure being undertaken and the potential consequences of contamination. Examples of different aseptic techniques and the measures required for them are given in Table 3.5. It is therefore difficult to provide a procedure guideline that will apply to the whole range of aseptic procedures. To provide a context, the following procedure contains steps for changing a wound dressing but is presented as a guide to aseptic technique in general. Local guidance and training should be sought before carrying out specific procedures. Some specific procedures are described in other chapters of this manual.

Figure 3.5 Avoiding contamination by avoiding contact with the key elements. *Source:* Reproduced with permission from ICU Medical, Inc.

Table 3.5 Examples of aseptic procedures

Procedure	Precautions required
Surgical joint replacement	Must be carried out in an operating theatre with specialist ventilation by a team who will wear sterile gowns and gloves, or even full body suits with individual exhaust systems to eliminate airborne contamination
Urinary catheterization	Can be carried out in an open ward by a practitioner wearing an apron and sterile gloves
Peripheral intravenous cannulation	Can be performed wearing non-sterile gloves and using an appropriate non-touch technique

Procedure guideline 3.10 Aseptic technique example: changing a wound dressing

Essential equipment (will vary depending on procedure)

- Sterile dressing pack containing gallipots or an indented plastic tray, low-linting swabs and/or medical foam, disposable forceps, gloves, sterile field, disposal bag. Please note that in your organization there may be specific packs available for particular procedures, for example IV packs. Because the usage and availability of these vary between organizations, reference is generally made to ‘sterile dressing pack’
- Fluids for cleaning and/or irrigation; 0.9% sodium chloride is normally appropriate
- Hypoallergenic tape (if required)
- Appropriate dressing (if required)
- Alcohol handrub (hand washing is an acceptable alternative but will take more time and may entail leaving the patient; alcohol handrub is the most appropriate method for hand hygiene during a procedure as long as hands are physically clean)
- Any extra equipment that may be needed during procedure, for example sterile scissors
- Traceability system for any reusable surgical instruments and patient record form
- Detergent wipe for cleaning trolley

Pre-procedure

Action	Rationale
1 Check that all the equipment required for the procedure is available and, where applicable, is sterile (i.e. that packaging is undamaged, intact and dry; that sterility indicators are present on any sterilized items and have changed colour where applicable).	To ensure that the patient is not disturbed unnecessarily if items are not available and to avoid unnecessary delays during the procedure. E To ensure that only sterile products are used (MHRA 2010, C).
2 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).

Procedure

- | | |
|--|--|
| 3 Clean hands with alcohol handrub or wash with soap and water and dry with paper towels. | Hands must be cleaned before and after every patient contact and before commencing the preparations for aseptic technique, to prevent cross-infection (Loveday et al. 2014, C). |
| 4 Clean trolley with detergent and water or detergent wipes and dry with a paper towel. If disinfection is also required (e.g. by local policy), use disposable wipes saturated with 70% isopropyl alcohol and leave to dry. | To provide a clean working surface (Fraise and Bradley 2009, E); alcohol is an effective and fast-acting disinfectant that will dry quickly (Fraise and Bradley 2009, E). |
| 5 Place all the equipment required for the procedure on the bottom shelf of the clean dressing trolley. | To maintain the top shelf as a clean working surface. E |
| 6 Take the patient to the treatment room or screen the bed. Ensure that any fans in the area are turned off and windows closed. Position the patient comfortably and so that the area to be dealt with is easily accessible without exposing the patient unduly. | To allow any airborne organisms to settle before the sterile field (and in this case, the wound) is exposed. Maintain the patient's dignity and comfort. E |
| 7 Put on a disposable plastic apron. | To reduce the risk of contaminating clothing and of contaminating the wound or any sterile items from clothing. E |
| 8 Take the trolley to the treatment room or patient's bedside, disturbing the curtains as little as possible. | To minimize airborne contamination. E |
| 9 Loosen the adhesive or tape on the existing dressing. | To make it easier to remove the dressing. E |
| 10 Clean hands with alcohol handrub. | Hands should be cleaned before any aseptic procedure (WHO 2009a, C). Using alcohol handrub avoids having to leave the patient to go to a sink. E |
| 11 Open the outer cover of the sterile pack and, once you have verified that the pack is the correct way up, slide the contents, without touching them, onto the top shelf of the trolley. | To minimize contamination of the contents. E |
| 12 Open the sterile field using only the corners of the paper. | So that areas of potential contamination are kept to a minimum. E |
| 13 Open any other packs, tipping their contents gently onto the centre of the sterile field. | To prepare the equipment and, in the case of a wound dressing, reduce the amount of time that the wound is uncovered. E |
| 14 Where appropriate, loosen the old dressing. | To minimize trauma when removing the old dressing. E |
| 15 Clean hands with alcohol handrub. | Hands may have become contaminated by handling outer packets or the old dressing (Loveday et al. 2014, C). |
| 16 Carefully lift the plastic disposal bag from the sterile field by its open end and, holding it by one edge of the open end, place your other hand in the bag. Using it as a sterile 'glove', arrange the contents of the dressing pack and any other sterile items on the sterile field. | To maintain the sterility of the items required for the procedure while arranging them so as to perform the procedure quickly and efficiently. E |
| 17 With your hand still enclosed within the disposal bag, remove the old dressing from the wound. Invert the bag so that the dressing is contained within it and stick it to the trolley below the top shelf. This is now the disposal bag for the remainder of the procedure for any waste other than sharps. | To minimize risk of contamination by containing dressing in bag. E
To ensure that any waste can be disposed of without contaminating the sterile field. E |
| 18 Pour any solutions into gallipots or onto the indented plastic tray. | To minimize risk of contamination of solutions. E |
| 19 Put on gloves, as described in Procedure guideline 3.3: Putting on and removing non-sterile gloves or Procedure guideline 3.8: Donning sterile gloves: open technique. The procedure will dictate whether gloves should be sterile or non-sterile. | Gloves should be worn whenever any contact with body fluids is anticipated (Loveday et al. 2014, C). Sterile gloves provide greater sensitivity than forceps for procedures that cannot be carried out with a non-touch technique and are less likely to cause trauma to the patient. E |
| 20 Carry out the relevant procedure according to the guidelines. | |

Post-procedure

- | | |
|--|---|
| 21 Make sure the patient is comfortable. | To minimize the risk of causing the patient distress or discomfort. E |
| 22 Dispose of waste in orange plastic waste bags. Remove apron and gloves and discard into orange waste bag. | To prevent environmental contamination. Orange is the recognized colour for hazardous infectious waste (DH 2013b, C). |

(continued)

Procedure guideline 3.10 Aseptic technique example: changing a wound dressing (continued)

80

Action	Rationale
23 Draw back curtains or help the patient back to the bed area and ensure that they are comfortable.	To minimize the risk of causing the patient distress or discomfort. E
24 Check that the trolley remains dry and physically clean. If necessary, wash with liquid detergent and water or detergent wipe and dry thoroughly with a paper towel.	To remove any contamination on the trolley and so minimize the risk of transferring any contamination elsewhere in the ward (Loveday et al. 2014, C).
25 Clean hands with alcohol handrub or soap and water.	Hands should be cleaned after any contact with the patient or body fluids (WHO 2009a, C).
26 Document the procedure clearly, including details of who carried it out, any devices or dressings used, particularly any left <i>in situ</i> , and any deviation from prescribed procedure. Fix any record labels from the outside packaging of any items used during the procedure on the patient record form and add this to the patient's notes.	Provides a record of the procedure and evidence that any items used have undergone an appropriate sterilization process (DH 2007b, C ; NMC 2010, C).

Source isolation

Evidence-based approaches

Rationale

Source isolation is used for patients who are infected with, or are colonized by, infectious agents that require additional precautions over and above the standard precautions used with every patient (Siegal et al. 2007). Source isolation is used to minimize the risk of transmission of that agent to other vulnerable persons, whether patients or staff. Common reasons for source isolation include infections that cause diarrhoea and vomiting, entailing the use of enteric precautions; infections that are spread through the air, entailing the use of airborne or droplet precautions; and infection or colonization with antibiotic-resistant bacteria, requiring contact precautions (Siegal et al. 2007). Note that the patient's other nursing and medical needs must always be taken into account and infection control precautions may need to be modified accordingly.

Patients requiring source isolation are normally cared for in a single room, although outbreaks of infection may require affected patients to be nursed in a cohort, that is, isolated as a group (Fraise and Bradley 2009). A single-occupancy room will physically separate patients who present a risk from others who may be at risk, and will act as a reminder to any staff dealing with that patient of the need for additional infection control precautions. Single-occupancy rooms used for source isolation should have en suite toilet and bathroom facilities wherever possible, and contain all items required to meet the patient's nursing needs during the period of isolation (e.g. instruments to assess vital signs); these should remain inside the room throughout the period of isolation. If this is not possible because insufficient equipment is available on the ward, any items taken from the room must be thoroughly cleaned and disinfected (normally with a chlorine solution) before being used with any other patient (Fraise and Bradley 2009).

The air pressure in the room should be negative or neutral in relation to the air pressure in the rest of the ward (note that some airborne infections will require a negative pressure room) (Siegal et al. 2007). A lobby will provide an additional degree of security and space for donning and removing personal protective equipment and performing hand hygiene. Some facilities have lobbies that are ventilated so as to have positive pressure with respect to both the rest of the ward and the single-occupancy room; this allows the room to be used for both source and protective isolation (DH 2013d). Where insufficient single rooms are available

for source isolation, they should be allocated to those patients who pose the greatest risk to others, using a tool such as the one shown in Figure 3.6 (Jeanes et al. 2011). As a general rule, patients with enteric symptoms, that is diarrhoea and vomiting, or serious airborne infections, such as tuberculosis, have the highest priority for single-occupancy rooms. If this situation arises, it will mean that additional precautions will be required for some patients on the open ward; for example, gloves and aprons will still be required while caring for someone colonized with MRSA even if they are not isolated. Patients should receive a clear explanation of prioritization and thus why they may be isolated some times and not others; they may lose confidence in the care provided if it appears inconsistent without explanation.

Principles of care

Attending to the patient in isolation

Meals

Meals should be served on normal crockery and the patient provided with normal cutlery. Cutlery and crockery should be washed in a dishwasher able to thermally disinfect items, that is, with a final rinse of 80°C for 1 minute or 71°C for 3 minutes. Disposable cutlery and crockery should only be used if specifically instructed by the infection prevention and control team. Disposables and uneaten food should be discarded in the appropriate bag.

Contaminated crockery is a potential vector for infectious agents, particularly those causing enteric disease, but thermal disinfection will minimize this risk (Fraise and Bradley 2009).

Urine and faeces

Wherever possible, a toilet should be kept solely for the patient's use. If this is not available, a commode should be left in the patient's room. Gloves and apron must be worn by staff when dealing with body fluids. Bedpans and urinals should be bagged in the isolation room and taken directly to the sluice for disposal. They should not be emptied before being placed in the bedpan washer or macerator unless the volume of the contents needs to be measured for a fluid balance or stool chart. Gloves and apron worn in the room should be kept on until the body waste is disposed of and then removed (gloves first) and discarded as infected waste.

This will minimize the risk of infection being spread from excreta, for example via a toilet seat or a bedpan (Loveday et al. 2014) and the risk of hands or clothing being contaminated by body waste.

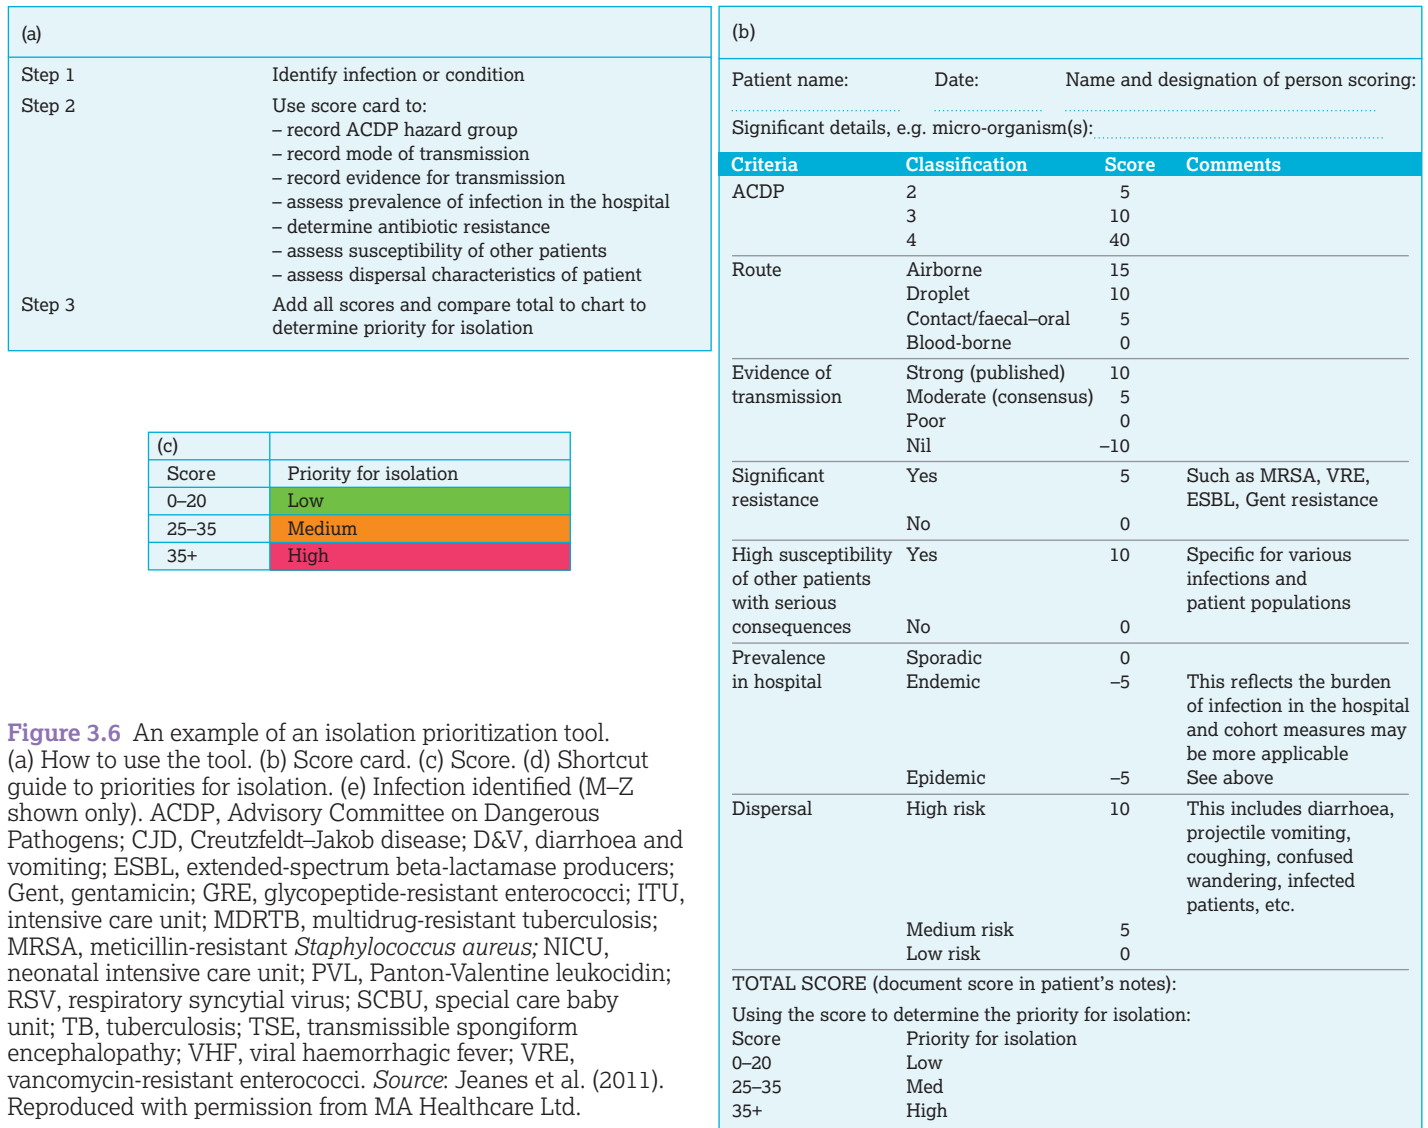

Figure 3.6 An example of an isolation prioritization tool. (a) How to use the tool. (b) Score card. (c) Score. (d) Shortcut guide to priorities for isolation. (e) Infection identified (M–Z shown only). ACDP, Advisory Committee on Dangerous Pathogens; CJD, Creutzfeldt–Jakob disease; D&V, diarrhoea and vomiting; ESBL, extended-spectrum beta-lactamase producers; Gent, gentamicin; GRE, glycopeptide-resistant enterococci; ITU, intensive care unit; MDRTB, multidrug-resistant tuberculosis; MRSA, methicillin-resistant *Staphylococcus aureus*; NICU, neonatal intensive care unit; PVL, Panton-Valentine leukocidin; RSV, respiratory syncytial virus; SCBU, special care baby unit; TB, tuberculosis; TSE, transmissible spongiform encephalopathy; VHF, viral haemorrhagic fever; VRE, vancomycin-resistant enterococci. *Source:* Jeanes et al. (2011). Reproduced with permission from MA Healthcare Ltd.

(e)			
Infection identified	Score & priority for isolation		Specific guidance
Measles	>35		Droplet
Meningitis undiagnosed (viral or bacterial)	30–40		Droplet/faecal–oral All meningitis cases should be isolated until cause is established. Meningococcal meningitis requires isolation until patient has received 48 hours of treatment
Meningococcal septicaemia	30–40		Droplet Remain in isolation until 48 hours of treatment given
Meticillin-resistant <i>Staphylococcus aureus</i> (MRSA)	25	>35	Contact/droplet Risk assess for isolation. High risk includes: <ul style="list-style-type: none"> major dispersers, i.e. dry or flaky skin, expectorating infected sputum surgical, especially in orthopaedic, cardiac or neurosurgery areas patients with multiple devices and interventions, e.g. ITU, NICU and SCBU PVL MRSA Medium risk includes positive screening swab but otherwise well and not in areas identified above. These patients may be cohorted
Mumps	30–40		Droplet
Norovirus/Small round structured virus (SRSV)	>45		Faecal–oral/contact
Respiratory syncytial virus (RSV)	25		Droplet A problem in newborn, children and immunodeficiency
Rotavirus	25		Droplet/faecal–oral A problem in newborn, children and immunodeficiency
Rubella	20	>30	Droplet Susceptibility of non immune may be an issue Medium risk paediatrics and women's health
Salmonella or Shigella	20	>30	Faecal–oral Dependent on potential for dispersal Medium risk for patients who are incontinent or have diarrhoea
Scabies (Confirmed)	20		Contact
Scarlet fever	30		Droplet
Severe acute respiratory syndrome (SARS)	40		Droplet/contact
Shingles (Herpes Zoster)	15	30	Contact No isolation needed if lesions are covered or dried Medium risk is weeping lesions, non-immune women of childbearing age, babies and children and immuno-deficient
Streptococcus pyogenes (Group A strep)	25		Droplet/contact Remain isolated for 24 hours following treatment
Tuberculosis (TB) non pulmonary	15		Contact Dependent on site and stage of disease
Tuberculosis (TB) open pulmonary or exuding lesion	25	35	Contact/airborne Isolated for period of 10–14 days following commencement of treatment. MDRTB patients should remain in isolation throughout hospital stay. High risk: patients who have a cough, MDRTB
Typhoid fever	15	25	Faecal–oral Dependant on potential for dispersal Medium risk for patients who are incontinent or have diarrhoea
Verotoxin producing strains of <i>Escherichia coli</i> (e.g. <i>E. coli</i> O157)	15	25	Faecal–oral Dependant on potential for dispersal Medium risk for patients who are incontinent or have diarrhoea
Viral haemorrhagic fever (VHF) Lassa/Ebola/Marburg	>70		Droplet/blood/contact Blood and body fluids are highly infectious – transfer to regional infectious diseases facility

Figure 3.6 Continued

Spillages

As elsewhere, any spillage must be mopped up immediately, using the appropriate method for the fluid spilt, and the area dried. This removes the risk of anyone slipping and removes and disinfects any contaminated fluid that may carry a risk of infection.

Bathing

If an en suite bathroom is not available, the patient must be bathed elsewhere on the ward. The patient does not need to use the bathroom last but the bathroom must be thoroughly cleaned

after use so bathing them last will minimize any delays to other patients that this may cause. However, if the patient requires an early bath, for example because they are leaving the ward for an examination elsewhere, this must be catered for.

Thorough cleaning and disinfection of the bathroom will minimize the risk of cross-infection to other patients.

Linen

Place infected linen in a red water-soluble alginate polythene bag, which must be secured tightly before it leaves the room. Just

outside the room, place this bag into a red linen bag which must be secured tightly and not used for other patients. These bags should await the laundry collection in the area designated for this.

Placing infected linen in a red alginate polythene bag confines the organisms and allows laundry staff to recognize the potential hazard and avoid handling the linen (DH 2013c).

Waste

Orange waste bags should be kept in the isolation room for disposal of all waste generated in the room. The top of the bag should be sealed and labelled with the name of the ward or department before it is removed from the room.

Cleaning the isolation room

- 1 Domestic staff must be instructed on the correct procedure to use when cleaning an isolation room, including an explanation as to why isolation is essential to reduce the risk of cross-infection, the materials and solutions used, and the correct colour coding for these materials. This will reduce the risk of mistakes and ensure that appropriate precautions are maintained (DH 2001).
- 2 Isolation rooms must be cleaned last, to reduce the risk of the transmission of contamination to 'clean' areas (NPSA 2009).
- 3 Separate cleaning equipment must be used for isolation rooms. Cross-infection may result from shared cleaning equipment (Wilson 2006).
- 4 Cleaners must wear gloves and plastic aprons while cleaning isolation rooms to minimize the risk of contaminating hands or clothing. Some PPE may also be required for the safe use of some cleaning solutions.
- 5 Floor (hard surface: carpeted rooms should not be used as isolation rooms). This must be washed daily with a disinfectant as appropriate. All excess water must be removed. Daily cleaning will reduce the number of bacteria in the environment. Organisms, especially Gram-negative bacteria, multiply quickly in the presence of moisture and on equipment (Wilson 2006).
- 6 Cleaning solutions must be freshly made up each day and the container emptied and cleaned daily. Disinfectants may lose activity over time; cleaning solutions can easily become contaminated (Dharan et al. 1999).
- 7 After use, the bucket must be cleaned and dried. Contaminated cleaning equipment and solutions will spread bacteria over surfaces being cleaned (Dharan et al. 1999).
- 8 Mop heads should be laundered in a hot wash daily as they become contaminated easily (Wilson 2006).
- 9 Furniture and fittings should be damp-dusted daily using a disposable cloth and a detergent or disinfectant solution by

nursing or cleaning staff as dictated by local protocol, in order to remove dirt and a proportion of any organisms contaminating the environment (Wilson 2006).

- 10 The toilet, shower and bathroom areas must be cleaned at least once a day and if they become contaminated, using a non-abrasive hypochlorite powder, cream or solution. Non-abrasive powders or creams preserve the integrity of the surfaces.

Cleaning the room after a patient has been discharged

- 1 The room should be stripped. All bedlinen and other textiles must be changed and curtains changed (reusable curtains must be laundered and disposable curtains discarded as infectious waste). Dispose of any unused disposable items. Curtains and other fabrics readily become colonized with bacteria (Patel 2005); paper packets cannot be easily cleaned.
- 2 Impervious surfaces, for example locker, bedframe, mattress cover, chairs, floor, blinds, soap dispenser, should be washed with soap and water, or a combined detergent/chlorine disinfectant if sporicidal activity is required, and dried. Relatively inaccessible places, for example ceilings, may be omitted. Wiping of surfaces is the most effective way of removing contaminants. Spores from, for example, *Clostridium difficile* will persist indefinitely in the environment unless destroyed by an effective disinfectant; bacteria will thrive more readily in damp conditions; inaccessible areas are not generally relevant to any infection risk (Wilson 2006).
- 3 The room can be reused as soon as it has been thoroughly cleaned and restocked. Effective cleaning will have removed infectious agents that may pose a risk to the next patient.

Discharging the patient from isolation

If the patient no longer requires isolation but is still to be a patient on the ward, inform them of this and the reasons why isolation is no longer required before moving them out of the room. Also inform them if there is any reason why they may need to be returned to isolation, for example if enteric symptoms return.

If the patient is to be discharged home or to another health or social care setting, ensure that the discharge documentation includes details of their condition, the infection control precautions taken while in hospital and any precautions or other actions that will need to be taken following discharge. Suitable accurate information on infections must be supplied to any person concerned with providing further support or nursing/medical care in a timely fashion (DH 2010a).

Procedure guideline 3.11 Source isolation: preparing an isolation room

Essential equipment

- Single-occupancy room
- Patient equipment
- Personal protective equipment
- Hand hygiene facilities
- Patient information material

Pre-procedure

Action

- 1 Identify the most suitable room available for source isolation, taking into account the risk to other patients and staff and the patient's other nursing needs.

Rationale

To ensure the best balance between minimizing the risk of cross-infection and maintaining the safety and comfort of the isolated patient. **E**

(continued)

Procedure guideline 3.11 Source isolation: preparing an isolation room (continued)**Procedure**

84

Action**Rationale**

- | | |
|--|--|
| 2 Remove all non-essential furniture and equipment from the room. The remaining furniture should be easy to clean. Ensure that the room is stocked with any equipment required for patient care and sufficient but not excessive numbers of any disposable items that will be required. | To ensure the availability of everything required for patient care while minimizing the number of items that will require cleaning or disposal at the end of the isolation period and the amount of traffic of people and equipment into and out of the room. E |
| 3 Ensure that a bin for clinical waste with an orange bag is present in the room. This will be used for all waste generated in the room. The bag must be sealed before it is removed from the room. | For containing contaminated rubbish within the room and minimizing further spread of infection. E |
| 4 Place a container for sharps in the room. | To contain contaminated sharps within the infected area (DH 2013b, C). |
| 5 Keep the patient's personal property to a minimum. All belongings taken into the room should be washable, cleanable or disposable. Contact the infection prevention and control team for advice as to how best to clean or wash specific items. | The patient's belongings may become contaminated and cannot be taken home unless they are washable or cleanable. E |
| 6 Ensure that all PPE required is available outside the room. Wall-mounted dispensers offer the best use of space and ease of use but, if necessary, set up a trolley outside the door for PPE and alcohol handrub. Ensure that this does not cause an obstruction or other hazard. | To have PPE readily available when required. E |
| 7 Explain the reason for isolation and the precise precautions required to the patient, their family and other visitors, providing relevant patient information material where available. Allow the patient to ask questions and ask for a member of the infection prevention and control team to visit the patient if ward staff cannot answer all questions to the patient's satisfaction. | Patients and their visitors may be more compliant if they understand the reasons for isolation, and the patient's anxiety may be reduced if they have as much information as possible about their condition. E |
| 8 Fix a suitable notice outside the room where it will be seen by anyone attempting to enter the room. This should indicate the special precautions required while preserving the patient's confidentiality. | To ensure all staff and visitors are aware of the need for additional infection control precautions. E |
| 9 Move the patient into the single-occupancy room. | To ensure isolation. E |
| 10 Arrange for terminal cleaning of the bed space that the patient has been occupying. | To remove any infectious agents that may pose a risk to the next patient to occupy that bed (NPSA 2009, C). |

Post-procedure

- | | |
|---|--|
| 11 Assess the patient daily to determine if source isolation is still required; for example, if enteric precautions have been required, has the patient been without symptoms for 48 hours? | There is often limited availability of isolation rooms (Wigglesworth and Wilcox 2006, R1b) so they must be used as effectively as possible. E |
|---|--|

Procedure guideline 3.12 Source isolation: entering the isolation room**Essential equipment**

- Personal protective equipment as dictated by the precautions required. Gloves and apron are the usual minimum; a respirator will be required for droplet precautions; eye protection if an aerosol-generating procedure is planned
- Any equipment required for any procedure you intend to carry out in the room

Pre-procedure**Action****Rationale**

- | | |
|---------------------------------|---|
| 1 Collect all equipment needed. | To avoid entering and leaving the infected area unnecessarily. E |
|---------------------------------|---|

Procedure

2 Ensure you are 'bare below the elbow' (see Procedure guideline 3.1: Hand washing).	To facilitate hand hygiene and avoid any contamination of long sleeves or cuffs that could be transferred to other patients. E
3 Put on a disposable plastic apron.	To protect the front of the uniform or clothing, which is the most likely area to come in contact with the patient. E
4 Put on a disposable well-fitting mask or respirator of the appropriate standard if droplet or airborne precautions are required, for example: <ul style="list-style-type: none"> (a) Meningococcal meningitis before completion of 24 hours of treatment (b) Pandemic influenza (c) Tuberculosis, if carrying out aerosol-generating procedure or the TB may be multiresistant. 	To reduce the risk of inhaling organisms (DH 2010b, C ; NICE 2006, C).
5 Don eye protection if instructed by infection prevention and control team (e.g. for pandemic influenza) or if conducting an aerosol-generating procedure (e.g. bronchoscopy or intubation) in a patient requiring airborne/droplet precautions.	To prevent infection via the conjunctiva (DH 2010b, C).
6 Clean hands with soap and water or alcohol handrub.	Hands must be cleaned before patient contact (WHO 2009a, C).
7 Don disposable gloves if you are intending to deal with blood, excreta or contaminated material, or if providing close personal care where contact precautions are required.	To reduce the risk of hand contamination (Loveday et al. 2014, C).
8 Enter the room, shutting the door behind you.	To reduce the risk of airborne organisms leaving the room (Kao and Yang 2006, R1a) and to preserve the patient's privacy and dignity. E

Procedure guideline 3.13 Source isolation: leaving the isolation room**Essential equipment**

- Orange waste bag
- Hand hygiene facilities

Procedure

Action	Rationale
1 If wearing gloves, remove and discard them in the orange waste bag.	To avoid transferring any contamination on the gloves to other areas or items (Loveday et al. 2014, C).
2 Remove apron by holding the inside of the apron and breaking the ties at neck and waist. Discard it into the orange waste bag.	To avoid transferring any contamination on the apron to other areas or items (Loveday et al. 2014, C).
3 Clean hands with soap and water or alcohol handrub. Do not use alcohol handrub when patients require enteric precautions: wash with soap and water.	Hands must be cleaned after contact with the patient or their immediate environment (WHO 2009a, C); alcohol is less effective against <i>Clostridium difficile</i> spores and some enteric viruses and in the presence of organic material such as faeces (Fraise and Bradley 2009, E).
4 Leave the room, shutting the door behind you.	To reduce the risk of airborne spread of infection (Kao and Yang 2006, R1a).
5 Clean hands with soap and water or alcohol handrub. If the patient requires enteric precautions, hands should be cleaned with soap and water.	Hands must be cleaned after contact with the patient or their immediate environment (WHO 2009a, C). Alcohol is not effective on all organisms that cause enteric infections (Fraise and Bradley 2009, E).

Procedure guideline 3.14 Source isolation: transporting infected patients outside the source isolation area**Procedure**

86

Action	Rationale
1 Inform the department concerned about the procedure required, the patient's diagnosis and the infection control precautions required at the earliest opportunity.	To allow the department time to make appropriate arrangements. E
2 If possible and appropriate, arrange for the patient to have the last appointment of the day.	The department concerned and any intervening areas will be less busy, so reducing the risk of contact with other vulnerable individuals, and additional cleaning required following any procedure will not disrupt subsequent appointments. E
3 Inform the portering service of the patient's diagnosis and the infection control precautions required; ensure that this information has been passed to any porters involved in transfer and reinforce the precautions required.	Explanation and reinforcement will minimize the risk of cross-infection through failure to comply with infection control precautions (Fraise and Bradley 2009, E).
4 Escort the patient if necessary.	To attend to the patient's nursing needs and to remind others of infection control precautions if required. E
5 If the patient has an infection requiring droplet or airborne precautions that may present a risk to people encountered in the other department or in transit, they will need to wear a mask or respirator of the appropriate standard. Provide the patient with the mask and explain why it is required and how and when it is to be worn (i.e. while outside their single-occupancy room) and assist them to don it if necessary.	To prevent airborne cross-infection. E Providing the patient with relevant information will reduce anxiety.

Protective isolation

Evidence-based approaches

Rationale

Protective isolation is used to minimize the exposure to infectious agents of patients who are particularly at risk of infection. The evidence that protective isolation successfully reduces the incidence of infection is limited (Wigglesworth 2003), probably because many infections are endogenous (i.e. caused by the patient's own bacterial flora). However, it is used to reduce the risk of exogenous infection (cross-infection from other people or the environment) in groups who have greatly impaired immune systems (Fraise and Bradley 2009), such as autologous and allogenic bone marrow transplant patients. Patients who have compromised immune systems often have greatly reduced numbers of a type of white blood cell called a neutrophil; this condition is known as neutropenia and those people suffering from it are described as neutropenic. Neutropenia is graded from mild to severe according to how few neutrophils are in the circulation and hence how much the risk of infection is raised (Godwin et al. 2013).

Single-occupancy rooms used for protective isolation should have neutral or positive air pressure with respect to the surrounding area. High-efficiency particulate air (HEPA) filtration of the air in the room may reduce exposure to airborne pathogens, particularly fungal spores. A room with positive pressure ventilation must not be used for any patient infected or colonized with an organism that may be spread through an airborne route; in this circumstance, if an immunocompromised patient has such an organism, they should be nursed in a room with neutral air pressure or with a positive pressure lobby (DH 2013d).

Principles of care

Diet for the immunocompromised patient

- Educate the patient about the importance of good food hygiene in reducing their exposure to potential pathogens; they should choose only cooked food from the hospital menu and avoid raw fruit, salads and uncooked vegetables. Stress the importance of good hand hygiene before eating or drinking. Uncooked foods are often heavily colonized by micro-organisms, particularly Gram-negative bacteria (Moody et al. 2006); potential pathogens on the hands may be inadvertently consumed while eating or drinking.
- Educate the patient's family about the importance of good food hygiene, particularly good hand hygiene, and advise that any food brought in for the patient should be in undamaged, sealed tins and packets obtained from well-known, reliable firms and within the expiry date. Correctly processed and packaged foods are more likely to be of an acceptable food hygiene standard.
- Provide the patient with filtered water or sealed cartons of fruit juice (not fresh) to drink (Vonberg et al. 2005). Do not supply bottled water. Tap water may occasionally be contaminated with potential pathogens; long-life fruit juice has been pasteurized to remove micro-organisms; bottled water is not normally of any better quality than tap water and the bacterial count may increase after bottling (Rosenberg 2003).

Discharging the neutropenic patient

- Crowded areas, for example shops, cinemas, pubs and discos, should be avoided. Although the patient's white cell count is usually high enough for discharge, the patient remains immunocompromised for some time (Calandra 2000).

- Pets should not be allowed to lick the patient, and new pets should not be obtained. Pets are known carriers of infection (Lefebvre et al. 2006).
- Certain foods, for example take-away meals, soft cheese and pâté, should continue to be avoided. These foodstuffs are more likely to be contaminated with potential pathogens (Gillespie et al. 2005).
- Salads and fruit should be washed carefully, dried and, if possible, peeled, to remove as many pathogens as possible (Moody et al. 2006).
- Any signs or symptoms of infection should be reported immediately to the patient's general practitioner or to the discharging hospital. Any infection may have serious consequences if left untreated.

Procedure guideline 3.15 Protective isolation: preparing the room

Essential equipment

- Single-occupancy room
- Patient equipment
- Personal protective equipment
- Hand hygiene facilities inside and outside the room
- Patient information material detailing the other infection prevention precautions required
- Cleaning materials for the room

Pre-procedure

Action

- 1 Identify the most suitable room available for protective isolation, taking into account the risk to the patient, the patient's other nursing needs and other demands on the available single rooms.

Rationale

To ensure the best balance between minimizing the risk of infection, maintaining the safety and comfort of the isolated patient and the availability of single rooms for other purposes. **E**

Procedure

- 2 Remove all non-essential furniture and equipment from the room. The remaining furniture should be easy to clean. Ensure that the room is stocked with any equipment required for patient care and sufficient numbers of any disposable items that will be required.

To ensure the availability of everything required for patient care while minimizing the amount of cleaning required and the amount of traffic of people and equipment into and out of the room. **E**

- 3 Ensure that all PPE required is available outside the room. Wall-mounted dispensers offer the best use of space and ease of use but, if necessary, set up a trolley outside the door for PPE and alcohol handrub. Ensure that this does not cause an obstruction or other hazard.

To have PPE readily available when required. **E**

- 4 Ensure that the room is thoroughly cleaned before the patient is admitted.

Effective cleaning will remove infectious agents that may pose a risk to the patient (NPSA 2009, **C**).

- 5 Explain the reason for isolation and the precise precautions required to the patient, their family and other visitors, providing relevant patient information material where available. Allow the patient to ask questions and ask for a member of the infection prevention and control team to visit the patient if ward staff cannot answer all questions to the patient's satisfaction.

Compliance may be more likely if patients and their visitors understand the reasons for isolation; the patient's anxiety may be reduced if they have as much information as possible about their condition. **E**

- 6 Fix a suitable notice outside the room where it will be seen by anyone attempting to enter the room. This should indicate the special precautions required while preserving the patient's confidentiality.

To ensure all staff and visitors are aware of the need for additional infection control precautions. **E**

- 7 Move the patient into the single-occupancy room.

To minimize exposure to potentially harmful micro-organisms (Wigglesworth 2003, **E**).

- 8 Ensure that surfaces and furniture are damp-dusted daily using disposable cleaning cloths and detergent solution, and the floor is mopped daily using soap and water.

Damp-dusting and mopping remove micro-organisms without distributing them into the air. **E**

Procedure guideline 3.16 Protective isolation: entering the isolation room**Essential equipment**

- Hand hygiene facilities
- Disposable plastic apron
- Additional equipment, including PPE, for any procedure to be undertaken

Pre-procedure**Action**

- 1 Collect all equipment needed.

Rationale

To avoid entering and leaving the room unnecessarily. **E**

Procedure

- 2 Ensure you are 'bare below the elbow' (see Procedure guideline 3.1: Hand washing).

To facilitate hand hygiene and to avoid transferring any contamination to the patient from long sleeves or cuffs. **E**

- 3 Put on a disposable plastic apron.

To provide a barrier between the front of the uniform or clothing, which is the most likely area to come in contact with the patient. **E**

- 4 Clean hands with soap and water or alcohol handrub.

To remove any contamination from the hands which could be transferred to the patient (WHO 2009a, **C**).

- 5 Close the room door after entering.

To reduce the risk of airborne transmission of infection from other areas of the ward and ensure that ventilation and air filtration systems work as efficiently as possible. **E**

Visitors

- 1 Ask the patient to nominate close relatives and friends who may then, after instruction (see steps 1–5, above), visit freely. The patient or their representative should ask other acquaintances and non-essential visitors to avoid visiting during the period of vulnerability.

The risk of infection is likely to increase in proportion to the number of people visiting but unlimited visiting by close relatives and friends may diminish the sense of isolation that the patient may experience; however, large numbers of visitors may be difficult to screen and educate. **E**

- 2 Exclude any visitor who has had symptoms of infection or been in contact with a communicable disease in the previous 48 hours.

Individuals may be infectious both before and after developing symptoms of infection (Goering et al. 2012). **E**

- 3 Educate all visitors to decontaminate their hands before entering the isolation room.

Hands carry large numbers of potentially pathogenic micro-organisms that can be easily removed (WHO 2009a, **C**).

- 4 Visiting by children, other than very close relatives, should be discouraged.

Children are more likely to have been in contact with infectious diseases but are less likely to be aware of this, and are more likely to develop infections because they have less acquired immunity. **E**

Prevention and management of inoculation injury**Related theory**

Healthcare workers are at risk of acquiring bloodborne infections such as human immunodeficiency virus (HIV), the virus that causes acquired immune deficiency syndrome (AIDS), hepatitis B and hepatitis C. While the risk is small, five episodes of occupationally acquired HIV infection had nonetheless been documented in the UK up to 2002 (Health Protection Agency 2005). In 2006–7, 914 incidents of occupational exposure to bloodborne viruses were reported, of which between one-fifth and one-third could have been prevented through proper adherence to universal precautions and the safe disposal of hazardous waste (Health Protection Agency 2008). An understanding of the risk of infection and the preventive measures to be taken is essential in promoting a safer work environment (UK Health Departments 1998).

Bloodborne viruses are present in the blood and in other high-risk fluids that should be handled with the same precautions as blood. High-risk fluids include:

- cerebrospinal fluid
- peritoneal fluid
- pleural fluid

- pericardial fluid
- synovial fluid
- amniotic fluid
- semen
- vaginal secretions
- breast milk
- any other body fluid or unfixed tissue or organ containing visible blood (including saliva in dentistry).

Body fluids that do not need to be regarded as high risk, unless they are bloodstained, are:

- urine
- faeces
- saliva
- sweat
- vomit.

The most likely route of infection for healthcare workers is through the percutaneous inoculation of infected blood via a sharps injury (often called a needlestick injury) or by blood or other high-risk fluid splashing onto broken skin or a mucous membrane in the mouth, nose or eyes. These incidents are collectively known as inoculation injuries. A European Union directive

recently incorporated into UK law requires healthcare organizations to use safe devices and systems of work to minimize the risk of inoculation injury (Health and Safety Executive 2013). Blood or another high-risk fluid coming into contact with intact skin is not regarded as an inoculation injury. It carries little or no risk due to the impervious nature of intact skin.

Evidence-based approaches

If the guidance in Box 3.2 is followed, it has been shown to reduce the risk of sharps injuries.

Complications

In the event of an inoculation injury occurring, prompt and appropriate action will reduce the risk of subsequent infection. These actions are described in Box 3.3 and should be taken regardless of what is thought to be known about the status of the patient whose blood has been inoculated. HIV, for example, has a 3-month 'window' following infection during which the patient has sufficient virus in their blood to be infectious but before their immune system is producing sufficient antibodies to be detected by the normal tests for HIV status.

Box 3.2 Actions to reduce the risk of inoculation injury

- Use safety devices as an alternative to sharp items wherever these are available (Health and Safety Executive 2013).
- Do not resheath used needles.
- Ensure that you are familiar with the local protocols for the use and disposal of sharps (e.g. location of sharps bins) and any other equipment before undertaking any procedure involving the use of a sharp item.
- Do not bend or break needles or disassemble them after use; discard needles and syringes into a sharps bin immediately after use.
- Handle sharps as little as possible.
- Do not pass sharps directly from hand to hand; use a receiver or similar receptacle.
- Discard all used sharps into a sharps container at the point of use; take a sharps container with you to the point of use if necessary. Do not dispose of sharps into anything other than a designated sharps container.
- Do not fill sharps bins above the mark that indicates that it is full.
- Sharps bins that are not full or in current (i.e. immediate) use should be kept out of reach of children and with any temporary closure in place.
- Sharps bins in use should be positioned at a height that enables safe disposal by all members of staff and secured to avoid spillage.
- Wear gloves in any situation where contact with blood is anticipated.
- Avoid wearing open footwear in any situation where blood may be spilt or where sharps are used.
- Always cover any cuts or abrasions, particularly on the hands, with a waterproof dressing while at work. Wear gloves if hands are particularly affected.
- Wear facial protection consisting of a mask and goggles or a face shield in any situation that may lead to a splash of blood or other high-risk fluid to the face. Do not rely on prescription glasses – they may not provide sufficient protection.
- Clear up any blood spillage promptly and disinfect the area. Use any materials or spillage management packs specifically provided for this purpose in accordance with the manufacturer's instructions.

Box 3.3 Actions to take in the event of inoculation injury

- Encourage any wound to bleed to wash out any foreign material that has been introduced. Do not squeeze the wound, as this may force any virus present into the tissues.
- Wash any wound with soap and water. Wash out splashes to mucous membranes (eyes or mouth) with large amounts of clean water.
- Cover any wound with a waterproof dressing to prevent entry of any other foreign material.
- Ensure the patient is safe then report the injury as quickly as possible to your immediate line manager and occupational health department. This is because post-exposure prophylaxis (PEP), which is medication given after any incident thought to carry a high risk of HIV transmission, is more effective the sooner after the incident it is commenced (DH 2008).
- Follow any instructions given by the occupational health department.
- Co-operate with any action to test yourself or the patient for infection with a bloodborne virus but do not obtain blood or consent for testing from the patient yourself; this should be done by someone not involved in the incident.
- Complete a report of the incident according to local protocols.

Management of waste in the healthcare environment

Definition

Waste is defined as 'any substance or object the holder discards, intends to discard or is required to discard' (European Parliament 2008).

Evidence-based approaches

Rationale

Waste material produced in the healthcare environment may carry a risk of infection to people who are not directly involved in providing healthcare but who are involved in the transport or disposal of that waste. All waste disposal is subject to regulation and hazardous waste is subject to further controls, depending on the nature of the hazard (DH 2013b). To ensure that everyone involved in waste management is aware of, and protected from, any hazard presented by the waste with which they are dealing, and that the waste is disposed of appropriately, a colour coding system is used. The colours in general use are shown in Table 3.6.

Waste receptacles are plastic bags or rigid plastic containers of the appropriate colour (Table 3.7).

Legal and professional issues

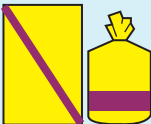

The producer of hazardous waste is legally responsible for that waste, and remains responsible for it until its final disposal by incineration, alternative treatment or landfill (DH 2013b). In order to track waste to its point of origin, for example if it is necessary to identify where waste has been disposed of into the wrong waste stream, healthcare organizations should have a system of identifying waste according to the ward or department where it is produced. This may be through the use of labelling or dedicated waste carts for particular areas. When assembling sharps bins, always complete the label on the outside of the bin, including the date and the initials of the assembler. When sharps bins are closed and disposed of, they should be dated and initialled at each stage (DH 2013b).

Table 3.6 Waste colours code

Colour	Description
 Yellow	Waste which requires disposal by incineration Indicative treatment/disposal required is incineration in a suitably permitted or licensed facility
 Orange	Waste which may be 'treated' Indicative treatment/disposal required is to be 'rendered safe' in a suitably permitted or licensed facility, usually alternative treatment plants (ATPs). However, this waste may also be disposed of by incineration
 Purple	Cytotoxic and cytostatic waste Indicative treatment/disposal required is incineration in a suitably permitted or licensed facility
 Yellow/black	Offensive/hygiene waste* Indicative treatment/disposal required is landfill or municipal incineration/energy from waste at a suitably permitted or licensed facility
 Red	Anatomical waste for incineration† Indicative treatment/disposal required is incineration in a suitably permitted facility
 Black	Domestic (municipal) waste Minimum treatment/disposal required is landfill , municipal incineration/energy from waste or other municipal waste treatment process at a suitably permitted or licensed facility. Recyclable components should be removed through segregation. Clear/opaque receptacles may also be used for domestic waste
 Blue	Medicinal waste for incineration† Indicative treatment/disposal required is incineration in a suitably permitted facility
	Amalgam waste For recovery

* The use of yellow/black for offensive/hygiene waste was chosen as these colours have historically been universally used for the sanitary/offensive/hygiene waste stream.
† The colours 'red' and 'blue' are new to the colour-coding system in this edition. Care should be taken when ordering red containers to ensure that they can be clearly differentiated from orange. The colour-coding should be agreed as part of a contract specification.

Table 3.7 Waste containers

Waste receptacle	Waste types	Example contents	Indicative treatment/disposal
 'Over-stickers' with the radioactive waste symbol may be used on yellow packaging	Healthcare waste contaminated with radioactive material	Dressings, tubing, etc., from treatment involving low-level radioactive isotopes	Appropriately licensed incineration facility
	Infectious waste contaminated with cytotoxic and/or cytostatic medicinal products	Dressings/tubing from cytotoxic and/or cytostatic treatment	Incineration
	Sharps contaminated with cytotoxic and cytostatic medicinal products*	Sharps used to administer cytotoxic products	Incineration
	Infectious and other waste requiring incineration including anatomical waste, diagnostic specimens, reagent or test vials, and kits containing chemicals	Anatomical waste from theatres	Incineration
	Partially discharged sharps not contaminated with cytoproducts*	Syringe body with residue medicinal product	Incineration

Waste receptacle	Waste types	Example contents	Indicative treatment/ disposal
	Medicines in original packaging	Waste in original packaging with original closures	Incineration
	Medicines NOT in original packaging	Waste tablets not in foil pack or bottle	Hazardous waste incineration
	Infectious waste, potentially infectious waste and autoclaved laboratory waste	Soiled dressings	Licensed/permitted treatment facility
	(i) Sharps not contaminated with medicinal products [†] or (ii) Fully discharged sharps contaminated with medicinal products other than cytotoxic and cytostatic medicines	Sharps from phlebotomy	Suitably authorized incineration or alternative treatment facility*
	Offensive/hygiene waste	Human hygiene waste and non-infectious disposable equipment, bedding and plaster casts	Deep landfill
	Domestic waste	General refuse, [‡] including confectionery products, flowers, etc.	Landfill
	Amalgam waste	Dental amalgam waste	Recovery

* The authorization type and content for alternative treatments in Northern Ireland, Scotland, England and Wales may differ. Not all facilities are authorized to process all types of waste.

Important: It is not acceptable practice to intentionally discharge syringes, etc., containing residual medicines in order to dispose of them in the fully discharged sharps receptacle. Partially discharged syringes contaminated with residual medicines should be disposed of in the yellow- or purple-lidded sharps receptacle shown above.

[†] The requirements for packaging are significantly affected by the presence of medicinal waste and the quantity of liquid present in the container.

[‡] General refuse is that waste remaining once recyclates (that is, paper, cardboard) have been removed.

Source: DH (2013c). © Crown copyright. Reproduced under the Open Government Licence v2.0.

Management of soiled linen in the healthcare environment

As with waste, soiled linen must be managed so as to minimize any risk to any person coming into contact with it. This is done by clearly identifying any soiled linen that may present a risk through the use of colour coding and limiting any contact with such linen through the use of water-soluble bags to contain the linen so that laundry staff do not have to handle it before it goes into the washer (DH 2013c).

Linen that may present a risk may be described as foul, infected or infested. The management of all hazardous linen is similar, so the following procedure applies to any linen that is wet with blood or other high-risk body fluids (see 'Prevention and management of inoculation injury') or faeces; has come from a patient in source isolation for any reason (that is, where enteric, contact or droplet/airborne precautions are in place); or is from a patient who is infested with lice, fleas, scabies or other ectoparasite. Note that this procedure can be much more easily carried out by two people working together.

Procedure guideline 3.17 Safe disposal of foul, infected or infested linen**Essential equipment**

- Disposable gloves and apron
- Water-soluble laundry bag
- Red plastic or linen laundry bag in holder
- Orange waste bag

Pre-procedure**Action****Rationale**

1 Assemble all the required equipment.

To avoid having to fetch anything else during the procedure and risk spreading contamination to other areas. **E**

2 Put on disposable gloves and apron.

To minimize contamination of your hands or clothing from the soiled linen. **E**

3 Separate the edges of the open end of the water-soluble laundry bag.

To make it easier to put the soiled linen in the bag. **E**

Procedure

4 Gather up the foul, infected or infested linen in such a way that any gross contamination (e.g. blood, faeces) is contained within the linen.

To minimize any contamination of the surrounding area. **E**

5 If there are two people, one holds the water-soluble laundry bag open while the other puts the soiled linen into it. If one person, hold one edge of the open end of the water-soluble bag in one hand and place the soiled linen in the bag with the other. In either case, take care not to contaminate the outside of the bag.

So as to remove the need for laundry workers to handle foul, infected or infested linen before it is washed (DH 2013c, **C**).

6 Tie the water-soluble bag closed using the tie provided or by knotting together the edges of the open end.

To keep the soiled laundry inside the bag. **E**

7 Place the full water-soluble bag of soiled linen into the red outer laundry bag. Do not touch this bag.

To identify the linen as requiring special treatment. **E**

8 Remove gloves and apron and dispose of them into an orange waste bag.

To avoid transferring contamination to other areas (DH 2013b, **C**).

9 Wash hands and forearms with soap and water, and dry hands thoroughly with a disposable paper towel.

To avoid transferring contamination to other areas (WHO 2009a, **C**).

10 Close the red outer laundry bag and transfer it to the designated collection area.

To ensure it does not cause an obstruction and is transferred to the laundry at the earliest opportunity. **E**

Overview

The aim of this chapter is to define and describe effective communication as well as its role in the psychological support of patients and those close to them. This chapter is mostly concerned with interpersonal communication using language comprising verbal (including tone) and non-verbal expression. The process of offering psychological support to patients and the management of factors that contribute to or compromise this process will also be considered.

There are specific sections on denial and collusion, anxiety, depression, anger management, delirium and finally, assisting those with sensory impairment to communicate.

Communication

Definition

Communication is a universal word with many definitions, many of which describe it as a transfer of information between a source

and a receiver (Kennedy Sheldon 2009); that is, the sending and receiving of verbal and non-verbal messages between two or more people (de Vito 2013). In nursing, this communication is primarily interpersonal: the process by which compassion and support are offered and information, decisions and feelings are shared (McCabe and Timmins 2013).

Anatomy and physiology

Physiologically being able to produce speech and to hear are the two dominant physical processes involved in communication.

The human voice is produced by exhaled air vibrating the vocal cords in the larynx to set up sound waves in the column of air in the pharynx, nose and mouth. Pitch is controlled by the tension on the vocal cords: the tighter they are, the more they vibrate and the higher the pitch. The sounds produced are amplified by the physical spaces of the pharynx and nose and modified by the lips, tongue and jaw into recognizable speech. The muscles of the face, tongue and lips help to enunciate words (Tortora and Derrickson 2011) (Figure 4.1).

Figure 4.1 Movement of the vocal cords. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

Figure 4.2 Events in the stimulation of auditory receptors in the right ear. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

The ear contains receptors for sound waves and the external or outer ear is designed to collect them and direct them inward. As the waves strike the tympanic membrane, it vibrates due to the alternate compression and decompression of the air. This vibration is passed on through the malleus, incus and stapes of the middle ear. As the stapes vibrates, it pushes the oval window. The movement of the oval window sets up waves in the perilymph of the cochlea that ultimately lead to the generation of nerve impulses that travel to the auditory area of the cerebral cortex (Tortora and Derrickson 2011) (Figure 4.2).

The physiological process of communication is, however, much greater than just speech and hearing. The central nervous system is central to both verbal and non-verbal communication. Not only does it continually receive information but it also selects that which is important to respond to, so that overstimulation is avoided. Communication issues may arise if any of these processes are altered.

Related theory

There are many theories about interpersonal communication. One of the earliest theories is the idea that communication can be represented as a linear process (Miller and Nicholson 1976).

This Linear Model of Communication makes certain assumptions such as: that the receiver will be a willing participant in the process and open to receive the message; that all messages will be clear and the sender certain about their purpose (McCabe and Timmins 2013). However, such a model is unidirectional so more relevant for electronic media and not necessarily representative of the complexity of human communication.

The Transactional Model is more useful, recognizing that human communication is a simultaneous process, so each person involved is a communicator rather than just a sender or receiver (McCabe and Timmins 2013) (Figure 4.3). In addition, the model recognizes that the interpersonal context or environment affects

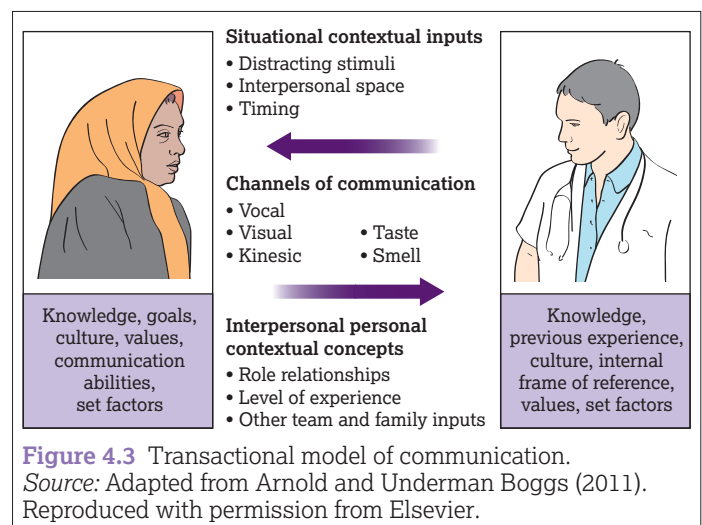

Figure 4.3 Transactional model of communication. *Source:* Adapted from Arnold and Underman Boggs (2011). Reproduced with permission from Elsevier.

the process significantly, as does the channel of communication (that is, visual, aural, gustatory, tangible or olfactory). This theory helps nurses to reflect on the multifaceted nature of communicating with patients and so recognize the many factors that can impact on an effective process.

An aim of interpersonal professional communication training is to support and maintain the patient's optimum level of communication while remaining aware of the impact that the disease and its management may have on the patient's ability and/or motivation to speak. An awareness of different coping styles and attitudes of the patient and key people in their lives, other co-morbidities, disease progression, fluctuating cognitive abilities and treatment side-effects is important. All these factors demand a flexible approach when supporting communication throughout the length of the patient pathway (Dwamena et al. 2012, White 2004).

Non-verbally, people communicate via gestures, body language, posture, facial expression, touch, and the items they surround themselves with, such as their personal possessions which will include their clothing and accessories, books and photographs in the hospital environment. Communication can be heavily influenced by a multitude of external and internal factors, for example illness, culture, class, self-esteem, immediate environment, gender, status, mood and depression, and the influence of these factors needs to be carefully considered in each circumstance. All patients and relatives should be assessed for their psychological needs and tailored support offered to meet individual needs.

Evidence-based approaches

Effective communication is widely regarded to be a key determinant of patient satisfaction, compliance and recovery (Dwamena et al. 2012, Webster and Bryan 2009), yet poor communication is one of the most common causes of complaints in healthcare (DH 2013, Strachan 2004). Supportive communication is important to create an environment where the individual patient feels heard and understood and can be helped appropriately. Communication needs to be highly flexible, dependent upon cultural, social and environmental factors. Nurses need to communicate effectively with patients in order to deliver individualized safe care and treatment and to manage psychosocial concerns appropriately. People with illness want to be approached with a 'caring and humane attitude' that respects their privacy and dignity (Maben and Griffiths 2008, Webster and Bryan 2009). Patients want their personal values to be respected and to be treated as equals by health professionals. This can be achieved by taking the time to communicate, not controlling dialogue, listening and offering emotional support (Smith et al. 2005) and by striving for open, clear and honest communication (Heyland et al. 2006, Jenkins et al. 2001). The patient's dignity can be promoted by enabling the expression of concerns in a safe environment.

Patients want to be able to experience a meaningful connection and a sense of 'being known' by the staff they encounter (Thorne et al. 2005, Webster and Bryan 2009). Nurses need to be able to accurately assess how much patients want to share their thoughts and feelings without assuming that they either do or do not wish to.

Communication occurs in a time-pressured environment. Practical and technical tasks demand the nurse's time and tend to be prioritized above psychological support. The resulting communication may be limited and prevent effective exploration of psychological issues. Without effective exploration, patients are not sufficiently encouraged to engage with and manage their own care. Nurses need to be aware of and consider other features of the environment that may contribute to the nature of the dialogue that takes place (Hargie 2011) – for example, the wearing of uniform. Patients may not expect to discuss psychosocial issues with nurses because of the communication bias toward physical and medical issues (Chant et al. 2004). The task-orientated short communication encounters that emerge do not encourage the disclosure of psychosocial concerns (Silverman et al. 2013).

Patient satisfaction is not necessarily related to the acquisition of specific communication skills (Dwamena et al. 2012, Thorne et al. 2005) but staff still need to be able to enquire about the nature and manner of support that patients want (so that satisfaction can be achieved wherever possible).

Listening and appropriate verbal responses that demonstrate empathy remain the key skills; if nothing else is achieved, adopting these qualities will be beneficial to patients and be a valuable use of time.

Listening

Listening is a skill often assumed to be natural. Rarely would we consider that we were physically unable to listen and perhaps this makes us pay little attention to this crucial skill area (Box 4.1).

Box 4.1 How to let someone know you are listening to them

- Non-verbal encouragement, e.g. head nodding, body position, eye contact
- Verbal responses
- Questioning
- Paraphrasing
- Clarifying
- Summarizing
- Empathy

Source: Hargie (2011). Reproduced with permission from Taylor & Francis.

The physical act of hearing is distinct from that of 'listening'. Hearing can be considered to be passive, but listening requires active processing and attaching meaning to what is heard.

It might be difficult for us to answer the question 'How do we listen?' and perhaps a procedure of 'how to listen' would not do justice to the sophistication and success of good listeners. However, there are ways of describing the constituent parts of listening that, if followed, would make the person speaking appreciate that they were being listened to.

Problems can emerge as two people may interpret the meaning of the same dialogue differently. For example, if you ask the question 'How are you?' and the patient replies 'Getting by', do you assume they are doing well and coping or that this means they are struggling and 'putting on a brave face'?

Hopefully, you will be attending to numerous non-verbal cues to decipher what the patient actually means. If there is a suggestion of 'incongruence', where the patient says 'Getting by' in a low and sad-sounding voice coupled with a simultaneous lowering of the head, we might consider the latter assumption. Alternatively, if the patient sounds upbeat and looks you in the face with a smile, you might be reassured they mean the former.

There are strategies to promote successful listening, for example 'summarizing' and 'clarifying' (at suitable moments) what the patient is saying.

Non-verbal responses

Non-verbal communication generally indicates information transmitted without speaking. Included in this would be the way you sit or stand, facial expression, gestures and posture, whether you nod or smile and the clothes worn; all will have an impact on the total communication taking place (Hargie 2011). Argyle (1988) suggests that of communication that takes place between people, only 7% is verbal (cited in Jootun and McGhee 2011).

Egan (2013) usefully describes the acronym SOLER to summarize the constituent elements of non-verbal communication.

- facing the patient **S**quarely
- maintaining an **O**pen posture
- L**eaning slightly towards the patient to convey interest
- having appropriate **E**ye contact, not staring nor avoiding (unless culturally appropriate)
- being **R**elaxed

By learning an awareness of these factors and making this behaviour part of your normal demeanour, patients will be encouraged to talk more openly, facilitating emotional disclosure.

Saying nothing can also be interpreted as meaning something, so there is always communication however reluctant or silent you or the patient may be.

It can be argued that non-verbal information is more powerful than verbal information, for example in the case of 'incongruence' where the verbal message indicates one thing and the non-verbal suggests another. There is a tendency to believe the non-verbal

message over the verbal in these instances. This highlights the need to communicate with genuine compassion. Without this, supportive communication can be severely reduced in its effectiveness.

Non-verbal communication becomes even more important in the case of people whose verbal communication is impaired, for example by stroke, trauma, learning disability, dementia or surgery. Patients need to be supported, ensuring, for example, that they have constant access to pen and paper; communication boards can be used to good effect and it is worth considering the use of information technology and communication software, if available. The experience of losing the ability to speak can be very isolating and frustrating and preparation of the patient and practice with communication aids is important to maximize the success of communication. It is essential that people with a speech deficit are given more time to communicate their needs, so patience and persistence are essential until interaction and understanding are gained at a satisfactory level.

Non-verbal behaviour to encourage patients to talk includes nodding/making affirming noises, for example 'Hmmm'. This 'affirming' is mostly done naturally, for example at points of eye contact, as specific points are made and during slight pauses in dialogue. It can be especially important to affirm when the patient is talking about psychological issues as they will need validation that this is an acceptable topic of conversation. Chambers (2003, p.878) suggests that for patients with 'limited verbal expression', nurses have a responsibility to build upon and recognize their non-verbal communication to support the development of a good working relationship with the patient.

Verbal responses

The way things are said makes a considerable difference, so attention needs to be paid to the tone, rate and depth of speech. This means sounding alert, interested and caring, but not patronizing. Speech should be delivered at an even rate, not too fast or too slow (unless presenting difficult or complex information).

Questioning

A skill that is used in close collaboration with listening is that of questioning. When specific information is required, for example in a crisis, closed questions are indicated, because they narrow the potential answer (Silverman et al. 2013) and allow the gathering of specific information for a purpose. Closed questions therefore are ones which are likely to generate a short 'yes or no' answer, for example 'Are you all right?'.

In care situations with significant life-changing implications, a broader assessment of the patient's perspective is required and there is also a need to show compassion and identify any underlying psychosocial issues. Open questions and listening are therefore required. Open questions do the opposite of closed questions; they broaden the potential answers (Silverman et al. 2013) giving the agenda and direction of the dialogue to the patient. So, for example, instead of asking 'Are you all right?', an open question would be 'How are you today?' or 'What has your experience of treatment been like?'.

A question that enquires about a patient's emotional experience indicates that this is also of interest to the nurse; for example, 'How did that make you feel?' or 'What are your main concerns?'.

Open questions cannot be used in isolation as the opportunity for open discussion can easily be blocked by failing to ensure that the rest of the fundamental communication elements are in place. Attention must therefore be paid to protecting sufficient time, verbal space (not interrupting) and encouragement (in the form of non-verbal cues, paraphrasing, clarifying and summarizing), so that the patient and/or relative can express their feelings and concerns.

Open questions may not be appropriate with people who have an acquired communication problem, such as changes to the oral cavity following head and neck surgery or if English is not their first language.

Asking one question at a time is important; it is easy to ask more than one question in a sentence and this can make it unclear where the focus is and lead the patient to answer only one part of the question.

Open questions can also be helpful to respond to cues that the patient may give about their underlying psychological state. Cues can be varied, numerous and difficult to define, but essentially these are either verbal or non-verbal hints of underlying unease or worry. Concerns may be easier to recognize where they are expressed verbally and unambiguously (del Piccolo et al. 2006).

Reflecting back

This is repeating the same words back to the patient, which signals that their focus is a legitimate topic for discussion (McCabe and Timmins 2013), but if this technique is overused it can sound unnatural (Silverman et al. 2013).

When it is used, it needs to be done with thought and include 'something of you in your response' (Egan 2013), meaning that you remain alert and caring.

Paraphrasing

This technique involves telling the patient what they have told you but using different words that retain the same meaning; for example:

Patient: I need to talk to them but whenever they start to talk to me about the future, I just start to get wound up and shut down.

Nurse: So when your family try to talk, you get tense and you stop talking ...

Clarifying

The aim of this technique is to reduce ambiguity and help the patient define and explore the central or pivotal aspect of the issues raised. As nurses, we can be reluctant to explore emotional or psychological issues in too much depth, for fear that the issues raised are too emotional and hard to deal with (Perry and Burgess 2002). However, if the principles of good communication are applied and a focus on the patient's agenda is maintained, distressing and difficult situations can be heard and support offered to the patient.

The use of open questions is likely to raise certain issues that would benefit from further exploration. Clarification encourages the expression of detail and context to situations, helping to draw out pertinent matters, perhaps not previously considered by either the patient or the nurse. A mixture of open or closed questions can be used in clarification (Box 4.2).

It is sometimes necessary for the nurse to clarify their own position, perhaps acknowledging that they don't know something and cannot answer certain questions, for example 'I am not in a position to know if the treatment will work'.

Sometimes not knowing can be a valuable position, as it prompts an enquiry about the patient's experience rather than making assumptions. The knowledge and experience gained through a nursing career may mean that the experience of the patient or relative is familiar; however, patients and relatives will

Box 4.2 Open and closed questions

- Are you feeling like that now? (closed)
- You seem to be down today, am I right? (closed)
- Can you describe how the experience made you feel? (closed)
- You say that you've not had enough information: can you tell me what you do know? (open)
- You mention that you are struggling: what kinds of things do you struggle with? (open)
- You say it's been hard getting this far: what has been the hardest thing to cope with? (open)

benefit from the opportunity to share their experience in their own words and to feel 'heard' (Williams and Iruita 2004).

Summarizing

This intervention can be used as a way of opening or closing dialogue. An opening can be facilitated by recapping a previous discussion or outlining the understanding of the patient's position. Summarizing can be used to punctuate a longer conversation and highlight specific issues raised.

This serves several purposes.

- It informs the patient that they have been listened to and that their situation is understood.
- It allows the patient to correct any mistakes or misconceptions that may have arisen.
- It brings the conversation from the specific to the general (which can help to contextualize issues).
- It gives an opportunity for agreement to be reached about what may need to happen.

An example of summarizing:

'It sounds like you are tired and are struggling to manage the treatment schedule. It also sounds like you don't have enough information and we could support you more with that ...'

Summarizing can be a useful opportunity to plan and agree what actions are necessary, but if summarizing is used in this situation, it is important to avoid getting caught up with planning and solution finding; the patient will gain the greatest benefit from empathic attentive listening. In our nursing role, we are familiar with 'doing' and correcting problematic situations; and although interventions can be helpful in psychosocial issues, sometimes it is necessary not to act and to just 'be' with the patient, accepting their experience as it is, however difficult this may be.

Recognizing when to act and when to sit with distress can be difficult. However, it is important to develop this awareness and to accept that sometimes there are no solutions to difficult situations. The temptation to always correct problems might only serve to negate the patient's experience of being listened to (Connolly et al. 2010). Sometimes all the patient may want in that moment is to be listened to and heard.

Empathy

Sharing time and physical space with other people demands the development of a relationship. In nursing, the relationship with patients is defined by many factors, for example physical and medical care. In clinical roles, it is possible to be emotionally detached and to exist behind a 'professional mask' (Taylor 1998, p.74) but when working in a supportive role, a shared experience and bond are generated, inclusive of feelings.

Recognizing our own feelings is important to allow us to understand and to 'tolerate another person's pain' (McKenzie 2002, p.34). Nurses demonstrate empathy when there is a desire to understand the client (patient) as fully as possible and to communicate this understanding back to them (Egan 2013, p.97).

This means attempting to gain an appreciation of what the patient might be going through, taking into consideration their physical, social and psychological environment. This inferred information can be used to 'connect' with the patient, all the time checking that our interpretation of their experience is accurate. Even if the nurse has experienced similar events, it is important to determine the patient's thoughts and feelings as they can be very different.

Rogers (1975, p.2) seminally described the skill of empathy as: 'The ability to experience another person's world as if it were one's own, without losing the "as if" quality'. That means allowing ourselves to get into the patient's shoes and experience some of what they might be experiencing, without allowing ourselves to enter the experience wholly (it isn't our experience). Empathy

allows for an opportunity to 'taste' and therefore attempt to understand the patient's perspective. Understanding emotions and behaviours in this way encourages an acceptance and positive negotiation of them. Maintaining the 'as if' quality protects us from adopting too great an emotional load. Having too much of a sense of loss or sorrow may prevent us from offering effective support, as we are drawn to focus on our own feelings more than is necessary or helpful for ourselves or the patient.

Empathy may not always come easily, especially if a patient is angry. What can be very useful in the development and use of empathy is the ability to step back from the situation and reflect upon what it is that you, as the nurse, feel and how this relates to what is happening for the patient.

Barriers to effective communication

Poor communication with patients can negatively affect decision making and quality of life (Dwamena et al. 2012, Fallowfield et al. 2001, Thorne et al. 2005).

The environmental conditions in which nurses work, with competing professional demands and time pressures, can reduce the capacity to form effective relationships with patients (Hemsley et al. 2012, Henderson et al. 2007).

There is a personal, emotional impact when providing a supportive role for patients with psychological and emotional issues (Botti et al. 2006, Dunne 2003, Turner et al. 2007) and it is therefore likely that blocking or avoidance of patients' emotional concerns relates to emotional self-preservation for the nurse. Young (2012) states that in caring for patients who have dementia, professional caregivers are likely to avoid communication which can result in further isolation and frustration in the patient which in turn could lead to anger.

When communicating and assessing patients' needs, nurses may be anxious about eliciting distress and managing expressed concerns. They may lack confidence in their ability to clarify patients' feelings without 'causing harm to the patient or getting into difficulty themselves' (Booth et al. 1996, p.526). As a consequence, nurses can make assumptions, rather than assessing concerns properly (Booth et al. 1996, Kelsey 2005, Schofield et al. 2008). To illustrate this point, Kruijver et al. (2001) demonstrated how nurses verbally focus upon physical issues, which accounted for 60% of communication with patients. Nurses often recognize this bias and suggest that they feel greater competence discussing physical rather than psychological issues and seek better skills to help them to manage challenging situations (McCaughan and Parahoo 2000). Being supported practically and emotionally by supervisors and/or senior staff can help to decrease blocking behaviours (Booth et al. 1996, Connolly et al. 2010). Clinical supervision can aid the transfer of communication skills into practice (Heaven et al. 2006).

Institutions, work environments and the nature of the senior staff within them can influence the nature of communication (Booth et al. 1996, Chant et al. 2002, McCabe 2004, Menzies-Lyth 1988, Wilkinson 1991). Nurses may improve their own practice by identifying where environmental barriers lie and attempting to mitigate the features of the clinical environment that inhibit psychological care. These barriers to communication may be even more significant for patients who have any cognitive or physical impairment, such as learning disability, dementia, hearing or sight impairment. Approaches to patients who have additional communication needs require consideration and planning.

Despite the difficulties outlined, it has been argued that nurses can communicate well when they are facilitated to provide individual patient-focused care (McCabe 2004).

Legal and professional issues

There are a number of legal and professional concepts and issues that impact on effective communication and psychological support. These include:

- professional responsibility for effective communication
- confidentiality and appropriate disclosure of information about the patient

- consent communicating about a procedure and ensuring that a patient is fully cognisant of what it involves
- assessment of an individual's mental capacity to engage in care and treatment.

Professional responsibility for effective communication

The Francis Report (DH 2013) recommended that there should be an increased focus on a culture of caring, compassion and consideration in nursing. The steps to achieving this are set out in *Compassion in Practice* (DH 2012a). Underpinning this vision are six fundamental values: care, compassion, competence, communication, courage and commitment, and associated with these are six areas of action to support nursing staff in delivering excellent care.

Communication is one of the six fundamental values in the vision and is defined as:

'central to the caring relationships and to effective team working. Listening is as important as what we say and do and essential for 'no decision about me without me'. Communication is the key to a good workplace with benefits for those in our care and staff alike' (DH 2012a, p.13).

However, it is also important to note that 'Compassion: care given through relationships based on empathy, respect and dignity ... also described as intelligent kindness' (DH 2012a, p.13) is also a fundamental professional responsibility.

This professional responsibility of every nurse to communicate effectively and compassionately is an explicit standard of *The Code* (NMC 2015):

'Make the care of people your first concern, treating them as individuals and respecting their dignity.

- You must listen to the people in your care and respond to their concerns and preferences.
- You must make arrangements to meet people's language and communication needs.
- You must share with people, in a way they can understand, the information they want or need to know about their health.
- You must uphold people's rights to be fully involved in their care'.

There are four essential features of maintaining dignity in communication.

- 1 *Attitude*. Being aware of the other person's experience, our attitudes towards them and how this affects the care provided.
- 2 *Behaviour*. Being respectful and kind, asking permission, giving your full attention and using understandable language.
- 3 *Compassion*. Being aware of and in touch with our own feelings and 'acknowledging the person beyond their illness' (Chochinov 2007, p.186).
- 4 *Dialogue*. Being able to demonstrate an appropriate knowledge of the patient's history, experience and family context (Webster and Bryan 2009). You might usefully make educated guesses about the likely experiences of the patient, for example 'It must have been difficult to have received the news at that point in your life'.

These qualities are recognized as so essential to nursing practice that the Francis Report (DH 2013) recommended that an aptitude test to explore an individual's qualities of caring and compassion should be included in the selection process of aspiring nurses.

Confidentiality

'Information provided in confidence should not be used or disclosed in a form that might identify a patient without his or her consent' (DH 2003, p.7). *The Code* (NMC 2015) states that every nurse must respect people's right to confidentiality, ensuring they are informed about how and why information is shared by those

who provide their care. In addition, it is a legal obligation and should be part of the terms and conditions of employment of any healthcare professional (DH 2003).

However, if there is a concern that an individual may be at risk of harm, this must be appropriately disclosed following the guidance of the organization in which the nurse works.

Consent

One of the principles that guides the NHS in the Constitution is: 'NHS services must reflect the needs and preferences of patients, their families and carers. Patients, their families and carers where appropriate will be involved and consulted on all decisions about their care and treatment' (DH 2012b).

The NHS Constitution (DH 2012b) also states that a patient has the right to accept or refuse treatment that is offered and not be given any physical examination or treatment unless they have given valid consent.

The Code (NMC 2015) states that nurses have a responsibility to ensure they gain consent and that they must:

- gain consent before treatment or care starts
- respect and support people's rights to accept or decline treatment or care
- uphold people's rights to be fully involved in decisions about their care
- be aware of the legislation regarding mental capacity
- be able to demonstrate that they have acted in someone's best interests if emergency care has been provided.

For consent to be valid, it must be given voluntarily by a competent person who has been appropriately informed and who has the capacity to consent to the intervention in question (NMC 2013). This will be the patient or someone authorized to do so under a Lasting Power of Attorney (LPA) or someone who has the authority to make treatment decisions as a court-appointed deputy (DH 2009).

The validity of consent does not depend on a signature on a form. Written consent merely serves as evidence of consent. Although completion of a consent form is in most cases not a legal requirement, the use of such forms is good practice where an intervention such as surgery is to be undertaken (DH 2009).

If there is any doubt about the person's capacity to make a decision about consent, the nurse should determine whether or not the person has the capacity to consent to the intervention and secondly that they have sufficient information to be able to make an informed decision (DH 2009). This should be done before the person is asked to sign the form. Documentation is necessary and the nurse should record all discussions relating to consent, details of the assessment of capacity, and the conclusion reached, in the patient's notes (NMC 2008).

Obtaining consent is a process and not a one-off event (NMC 2013). Usually the person undertaking the procedure should be the person seeking to obtain consent. There may be situations when a nurse has been asked to seek consent on behalf of other staff. Providing the nurse has had training for that specific area, they may seek to obtain consent (NMC 2013).

As part of the nursing assessment, the nurse needs to establish if the person can understand the verbal communication, what they are being consented for and that they are able to read or write or communicate their decision in a reliable manner. If they are unable, they may be able to make their mark on the form to indicate consent by any reasonable means. If consent has been given validly, the lack of a completed form is no bar to treatment, but a form can be important evidence of such consent (DH 2009). If the patient is unable to consent because they do not understand the information or are unable to communicate their decision, the Mental Capacity Act 2005 allows decisions to be made in the patient's best interest. If the consent is about medical treatment then a best interest decision may be required; this will depend on the seriousness of the decision (Mental Capacity Act 2005).

Consent may be expressed by a person verbally, in writing or by implication (NMC 2013); an example of implied consent would be where a person, after receiving appropriate information, holds out an arm for their blood pressure to be taken. The nurse should ensure that the person has understood what examination or treatment is intended, and why, for such consent to be valid (DH 2009). It is good practice to obtain written consent for any significant procedure, such as a surgical operation or when the person participates in a research project or a video recording (NMC 2013).

A competent adult may refuse to consent to treatment or care and nurses must respect that refusal (NMC 2013). Where a patient declines an intervention, consideration must be given to the patient's capacity. If the patient is deemed to have capacity and refuses care, this needs to be recorded clearly in their notes.

Equality and diversity

An additional aspect of communication and psychological support from the legal perspective is to ensure that it is as equitable as possible. The Equality Act (2010) reinforces the duty to ensure that everybody, irrespective of their disability, sex, gender, race, ethnic origin, age, relationship status, religion or faith, has equal access to information and is communicated with equitably. This means, for example, that provision is necessary to meet the information needs of blind and partially sighted people (Section 21 of the Disability Discrimination Act, October 1999).

People from black and minority ethnic (BME) groups constitute 14% of the population in England and Wales (Jivraj 2012). Originating primarily from the Caribbean, Africa, South Asia and China, the majority of people falling into this group continue to maintain strong cultural links with their countries of origin even after being resident in the United Kingdom for several generations.

Communication needs are individual and information requirements are also culturally sensitive. People may hold different beliefs about why they have developed an illness, for instance thinking that they are being punished for something that they may or may not have done (Dein 2006, McEvoy et al. 2009).

Medical language is full of technical vocabulary and jargon which is often difficult to comprehend even for native English speakers. Macdonald (2004) suggests that people from BME groups may often come from communities where the opportunity for education is limited, thus making it difficult for them to comprehend the information that has been provided, particularly when their first language is not English. Macdonald (2004, p.131) states that 'sentences should be short, clear and precise'.

Patients from different ethnic backgrounds will often take a family member to health-related appointments. The family member is there to assist in the dialogue between the patient and the medical/nursing practitioner. Macdonald (2004) discusses the fact that communication is a two-way process and suggests that for it to be effective, the information provided needs to be patient focused. The process of translation and interpretation is never without potential problems, however, and it is important to try to find more effective ways of ensuring that the information provided is not misunderstood or misinterpreted (McEvoy et al. 2009).

In addition to the written word, there are also reputable telephone helplines that can facilitate the translation from one language to another. It is good practice that these services be utilized rather than relying on family or friends of the patient (Macdonald 2004). The reason for this is that the latter may not fully understand what they are being asked to translate, or might misconstrue or misrepresent what is being said (Macmillan Cancer Relief 2002).

Patients who are elderly may need additional support to be able to make informed decisions about care. Older patients are more likely to have hearing or sight loss although this should not be assumed. This needs to be considered when communicating as well as considering the patient's dignity. If a patient is hearing impaired there may be a temptation to shout, but in a busy clinical environment this might breach a patient's right to confidentiality and to be treated with dignity. Information provided in small print

may be inappropriate and inaccessible for the patient, impacting on their ability to make an informed choice.

Patients with dementia may have additional communication needs, and there is a danger of assuming that because a person has dementia they will not be able to make decisions for themselves. Daniel and Dewing (2012) suggest that this idea needs to be avoided as it fails to meet the requirements of the Mental Capacity Act (2005). The Mental Capacity Act (2005) makes it clear that consent must be decision specific and, as such, each significant decision needs to be assessed. If a patient with dementia has communication issues, it is important to work with them and their family to maximize their ability to be involved in decision making even when the person is assessed as lacking capacity. The Mental Capacity Act 'promotes the autonomy and rights of an individual who lacks decision-making capacity' (Griffith and Tengnah 2008, p.337).

In communication with people who have a learning disability, 50–90% experience communication difficulties, such as impaired speech, hearing or sight loss (Jones 2002, p.566). It is important to know what tools can be used to support this patient group to communicate their needs whilst receiving healthcare, the most important of which are the communication skills of the person providing the care (Chambers 2003). Many patients with learning disabilities will have a hospital or My Health passport which will include information on how best to communicate with the person. The person with a learning disability may have a communication book, which is full of symbols which they can use to communicate their needs.

With any patient who has additional communication needs, it is important to work with the people who know them well such as family, carers or other professionals. The family, carers and friends will be able to interpret the non-verbal communication more easily and so can support nurses in providing care; carers should be seen as partners in the caring process.

Mental Capacity Act (2005)

The Code also makes explicit the responsibility to be aware of the legislation regarding mental capacity, a factor that can have a significant impact on communication. The Mental Capacity Act (2005) sets out clear guidance and has produced a code of practice to support professionals working with people who may have impairment in their capacity.

The first principle of the act is the presumption of capacity and so we must presume a person has mental capacity unless they:

- are unable to understand information given to them to make choices
- can understand but are unable to retain the information
- are unable to weigh up and relate the information accurately to their situation
- are unable to communicate their wishes or choices (by any means) (BMA 2007).

If any of these factors are in question, the Mental Capacity Act (2005) recommends that determining an individual's decision-making capacity is best achieved through multidisciplinary assessment. A separate assessment of capacity must take place for every decision involving the individual. It is important, however, to ensure that the person is involved as much as they can be in the decision making and that all reasonable steps have been made to support the patient to make the decision for themselves (Dimond 2008). Brady Wagner (2003) specifies four key areas that need to be fulfilled in order to have the capacity to make a decision.

- 1 Understanding the diagnosis and other information given regarding treatment and non-treatment options.
- 2 Manipulating those options and consequences in relation to one's personal values and goals.
- 3 Reasoning through a decision.
- 4 Communicating the preference/decision.

Table 4.1 NHS *Knowledge and Skills Framework*: four dimensions of communication competence

1	2	3	4
Establish and maintain communication with other people on routine and operational matters	Establish and maintain communication with people about routine and daily activities, overcoming any differences in communication between the people involved	Establish and maintain communication with individuals and groups about difficult or complex matters, overcoming any problems in communication	Establish and maintain communication with various individuals and groups on complex potentially stressful topics in a range of situations

Source: Adapted from NHS Knowledge and Skills Framework and Development Review Guidance. Working draft, v6.0 (2003).

The mental capacity of an individual needs to be considered in any communication but particularly if it involves the patient making a decision about treatment or care options and in respect of consent. The assessment as to whether an individual has capacity or not can be a complex one and it is important to ensure that the principles of the Mental Capacity Act (2005) are applied in any decisions relating to a patient where there is a concern about impairment in the functioning of mind or brain and as such the person's capacity to communicate their consent is questioned (Daniel and Dewing 2012). At any time before making any referral or sharing patient information to enable access to further support, it is important that the patient fully understands and consents and, where this is not possible, the decision may need to be made in the patient's best interests, ensuring the principles of the Mental Capacity Act (2005) are applied.

There are some patient groups in which the issue of communication and consent may be more challenging, particularly when the person does not wish to engage in the care or treatment. If, for instance, a person with dementia was indicating by their non-verbal communication that they did not want to be treated but the treatment was required, in an adult with capacity this would be considered withdrawal of implied consent. In these situations where the adult has been assessed as lacking capacity and treatment is to be given, how the person is communicated with during this process is really important. The patient may feel threatened and anxious and so explaining what is happening, keeping calm and talking in a quiet voice may help facilitate the care without causing more distress to the patient.

Competencies

Communication is such an essential aspect of the role of anybody in healthcare that the NHS *Knowledge and Skills Framework* specifies four levels of skill in communication (Table 4.1). Nurses are expected to be competent as a minimum to level 3. This is a baseline and much work has been done in developing programmes to advance communication skills further.

The consistency of the success of training interventions has been widely discussed (Chant et al. 2004, Heaven et al. 2006, Schofield et al. 2008). The NHS Connected programme was developed initially to develop further the skills of key members of multidisciplinary teams in cancer care (Fellowes et al. 2004); this work has now been merged with the Health and Social Care Information Centre (<http://systems.hscic.gov.uk/>).

Ongoing development of communication skills should include learning how to negotiate barriers to good communication in the clinical environment, tailoring and individualizing communication approaches for different patients, conflict resolution and negotiation skills (Gysels et al. 2005, Roberts and Snowball 1999, Schofield et al. 2008, Wilkinson 1991).

Courses with a behavioural component of communication training, that is, role-playing situations in the classroom, are preferable as this is indicated to influence effectiveness (Gysels et al. 2005).

If an issue appears to be beyond the scope of practice of the nurse, it is essential that further advice and help are sought to manage a patient's psychosocial needs. Self-care and supervision are key factors in maintaining the ability to support other people. This will mean having a balanced lifestyle, knowing self, and having relevant accessible support structures in place.

Pre-procedural considerations

Time

In an acute hospital environment time is always pressured. This has an impact on communication unless steps are taken to create time for effective, supportive communication to take place. From the patient's perspective, they need to know that they have the nurse's attention for a set period of time. It is therefore essential to be realistic and proactive with the patient to negotiate a specific conversation for a prescribed length of time at a prearranged point in the day. It is important to be realistic but also to keep to the arrangement, otherwise there is the potential for the patient to consider that their psychological needs are not important (Towers 2007).

Environment

Conversations in a hospital environment can be very difficult, especially if privacy is sought. However, there are actions that can be taken to make the environment as conducive as possible to enable supportive communication to take place (Towers 2007) (Box 4.3). This preliminary work might seem

Box 4.3 Making the environment conducive to supportive communication

- Can the patient safely and comfortably move to a more suitable area to talk with more privacy?
- Do they wish to move?
- Do they wish other people/members of the family to be there?
- Clear a space if necessary, respecting the patient's privacy and property.
- Check whether sitting on one side or another is preferable to them.
- Remove distractions, for example switch off a television, with the patient's permission.
- Is the patient able to sit comfortably?
- Will the patient be too hot or cold?
- As far as possible, choose a seat for yourself that is comfortable, and on the same level as the patient.
- Position your seat so you can have eye contact with each other easily without having to turn significantly.
- If you are in an open area on a ward, draw the curtains (with the patient's permission), to give you some privacy. Obviously, this does not prevent sound transfer and it is worth acknowledging the limitations of privacy.

Communication with a patient that is compassionate and supportive in a clinical environment cannot be described as a linear process but certain principles can increase its effectiveness.

Principles Table 4.1 Communication

Principle	Rationale
Consider whether the patient is comfortable and doesn't need pain relief or to use the toilet before you begin.	Pain and the medication used to treat it and other distractions and discomforts may limit a patient's ability to reason and concentrate. E
Protect the time for psychosocial focus of conversation. This involves telling other staff that you don't wish to be disturbed for a prescribed period.	Patients may observe how busy nurses are and withhold worries and concerns unless given explicit permission to talk (McCabe 2004, R3b).
Set a realistic time boundary for your conversation at the beginning.	You may only have 10 minutes and therefore you need to articulate the scope of your available time; this will help you to avoid distraction and give your full attention during the time available. E
Introduce yourself and your role and check what the patient wishes to be called.	This helps to establish initial rapport (Silverman et al. 2013, C).
Spend a short time developing a rapport and indicating your interest in the patient, for example comment on a picture by the bedside.	Patients want to feel known. P
Be ready to move the conversation on to issues that may be concerning the patient.	Be aware that some patients may stay with neutral topics as the central focus of the conversation and withhold disclosure of psychosocial concerns until later in a conversation (Silverman et al. 2013, C).
Suggest the focus of conversation, for example 'I would like to talk about how you have been feeling' or 'I wondered how you have been coping with everything'.	This indicates to the patient that you are interested in their psychological issues. E
Respond to and refer to cues.	Patients frequently offer cues – either verbal or non-verbal hints about underlying emotional concerns – and these need to be explored and clarified (Levinson et al. 2000, R3b ; Oguchi et al. 2010, R3b).
Responding to cues: 'I noticed you seemed upset earlier. I have 10 minutes to spare in which we can talk about it if you wish' or 'You seem a little frustrated. Is now a good time to talk about how I can help you with this?'	
If the patient does not wish to talk, respect this (it is still important that you have offered to talk and the patient may well wish to talk at another time).	The patient may not wish to talk at that moment or may prefer to talk to someone else. E
Ask open questions: prefix your question with 'what', 'how'.	Open questions encourage patients to talk (Hargie 2011, R5).
Use closed questions sparingly.	If patients have a complicated issue to discuss, closed questions can help them be specific and can be used for clarification as well as when closing dialogue (Hargie 2011, R5).
Add a psychological focus where you can, for example 'How have you felt about that?'	This will help elicit information about psychological and emotional issues (Ryan et al. 2005, R3a).
Listen carefully and feed back your understanding of what is being said at opportune moments.	Listening is a key skill – it is an active process requiring concentration, verbal and non-verbal affirmations (Silverman et al. 2013; Wosket 2006, R5).
Be empathic (try to appreciate what the other person may be experiencing and recognize how difficult that is for them).	Empathy is about creating a human connection with your patient (DH 2012a, C ; Egan 2013, R5).
Allow for silences.	This can give rise to further expression and allows useful thinking time for yourself and the patient (Silverman et al. 2013, C).
Initially avoid trying to 'fix' people's concerns and the problems that they express. It might be more powerful and important to simply sit, listen and show your understanding.	As an individual is listened to, they may feel comfort, relief and a sense of human connection essential for support (Egan 2013, R5).
Ask the patient how they think you may be able to help them.	The patient will know what they need better than you do. E
Avoid blocking (Box 4.4).	Blocking results in failing to elicit the full range of concerns a patient may have (Back et al. 2005, R3a).
When you are nearing the end of the time you have agreed to be with the patient, let the patient know; that is, mention that soon you will need to stop your discussion.	The patient can find this easier to accept if you have clearly expressed the time you had available in the first place (Towers 2007, R5).

(continued)

Principles Table 4.1 Communication (continued)

Principle	Rationale
Acknowledge that you may not have been able to cover all concerns and summarize what has been discussed, checking with the patient how accurate your understanding is.	The patient can correct any misinterpretations and this can lead to satisfactory agreement about the meeting. It also signifies closure of a meeting (Hargie 2011, R5).
If further concerns are raised at this point, you will need to make it clear that you cannot support them at the current time. Let the patient know when you or other staff may be available to talk again, or where else they may get further support.	Clarity and honesty are important, as is working within boundaries. Knowing the limits of your time and expertise will help to prevent confusion about where the patient can receive types of support. E
Agree any action points and follow up as necessary. If needs remain unmet, offer support from a clinical nurse specialist or a counselling service, if available. You must discuss what this means and be realistic with regard to waiting times. Consent from the patient for any further referral is essential (unless you consider the patient to be at risk).	Having made a suitable assessment, you can involve further support if appropriate. E
Document your conversation, having agreed with the patient what is appropriate to share with the rest of the team.	It is essential to document your conversation so other members of the team are informed and to meet your professional requirements (NMC 2015, C; NMC 2010, C).
Reflect upon your own practice.	You may have unintentionally controlled the communication or blocked expression of emotion. Reflection will increase your self-awareness and help develop your skills. E
Consider your own support needs. If you are affected by any discussions you have had, seek discussion with supportive senior members of staff or consider debriefing and/or supervision.	Clinical supervision supports practice, enabling registered nurses to maintain and improve standards of care (NMC 2008, C).

Box 4.4 Characteristics of blocking behaviours

Blocking can be defined as:

- failing to pick up on cues (ignoring emotional content)
- selectively focusing on the physical/medical aspects of care
- premature or false reassurance, for example telling people not to worry
- inappropriate encouragement or trivializing, for example telling someone they look fine when they have expressed altered body image
- passing the buck, for example suggesting it is another professional's responsibility to answer questions or sort out the problem (doctors or counsellors, for example)
- changing the subject, for example asking about something mundane or about other family members to deflect the conversation away from issues that may make the nurse feel uncomfortable
- jolly along, for example 'You'll feel better when you get home'
- using closed questions (any question that can be answered with a yes or a no is a closed question).

Communicating with those who are worried or distressed

Definition

Interpersonal communication is the process of discussion between healthcare professionals and patients and carers, which allows patients and carers to explore issues and arrive at decisions (NICE 2004).

Related theory

Patients will naturally have an emotional response to serious illness. At its most mild, this is seen as sadness and worry. At its most serious, however, patients experience severe psychological responses such as adjustment reactions, anxiety states or depression (NICE 2004). This is because illness changes lives, or at least threatens to. Nurses must know how to respond, therefore, to sad and worried patients. The ability to listen fully is perhaps the most frequently used skill or competence of a nurse. Noticing when a patient is worried, listening carefully to their concerns without interrupting, and responding helpfully are components of effective communication with an individual who is distressed. When health workers have such skills, patient outcomes are improved and staff feel more satisfied with their work (Fallowfield and Jenkins 1999, Fellowes et al. 2004, Ong et al. 2000, Razavi et al. 2000, Stewart 1996, Taylor et al. 2005).

Before learning how to listen and respond to patient worries, it is worth knowing about unhelpful communication habits. Health workers often focus on physical and practical concerns but ignore the emotional issues of patients (Booth et al. 1999, Maguire et al. 1996). This is despite the fact that patients hint at their worries (Uitterhoeve et al. 2010). It seems that health workers are eager to give advice, reassurance and information before hearing all the patient's concerns (Booth et al. 1999). This rush to fix problems may be one cause of incomplete listening.

Evidence-based approaches

Research evidence suggests that nurses and other health workers should listen to all of the concerns, even those that have no resolution (Booth et al. 1999, Pennebaker 1993). Nurses should enquire about the resources (help) that patients have around them and patients should be given an opportunity to describe for themselves what would help, before the health worker offers advice, information or reassurance (Booth et al. 1999, Tate 2010). It is also

known to be helpful for health workers to use a structure in their own minds to organize their thoughts and questions (Silverman et al. 2013). Patients or their carers will often have disorganized thoughts because their thinking is clouded by emotions. A helpful health worker, on the other hand, needs to be calm, organized and sensitive. The SAGE & THYME model (Connolly et al. 2010) presented below is one way for nurses and other health workers to conduct a structured and evidence-based conversation. The model suggests a sequence of sensitive questions which allow the health worker to hear about strong emotions and remain calm themselves.

Pre-procedural considerations

Patients need privacy to discuss emotions and worries: they also need time. Nurses, therefore, should create the conditions for patients to describe their worries. Nurses are often busy because there are many competing demands for their time, yet proper listening requires time and privacy. Nurses create time and privacy to dress a wound. They dress wounds expertly, in a logical and sequential way which has been carefully learned and practised. Listening to the worries of the patient also needs uninterrupted time and a logical sequence. This skill must also be learned and mastered if the nurse is to become an expert listener.

Principles Table 4.2 SAGE & THYME

Principle	Rationale
SETTING – think first about the setting. Can you respond to this hint from the patient now or should you return when you and they can protect ten minutes? Can you create some privacy? Would they like to talk?	Patients notice that nurses are busy and withhold worries unless given an explicit opportunity to describe their concerns (McCabe 2004, R3b). It is important to create the setting or environment within which patients or carers can disclose their concerns (Hase and Douglas 1986, R5).
ASK – ask the patient what is concerning or worrying them (don't worry yourself about problems that you cannot solve – just listen).	Patients frequently hint about their underlying concerns. These hints need to be noticed and responded to (Oguchi et al. 2010, R3b). Asking specifically about emotions encourages patients to describe psychological and emotional issues (Ryan et al. 2005, R3a). Specific questions about psychological concerns are important (Booth et al. 1999, R3b ; Maguire et al. 1996, R3b).
GATHER – gather all of the concerns, not just the first few (ask if there is something else). Repeat back to the patient what you have heard (this proves that you are listening) and make a list of all the concerns (actually write them down).	Listening is an active process, requiring concentration, silences and verbal affirmation that you hear what is being said (Silverman et al. 2013, R5 ; Wosket 2006, R5). It is important to hear all the patient's concerns, to summarize and check that you have understood correctly (Maguire et al. 1996, R3b ; Pennebaker 1993, R3b).
EMPATHY – say something which suggests that you are aware of the burden of their worry, such as: 'I can see that you have a lot to be worried about at the moment'.	Empathy is about creating a human connection with your patient (Egan 2013, R5). Empathy shows that you have some sense of how the patient is feeling (Booth et al. 1999, R3b ; Maguire and Pitceathley 2002, R3b).
TALK – ask who they have to talk to and what support they have. Make a list of all the people who would help. 'Who do you have that you can talk to about your concerns?'	Patients commonly rely on family and friends for support (Ell 1996, R5). Good social support is associated with enhanced coping skills for the patient (Chou et al. 2012, R3b). Supportive ties may enhance well-being by meeting basic human needs for companionship, intimacy and a sense of belonging (Berkman et al. 2000, R5). It is helpful to know what social support surrounds the patient (Stewart 1996, R5).
HELP – ask 'How do these people help?'	People's social networks may help them reinterpret events or problems in a more positive and constructive light (Thoits 1995, R5). The support from family and friends commonly involves reassurance, comfort and problem solving (Schroevers et al. 2010, R5).
YOU – ask the patient: 'What do you think would help?' or 'What would help?'	It is helpful to use a style of problem solving which seeks the patient's own solutions first (Booth et al. 1999, R3b ; Tate 2010, R5).
ME – ask the patient: 'Is there something you would like me to do?'	It is helpful to use a negotiated style of communication which gives the patient control over what, if any, professional help they receive with their concerns or dilemmas (Fallowfield and Jenkins 1999, R3b).
END – summary and strategy. 'I now know what you are worried about and the support you have. I know what you think would help and what you want me to do. I'll get on with that and come back to you when I can. Is it OK to leave it there for now?'	It is important to know how to summarize and close an interaction (Bradley and Edinberg 1990, R5).

Problem-solving table 4.1 Prevention and resolution (Principles table 4.2)

Problem	Action
DIRECT REQUESTS Patients often have concerns at the same time as direct requests or direct questions. When listening for all the concerns, it is easy to be distracted by the direct request. The following is an example: 'I keep hearing different things and it makes me feel as though nobody really knows what is happening. That's scary for me. Am I having this scan or not?'	It is tempting to deal only with the direct request (about the scan) and to ignore the other cues and concerns (different messages, nobody knows what is happening, scary). However, the direct request cannot be ignored either. A clear-thinking nurse will notice both the direct question and the other cues and concerns. 'I hear that you are scared, that you feel that nobody knows what is going on, that you are getting different messages and that you want to know about the scan. I promise to find out about the scan; would you prefer me to do that straight away or can I come back to that once we've discussed you feeling scared and that nobody knows what is going on?' In this way, the direct question is addressed but the process of gathering concerns continues. You are back in SAGE because you have 'parked' the request about the scan. Alternatively, you find out immediately about the scan and then return to the other concerns.
MISTAKING THE 'Y' OF THYME Some learners of the SAGE & THYME model mistake the You of THYME by wrongly interpreting this as a challenge to patients: 'What can you do for yourself?'	This is not recommended. It risks the unfair suggestion that the patient is not doing enough for themselves. Nurses should practise hearing themselves asking the correct questions as follows: 'What do <i>you</i> think would help?' and 'Is there something else that would help?'. The questions relate to the patient's own ideas about what could be helpful: 'What do <i>you</i> think would help?' or 'What would help?'. These questions are important because research suggests that we should seek the patient's own ideas about what would help before we ask about what we can do to help.
NOBODY IN THE 'T' OF THYME Some patients will have no support. No people in their lives to help them think through or cope with the difficulties they face. This becomes obvious in the 'T' question in THYME ('Who do you have to talk to about your worries/concerns?').	In these circumstances, there is no purpose asking the 'H' question ('How do these people help?'). Move straight on to the next question: 'What do you think would help?'

Informing patients

Here we cover the principles of providing information to patients and discussing procedures to be carried out.

Related theory

Research conducted by the Picker Institute (Ellins and Coulter 2005) shows that 80% of people actively seek information about how to cope with health problems. Information is of prime importance in helping to support people in the decision-making process, particularly when they are vulnerable and feeling anxious. It is important that high-quality, reliable and evidence-based information should be accessible to patients, their relatives and carers at the right time, making it an integral part of their care (DH 2008a). This is reiterated in the White Paper *Our Health, Our Care, Our Say* (DH 2006), which states that 'people with a long-term condition and/or long-term need for support – and their carers – should routinely receive information about their condition' and the services available to them. Information prescriptions represent good practice for supporting the information needs of individuals (DH 2009). *High Quality Care for All* (DH 2008b) requires NHS organizations to provide accessible information to patients who have a learning disability.

Evidence-based approaches

With any procedure, it is essential that the patient (assuming consciousness and ability to make rational decisions) is psychologically prepared and consented. This requires careful explanation and discussion before a procedure is carried out.

As nurses, we can become so familiar with procedures that we expect them to be considered 'routine' by our patients. This can prevent us from providing thorough and necessary information

and gaining acceptance and co-operation from our patients. We therefore need to avoid assuming that repetitive or frequent procedures do not require consent, explanation and potential discussion, for example taking a temperature.

It is important to consider giving information in small amounts and checking whether the patient understands what has been said after each part has been explained. Keep language simple and clarify common and complex medical terms, for example 'cannula', 'catheter'.

Check frequently whether the patient wishes you to continue to provide them with the same level of information. If confusion is arising, consider whether you are providing too much detail or using too many medical terms. Be aware whether the patient is paying attention or appears anxious (e.g. fidgety/non-attentive behaviour). Do not ignore these cues: name them. For example: 'I notice you seem a little anxious while I am describing this ...' or 'You seem concerned about the procedure, what can I do to help?'. This recognition of behaviour will help to fully explore and support the patient's concerns.

Prior to starting, establish how the patient can communicate with you during the procedure; for example, confirm that they can ask questions, request more analgesia or ask for the procedure to stop (if this is realistic).

Information must be presented accurately and calmly and without 'false reassurance'; for example, do not say something 'will not hurt' or it 'will not go wrong', when it might. It is better to explain the risk and likely outcome. Explain that working with the nurse and co-operating with instructions are likely to improve the outcome and that every effort will be made to reduce risk and manage any problems efficiently.

Respect any refusal unconditionally; however, you may wish to explore the reasons for refusal and explain the potential (realistic)

consequences. Document carefully and discuss with the multi-disciplinary team. If a patient has had a procedure before, do not assume that they are fully aware of the potential experience or risks involved, which may well have changed.

Attention to good communication, honesty, confidence and calmness will help to reassure the patient, thus gaining their compliance and improving the potential outcome (Maguire and Pitceathly 2002).

Giving the right amount of information is important; for example, it has been shown that getting the level of information wrong (too much or too little) at diagnosis can significantly affect the subsequent level of coping (Fallowfield et al. 2002). Getting the level right can be achieved by simply asking how much people want to know and frequently checking if the level of information is satisfactory for the individual.

Principles of giving information to a patient

The term 'giving information' implies that the healthcare professional's agenda is uppermost and results in a paternalistic model of care (Redsell and Buck 2009). Whilst this approach can at times be justified (e.g. in an emergency situation), wherever possible, it is important to allow patients the opportunity to be a partner in their care and to be involved in decision making (DH 2012b). In addition, the principles of 'facilitative' communication (Wilkinson 1991) remain relevant when giving information; this type of conversation is still a dialogue – therefore patients should be allowed time to speak, be listened to and to contribute.

There are many different theories and models for giving information to patients, but the following paragraphs are based on the principles of giving information taken from self-management and person-centred approaches to care.

Giving information implies that there is a message to be shared and someone who is to receive it. This means that the person receiving the information is able and willing to have information given to them. The first step to giving information is to assess the patient's readiness and ability to hear what is going to be said.

It is wise to ensure patients are comfortable and able to absorb information, so attend to analgesia, and allow them to visit the toilet if necessary. It is helpful to outline the purpose of the conversation at the beginning, before any information is shared – this will enable the patient to begin to actively listen, which requires concentration and is tiring. Therefore, make sure that the session is brief and that as much verbal information as possible is supplemented and reinforced with written and visual resources.

Patients should be asked their preferred role in the decision-making process before information is given, so that the style of delivery can be tailored to their preferences and wishes (Alexander et al. 2012, Redsell and Buck 2009). In addition, many patients will be well informed about their condition or have existing understanding or knowledge, so it is important to establish and assess patients' existing knowledge and ability/capacity to learn something new (Price 2013).

Information should be given in 'chunks' or small sections (Smets et al. 2013), pausing after a key point to allow the information to be absorbed and processed, and giving the patient the opportunity to respond, ask questions or make comments.

During the conversation, remember to use empathic statements (Egan 2013) and encourage the patient to express their worries and concerns. Giving information is more than a cognitive exercise – it also includes relational, affective aspects (Smets et al. 2013) and therefore the principles of supportive communication apply, especially the need to notice, listen and respond to patients' cues and concerns.

Principles Table 4.3 Information giving

Principle	Rationale
There are benefits if a patient is well informed.	Informed patients can better manage their health, illness, treatment and medication. Informed patients have lower rates of depression and anxiety. Informed patients have lower levels of pain, e.g. if they understand the causes of pain and the principles of pain management.
Be honest when giving information.	Patients value honesty from their healthcare professionals – it increases a sense of trust.
Patients can find it difficult to absorb information.	Anxiety, distressing symptoms, fear and denial can affect a person's ability or willingness to listen and retain information. Write down information so that there is a record of the conversation or instructions which can be followed. Keep the written information simple. Avoid using jargon or technical language or abbreviations when giving information to patients. If appropriate, use pictures, e.g. to explain anatomy. Colours can be used to colour code information if this would be helpful.
Information should be paced.	Encourage a relative or friend to be present whilst information is being given – so that someone else is hearing what is being said and can support the patient later. Giving too much information in one session can be overwhelming and prevent a patient from remembering what was said. Never rush information giving – patients will feel overwhelmed and exhausted. If you are short of time, give a small part of the information.
Chunk and check.	Observe the patient closely – read their non-verbal cues and, if necessary, stop and allow them to process what they have been told. Divide the information into small sections. Check that the patient has understood before moving on, e.g. ask 'Do you understand?', 'Is there something you would like to ask at this point?', 'Would you like to explain to me what I have just shared with you?'.

(continued)

Principles Table 4.3 Information giving (continued)

Principle	Rationale
Encourage the patient to repeat back to you what you have explained.	You could ask the patient to explain what they are going to tell their family when they get home – this will help you to identify whether they have misunderstood anything you have told them.
Allow the patient to ask questions.	Listen carefully to the questions the patient asks you – these can indicate where misunderstandings have occurred.
Monitor the patient's response and non-verbal cues.	Receiving information is tiring. Be prepared to pause or stop the session and allow the patient time to absorb and process what has been explained.
Show empathy.	Remember that the information might have an emotional impact on the patient – acknowledge this and be supportive.

Pre-procedural considerations

Patient information

Patient information in this context refers to information about disease, its treatment, effects and side-effects, and the help and support available to people living with a chronic condition, their relatives and carers.

When writing information for patients and carers, consideration should be given to information already available on the chosen topic. The purpose of the information may be to:

- address frequently asked questions
- inform about a treatment or service
- reduce anxiety
- give reference material.

Ideas should be shared with other members of the team or clinical unit, and patients and carers involved, from the outset. The content of the material should be accurate and evidence based and meet the current Department of Health and NHS Litigation Authority requirements.

When writing the information, everyday language should be used as if speaking face to face and avoiding the use of jargon; 16% of adults in England do not have the literacy levels expected of an 11-year-old (DfES 2003). However, there is no need to be patronizing or use childish language. The Plain English campaign (www.plainenglish.co.uk) offers a downloadable guide entitled *How to Write Plain English*.

When producing written information for patients, it may be worth considering accessibility for patients who may be non-verbal or have a learning disability. An easy-to-read, information resource with pictures and images and few words can support people with learning disabilities to have a greater understanding of information and support their decision making.

Information should be dated and carry a planned review date. Sources of information should be acknowledged. This gives the reader confidence in the material.

The provision and production of information must take into account diversity in ethnicity, culture, religion, language, gender, age, disability, socio-economic status and literacy levels, as stated in the Department of Health publication *Better Information, Better Choice, Better Health* (2004). See Principles table 4.4: Giving information about a clinical procedure for the provision of information.

Information should be ratified according to local trust policy. Where a trust does not produce patient information materials to meet specific patient needs, suitable alternative sources of information should be sought.

Other sources of information

Patients and their families may benefit from information and support available in the wider community, away from the environment of statutory health services. Sources of additional information include:

- *disease-specific national charities*, for example the Multiple Sclerosis Society or the British Heart Foundation: these organizations produce written material in booklet and fact sheet format, as well as having websites
- *the 'illness memoir' and internet blogs*: personal accounts are easily accessible online and through bookstores. It may help patients to hear other people's stories as this can reduce the sense of isolation and powerlessness and promote hope (Chelf et al. 2001). It must be borne in mind that not everyone will benefit from these sources of information
- *peer support*: the therapeutic benefits of groups are extensively documented (NICE 2004) and most of the support charities will have a directory of local and national groups available.

Principles Table 4.4 Giving information about a clinical procedure

Principle	Rationale
Review the changing context of the patient's situation.	What may have been relevant before may now not be the same. People's circumstances and needs change. E
Prepare for discussion, ensuring you are familiar with the procedure, disease process, medication or other aspect of care to be discussed.	Accurate information giving is an essential part of nursing care. E
If possible, discuss the procedure some time before it is to be carried out for the first time. Provide the patient with leaflets, DVDs or videos, if available, so the patient has time to review the information at their own pace.	Give patients the opportunity to digest information in their own time (Lowry 1995, E). In certain groups it can be demonstrated to improve clinical outcomes, satisfaction, chances of meeting the targeted discharge date and quicker return to prior functional status (Lookinland and Pool 1998, R2b).
Introduce yourself.	Ensure the patient understands who you are and your role and specific aim. Promote patient satisfaction (Delvaux et al. 2004, R1b).

Principle	Rationale
Maintain a warm and approachable demeanour. Do not rush.	Promote patient satisfaction (Delvaux et al. 2004, R1b).
Explain that you have a procedure to carry out, considering privacy in giving information.	Promote dignity/preserve confidentiality (NMC 2015, C).
Name the procedure. Elicit, clarify and check the information received by the patient.	Promote understanding and patient satisfaction. E
Explain the procedure, avoiding the use of medical jargon. Be prepared to repeat information or rephrase until the patient understands. (If the patient doesn't understand, they haven't consented.)	Establish mutual understanding. Gain compliance with procedure: minimize risk (NMC 2015, C). Improve outcome (Fellowes et al. 2004, R1a). Help patients manage side-effects and adhere to care and treatment (Dwamena et al. 2012, R3a).
Confirm consent: ensure that the patient is happy for you to proceed. Allow the patient an opportunity to ask further questions or say no to the procedure. (If the patient fully understands what is involved, they may decide that they are not ready to proceed.)	Respecting the rights of the individual (NMC 2015, C). Obtaining consent correctly (NMC 2013, C).
Start the procedure, reiterating the main issues as you go along and keeping the patient updated on progress.	To maintain open dialogue and address issues and questions, as they arise. E
Make it clear when the procedure has finished and what has been achieved. Offer opportunity for discussion of implications, disclosing as much information as the patient wishes.	So that the patient is aware and has the information they need and want (Jenkins et al. 2001, R2b).

Communicating with those with specific psychological needs

Denial and collusion

Definitions

Denial is a complex phenomenon (Vos and Haes 2010) and can be considered a mechanism for slowing down and filtering the absorption of traumatic information, 'allowing for avoidance of painful or distressing information' (Goldbeck 1997, p.586).

Collusion is when two or more parties develop a shared, sometimes secret understanding, that may involve withholding information from another person. It is important that health professionals resist invitations to collude with inaccurate patient understanding (Macdonald 2004). It can be argued that collusion is consistent with some patients' wishes (Helft 2005) and can be a necessary protection against unbearable facts and feelings (Vos and Haes 2010, p.227).

Related theory

Diagnosis of any potentially life-threatening illness is experienced in many different ways and can cause strong emotional responses. Patients are likely to feel a degree of distress and experience a wide range of emotions that may be lessened if healthcare professionals (HCPs) are truthful and open with patients about their diagnosis and prognosis.

People may use denial as a way of coping when faced with frightening situations. Denial can be conscious or unconscious and is commonly recognized in cancer settings (Vos and Haes 2011).

Literature on denial tends to be focused within the cancer field and prevalence rates are difficult to assess. Vos (2008) found that most lung cancer patients displayed some level of denial, which increased over the course of the illness. This was considered to be a normal phenomenon and not a sign of disturbed coping (Vos 2008). Denial may be conscious or unconscious (Vos and Haes 2011).

Nurses can be unsettled by the presentation of denial as it creates uncertainty about levels of understanding, coping and engagement with treatment. Family members and nurses can collude with patient denial, perhaps as a means of protecting the patient or themselves from facing the full impact and pain of the situation.

Nurses need to be aware of the pitfalls of colluding with patient or family denial and consider how they may contribute to it.

As human beings, we live our lives in our own individual, unique ways and also deal with a life-threatening diagnosis in our own way. For some people, focusing on hope and cure is the priority, whilst for others it is first necessary to prepare themselves and their family for the possibility that their illness may be incurable. Denial is a complex, fluid process, as is living with a life-threatening diagnosis. Patients' understanding of what is happening to them can fluctuate from minute to minute.

Denial is not an 'all or nothing' phenomenon. A patient may accept his illness in the morning, but by evening deny that he has it (Dein 2005, p.251).

Medical and nursing staff, family members and patients may all be 'in denial' at some point – to protect either themselves or those they care about.

Evidence-based approaches

Assessment of denial

In order to try to understand as fully as possible the emotions that patients are experiencing and the resources they have for coping, a careful assessment of each patient's circumstances is important.

Nurses need to establish what information the patient has been given, before assuming that the patient is experiencing denial. We need to be sure that patients have been given adequate, digestible information, if necessary on several occasions.

It is helpful to view denial as a process (Vos and Haes 2011) and to see its expression along a continuum. This needs to be acknowledged in the assessment process.

Repeated assessments of denial may help us to understand how various factors might influence denial and to better understand its dynamic nature.

Complications

Balancing the reality of the illness with reasonable hope is often difficult for health professionals and caregivers (Kogan et al. 2013, Parker et al. 2010). When working with patients who we think are in denial, the challenge for healthcare professionals is not so much the confrontation of denial but rather the avoidance of collusion with it (Houldin 2000) as doing this offers the health professional the opportunity to avoid the distress.

Principles Table 4.5 Supporting a patient in denial

Principle	Rationale
Healthcare professionals should aim to provide honest information to patients with the use of good communication skills, to the depth and detail the patient requests.	This enables patients to have control over the rate at which they absorb and integrate news and information that may have life-threatening implications for them (Maguire 2000, R5).
Useful skills are those of listening, reflecting and summarizing.	This will establish a supportive relationship which in the future may provide the patient with the security to acknowledge the gravity of the information they have been given. E
If denial is affecting a treatment regime or decisions for the future, it may need to be gently challenged. This can be done by either questioning any inconsistencies in the patient's story or asking if at any point they have thought that their illness may be more serious.	These questions may help the patient get closer to knowledge they may already have about the seriousness of their illness. With the right support, they might be able to face their fears and be more fully involved in decisions about future care and treatment. E
If the patient remains in denial it shouldn't be challenged any further (Dein 2005).	'Confrontation, if pursued in an insensitive or dismissive way or in the absence of adequate trust and support mechanisms, may increase denial, may reduce treatment compliance, or may even precipitate a complete breakdown in the health care professional-patient relationship' (Goldbeck 1997, p.586).
The delivery of bad news and information giving needs to be recorded clearly. The degree to which the patient accepts the information is variable and needs to be respected and carefully documented.	Good communication can help prevent patients receiving mixed messages. E

Collusion can leave healthcare professionals, patients and relatives feeling confused. Recognizing collusion, challenging it and discussing our concerns with colleagues is important. Working with our multiprofessional team helps to improve communication and to ensure a collaborative approach to care. Drawing on the richness of experience of others can help.

Clinical supervision can provide a safe reflective space for healthcare professionals to explore their practice. It is an ideal place to explore the complex phenomenon of denial and collusion, and be supported with it.

Anxiety

Definition

Anxiety is a feeling of fear and apprehension about a real or perceived threat and may cause excessive worry and heightened tension, affecting important areas of normal functioning (NICE 2011). The source of the feeling may or may not be known (Kennedy Sheldon 2009).

Anatomy and physiology

Anxious feelings can result in physical symptoms related to the flight or fight response as the body responds to the threat, real or otherwise. The sympathetic nervous system releases adrenaline

that is responsible for an increase in heart rate and therefore palpitations and raised blood pressure, faster, shallower breathing (hyperventilation), dizziness, dry mouth and difficulty swallowing, relaxation of sphincters leading to an increase in urinary and faecal elimination, reduction in blood supply to the intestines leading to feelings of 'butterflies', knotted stomach and nausea, increase in perspiration as the body seeks to cool down the tense muscles, and musculoskeletal pains (particularly in the back and neck) (Powell and Enright 1990). These are all unpleasant physical symptoms for the patient and can escalate further if not managed at an early stage.

Related theory

There are a number of theories about anxiety, its causes and how to manage it (Powell and Enright 1990). To be effective in supporting and communicating with a patient with anxiety, it is necessary to know that there are three aspects of feeling anxious.

- *Bodily sensations.*
- *Behaviour:* how the individual behaves when faced with the fear, especially if the behaviour involves avoiding it.
- *Thinking:* this is the ideas, beliefs and mental pictures about what might happen in the situation feared (Powell 2009).

Principles Table 4.6 Supporting an anxious individual

Principle	Rationale
Listen to and incorporate individual needs and preferences to promote informed decision making about treatment and care.	If people feel in control they are likely to feel less worried (NICE 2011, C).
Be alert to the signs and symptoms of anxiety.	Early recognition and intervention may help to prevent worsening of symptoms. E
Encourage the patient to talk about the source of their anxiety if they can. Work openly to explore worries, information requirements and treatment options.	Patients may find some benefit from expressing their concerns and being heard. E
Listen and only when the patient has expressed all their concerns offer tailored information. Gentle challenging of misunderstanding about treatment, processes or outcomes may be beneficial if this is the source of the anxiety.	Information about a procedure, particularly an operation, can reduce anxiety and improve outcomes (Nordahl et al. 2003, R2b ; Scott 2004, R3a).

Principle

If the patient doesn't know why they are feeling anxious, encourage them to describe what is happening in their body, when it started, what makes it worse, what makes it better.

Ask the patient if they have had the feelings before. What has helped previously (coping mechanisms) and what do they think may help this time?

Rationale

Patient feels listened to and less alone, which may increase their sense of security and therefore reduce anxiety. **E**

The patient is encouraged to take control and apply their own coping mechanisms. **E**

Anxiety is a normal response to threatening events but can become a problem when it is frequent, exaggerated or experienced out of context (Blake and Ledger 2007). As levels of anxiety increase, awareness and interaction with the environment decrease, and recall and general function are also impaired (Kennedy Sheldon 2009). Anxiety can become a general and protracted problem, even when the immediate source of anxiety has abated.

Evidence-based approaches

Managing generalized anxiety is initially about early recognition and helping people understand the problem, providing them with appropriate information that might allay the source of anxiety. If this is not effective then people can choose between 'individual non-facilitated self-help, individual guided self-help or psycho-educational groups'. If these interventions are ineffective, individual high-intensity psychological interventions (involving cognitive behavioural therapy and relaxation) **or** drug treatments are advocated (NICE 2011).

Panic attacks (acute anxiety)**Related theory**

The body has a normal response to fear and stress but, if this response is exaggerated, people might experience a sense of panic. A number of symptoms can be experienced including palpitations, nausea, trembling, weak legs and dizziness (Box 4.5). Panic attacks can have a sudden onset and may last 5–20 minutes (MIND 2013). The more these thoughts intrude, the more extreme the physiological response becomes (Powell 2009). An indication for many individuals that a panic attack is beginning is a feeling of tightness in the chest or being aware that their breathing is fast. If not managed, this progresses to hyperventilation (Powell 2009).

Box 4.5 Criteria for defining a panic attack

A discrete period of intense fear or discomfort in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes.

- Palpitations, pounding heart or accelerated heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy, unsteady, light-headed or faint
- Derealization or depersonalization
- Fear of losing control or going crazy
- Fear of dying
- Pins and needles in extremities
- Chills or hot flushes

Source: Adapted from Donohoe and Ricketts (2006). Reproduced with permission from Sage Publications Ltd.

Evidence-based approaches

Managing acute anxiety (including panic attacks) can help to avoid the development of a panic disorder and generalized anxiety disorder. Nurses can support patients to avoid anxiety attacks by taking time to talk issues through. If the anxiety has progressed further and the patient is experiencing the warning signs that they are on the verge of hyperventilation, it is helpful to:

- remind them that the symptoms they are feeling are not harmful
- help them to actively release tension in the upper body by encouraging them to sit up and drop their shoulders in a side-ways widening direction. This makes hyperventilation more difficult since the chest and diaphragm muscles are stretched outwards
- breathe slowly ... in to a count of 4 and out to a count of 4. (Slowing your own breathing down can help the patient)
- encourage them to concentrate on breathing out and trying to breathe through their nose (adapted from Powell 2009).

A panic or anxiety attack does not necessarily mean that the patient has a pathological disorder. Prompt treatment and management are important to prevent transient anxiety turning into a disorder (NICE 2011).

If the patient has a history of panic attacks and these become a prolonged problem for the individual, it is important to provide them with evidence-based information about treatment, including the use of medication (and its side-effects), self-help groups and individual intensive cognitive behavioural therapy (NICE 2011). It is important to include families and carers and support them to help.

Pre-procedural considerations**Pharmacological support****Panic disorder**

Benzodiazepines, antipsychotics and sedating antihistamines are associated with a worse long-term outcome and pharmacological interventions should be either tricyclic or selective serotonin reuptake inhibitor (SSRI) antidepressant medication (NICE 2011).

Non-pharmacological support**The rebreathing technique**

This involves the patient rebreathing the air they have just breathed out (Box 4.6, Figure 4.5). This air is high in carbon dioxide so has less oxygen. This means that there will be a lower amount of oxygen in the blood, thus activating the parasympathetic nervous system and promoting relaxation (Blake and Ledger 2007).

After the panic attack, it is important to reflect with the patient about what happened and try to identify any triggers. Explanation and education about physiological responses can help to show the patient the importance of slowing their breathing which will in turn give them a sense of control.

If these panic attacks continue or if the patient has a history of anxiety then the management of this will include a referral for psychological support (with consent). Medication may be indicated after assessment (NICE 2011).

Principles Table 4.7 Supporting an individual having a panic attack

Principle	Rationale
Firstly, exclude any physical reasons for the patient's distress such as an acute angina episode or asthma attack.	If the symptoms of a panic attack have a physical cause, management needs to be instigated as soon as possible. E
Remain calm and stay with the patient. Ask them about history of anxiety or panic attacks.	The patient will not be reassured by others reacting with tension or anxiety about the situation. E
Maintain eye contact with the patient. Consider holding the patient's hand.	This helps the patient to be connected to reality and engage with your attempts to support them. Some patients may be reassured by physical touch, but assess each individual for appropriateness. E
Guide the patient to breathe deeply and slowly, demonstrating where necessary.	This gives the patient an activity to concentrate on and may help normalize any carbon dioxide and oxygen blood imbalance. E

Box 4.6 Rebreathing technique instructions for a patient

- Make a mask of your hands and put them over your nose and mouth and keep them there (see Figure 4.5).
 - Breathe in and out through your nose once.
 - Breathe in your own exhaled air through your nose.
 - Breathe out hard through your mouth.
- This should be done slowly without holding your breath. Repeat this four or five times but no more. Remain calm and relaxed while doing it.

Depression

Definition

Depression is a broad and heterogeneous diagnosis. Central to it is a depressed mood and/or loss of pleasure in most activities (NICE 2009b). Depression is often accompanied by symptoms of anxiety, and can be short-lived (sometimes dependent upon physical symptoms) or chronic.

Related theory

Depression is a common psychological response in patients with a chronic physical illness such as heart disease, diabetes and cancer. When this occurs, it is referred to as a ‘co-morbid’

depression. Co-morbid depression is difficult to detect as symptoms can be similar to the expected side-effects of the illness or treatment. For example, undetected depression rates in adult patients with cancer can be as high as 50% (Brown et al. 2009). Depression can be found in 20% of patients with a chronic physical illness (NICE 2009a), which is 2–3 times higher than individuals in good health. It is therefore essential that patients with a long-term physical illness are regularly assessed for anxiety and depression.

Box 4.7 sets out some of the symptoms of depression (NICE 2009a).

A normal low mood is differentiated from what is medically diagnosed as a depressive episode by the length of time the low

Box 4.7 Symptoms that indicate a diagnosis of clinical depression

Behavioural

- Tearfulness
- Irritability
- Socially withdrawn
- Changes to sleep patterns
- Lowered appetite
- Lack of libido
- Fatigue
- Diminished activity
- Attempts at self-harm or suicide

Physical

- Exacerbation of pre-existing pains
- Pains secondary to increased muscle tension
- Agitation and restlessness
- Changes in weight

Cognitive

- Poor concentration
- Reduced attention
- Pessimistic thoughts
- Recurring negative thoughts about oneself, past and future
- Mental slowing
- Rumination

Emotional

- Feelings of guilt
- Worthlessness
- Deserving of punishment
- Lowered self-esteem
- Loss of confidence
- Feelings of helplessness
- Suicidal ideation

mood is experienced. Low mood that persists for 2 weeks or more or rapid-onset/severe low mood are reasons for concern. The presence of other depressive symptoms contributes to a diagnosis as well as a consideration of how this low mood affects the individual's ability to interact socially. Depression frequently follows a pattern of relapse and remission and the key aim of intervention is to relieve symptoms (NICE 2009a).

Evidence-based approaches

Approaches to treatment of depression are influenced by the severity of the condition. Diagnosing depression has improved following the introduction of ICD-10 which lists ten depressive symptoms, dividing them into:

- subthreshold <4 symptoms
- mild 4 symptoms
- moderately depressed 5–6 symptoms
- severe 7 or more symptoms with or without psychosis.
- Symptoms need to be present for greater than 2 weeks.

Core management skills include risk assessment plus the following:

- good communication skills are required to enable the nurse to elicit information from the patient (Brown et al. 2009) and show understanding of the problem
- a sufficient understanding of the signs and symptoms of anxiety and depression and ability to make a preliminary assessment
- a sufficient understanding of antidepressant medication to enable an explanation of its actions to the patient
- an ability to 'refer on' when it is recognized that the issues are beyond the scope of experience. This must be done with the patient's consent
- awareness of the stigma attached to a diagnosis of depression, and protection of the patient's privacy and dignity
- sensitivity to diverse cultural ethnic and religious backgrounds considering variations in presentations of low mood
- awareness of any cognitive impairments or learning disabilities to ensure that specialist therapists are involved (where needed).

Use of available psychological support services can assist with the care and treatment of patients as well as providing a supervisory and support framework for staff. Working with psychological support services can enable nurses develop their assessment skills of anxiety and depression, helping them to identify the appropriate time for referral to a specialist service if required (Towers 2007).

Pre-procedural considerations

Pharmacological support

There are four main types of antidepressant: tricyclic, monoamine oxidase inhibitors (MAOI), selective serotonin reuptake inhibitors (SSRI) and serotonin-norepinephrine reuptake inhibitors (SNRI) (RCPsych 2013). When a patient is prescribed antidepressants, the two main considerations are the presence of other physical health problems and the side-effects of the drugs which may affect the underlying physical disease.

There is little difference between the effectiveness of each type of antidepressant; however, there are clear differences in the side-effects of the different classes and types of antidepressants. Selective serotonin reuptake inhibitors are safer in overdose than tricyclic antidepressants (TCAs), which can be dangerous. There is, however, an increased risk of gastrointestinal bleeding with SSRIs so they should be avoided for patients who are taking non-steroidal anti-inflammatory drugs. Monoamine oxidase inhibitors can affect blood pressure, particularly when certain food types are eaten.

Table 4.2 Most commonly prescribed antidepressants

Medication	Trade name	Group
Amitriptyline	Tryptizol	Tricyclic
Clomipramine	Anafranil	Tricyclic
Citalopram	Cipramil	SSRI
Dosulepin	Prothiaden	Tricyclic
Doxepin	Sinequan	Tricyclic
Fluoxetine	Prozac	SSRI
Imipramine	Tofranil	Tricyclic
Lofepramine	Gamanil	Tricyclic
Mirtazapine	Zispin	NaSSA
Moclobemide	Manerix	MAOI
Nortriptyline	Allegron	Tricyclic
Paroxetine	Seroxat	SSRI
Phenelzine	Nardil	MAOI
Reboxetine	Edronax	SNRI
Sertraline	Lustral	SSRI
Tranlycypromine	Parnate	MAOI
Trazodone	Molipaxin	Tricyclic related
Venlafaxine	Efexor	SNRI

MAOI, monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Serotonin-norepinephrine reuptake inhibitors are not appropriate for patients with heart conditions as they too increase blood pressure. Citalopram and sertraline (both SSRIs) are associated with fewer interactions and so are more likely to be prescribed if the patient has a long-term chronic condition (NICE 2009b).

Table 4.2 lists the most commonly prescribed antidepressants. The therapeutic effect of antidepressants may take some time to appear and treatment should continue for at least 6 months after a response to the treatment.

Nurses have an important role in exploring with the patient any concerns they may have about taking an antidepressant. The patient should be given all the necessary information regarding the optimum time to take the medication and the expected length of time before any therapeutic effect becomes apparent. Medication should be taken for at least 6 months following remission.

In general, treatment should not be stopped abruptly and discontinuation of treatment usually requires gradual reduction of dose over 4 weeks (NICE 2009b). Concerns regarding addiction require further information and reassurance confirming that this is unlikely to happen with modern antidepressant treatments. Further information on pharmacological intervention can be found in the NICE guidelines on depression (NICE 2009a).

Non-pharmacological support

Nurses can be involved in assessing depression in patients with physical illness. NICE guidance sets out a four-step model for managing a patient with depression. The first step (Box 4.8) could be managed by a nurse in an acute environment.

Assessment of how the patient's low mood has affected their usual daily activities such as eating, dressing and sleeping is important. The nurse can also encourage the patient to engage with activities that would be normal for them.

Principles Table 4.8 Communicating with a depressed person

Principle	Rationale
Initiate the conversation, develop rapport. Develop a person-centred communication style.	Good communication is essential to assess and individualize support (NICE 2009a, C).
Show understanding, caring and acceptance of behaviours, including tears or anger.	Accepting the patient as they are without attempting to block or contain their emotions helps them to express their feelings accurately. E
Encourage patient to identify their own abilities or strategies for coping with the situation.	Promote self-efficacy. E

Problem-solving table 4.2 Prevention and resolution (Principles table 4.8)

Problem	Cause	Prevention	Action
Patient expresses ideas of self-harm or taking their own life.	Low mood, depression.	Assess for risk: this can be as simple as remarking upon the person's low mood and asking them if they have ever thought of hurting themselves. Explore any expressions of suicidal ideas for intention to act. This can be achieved by asking if the patient has a plan. Crucially you will also need to explore what stops the patient from acting and what changes might cause them to act. If you consider the patient is at risk, explain to them that you need to refer them for further support.	If you have any concerns that the patient is at risk, follow the procedure of your organization. This may include contacting psychiatric liaison services or other psychological support.

Box 4.8 Managing the patient with depression: NICE guidance, step 1

Key questions

- During the last month, have you often been bothered by:
 - feeling down, depressed or hopeless?
 - having little interest or pleasure in doing things?
- How long have you felt like this for?

If the patient answers 'yes' to question 1 and the time scale is longer than 2 weeks, it is important that a referral is made for further assessment by a healthcare professional with clinical competence in managing depression, such as a clinical psychologist or a registered mental health nurse, so they can determine if the patient has been bothered by 'feelings of worthlessness, poor concentration or thoughts of death' (NICE 2009a, p.4).

Other questions should assess for the following

- Other physical health problems that may be significantly affecting their mood such as uncontrolled pain, sleep disruption, excessive nausea and vomiting, physical limitations on their independence or body image disturbance.
- A history of psychological illness such as depression.
- A consideration of the medication the patient is taking, specifically medication for mental health problems. Have they been able to take it and absorb it or have they had any digestive issues?
- Social support for the patient: who else is around to support the person, are they isolated?

Source: Adapted from NICE (2009a).

challenge. Of itself, anger is not classified as an emotional disorder. This emotional state may range in intensity from mild irritation to intense fury and rage and becomes a problem when it is associated with poor impulse control.

Related theory

Nurses may be exposed to anger and aggression. Poor communication is frequently a precursor to aggressive behaviour (Duxbury and Whittington 2005). Aggression and abuse tend to be discussed synonymously in the literature and are reported to occur with some frequency in nursing (McLaughlin et al. 2009). Anger is felt or displayed when someone's annoyance or irritation has increased to a point where they feel or display extreme displeasure. Verbal aggression is the expression of anger via hostile language; this language causes offence and may result in physical assault. Verbal abuse may actually be experienced as worse than a minor physical assault (Adams and Whittington 1995).

Whatever the cause of anger or conflict, people can behave in a number of challenging ways and with varying degrees of resistance to social and hospital rules. People may simply refuse to comply with a request or may behave more aggressively, for example by pushing someone aside (without intent to harm) or by deliberately striking out at others. Mental capacity issues should be considered when assessing the causes of aggressive behaviours.

When patients do feel anger, they may feel too depleted by experiences of disease and treatment to express it (Bowes et al. 2002).

For some people, anger may be the least distressing emotion to display. Sometimes helplessness, sadness and loss are far harder to explore and show to others. Anger therefore can be a way of controlling intimacy and disclosure, but it can escalate to threatening, abusive or violent behaviour.

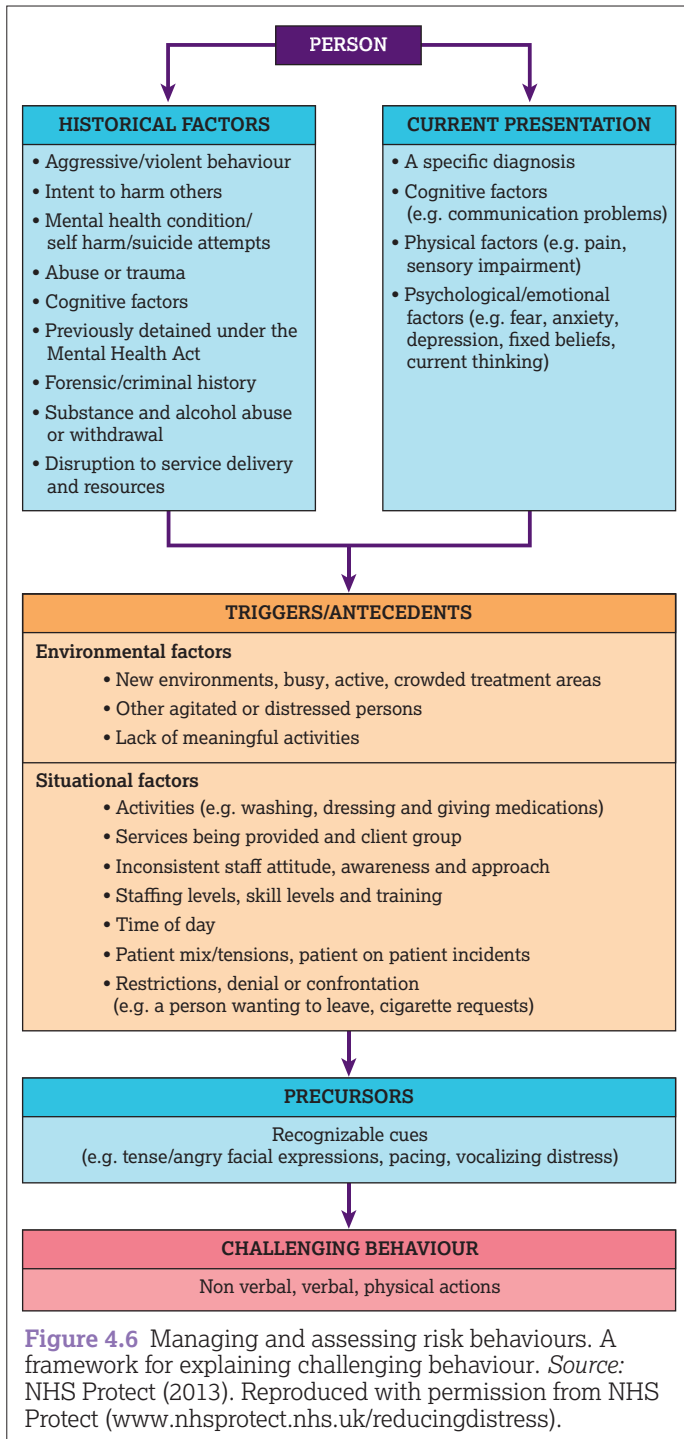

Anger, aggression and violence management

Definition

Anger is an emotional state experienced as the impulse to behave in order to protect, defend or attack in response to a threat or

Evidence-based approaches

Prevention is the most effective method of managing anger; that is, diffusing stressful or difficult interactions before they become a crisis. Understanding why angry or challenging behaviour occurs can be helpful in establishing a

comprehensive approach to prevention. NHS Protect (2013) proposes a framework for explaining challenging behaviour. This includes considering:

- *historical factors*: such as substance and alcohol abuse
- *current presentation*: diagnosis, physical factors such as pain
- *triggers or antecedents*: which include environmental factors such as other agitated individuals, busy or noisy areas and situational factors such as inconsistent staff attitude, time of day. Figure 4.6 presents this in more detail.

In some instances, challenging or difficult behaviour can be seen to be related to underlying stress and difficulty in a

person's situation. Anger, aggression and violence may have 'biological, psychological, social and environmental roots' (Krug 2002, p.25). People frequently get angry when they feel they are not being heard or when their control of a situation and self-esteem are compromised. Institutional pressures can influence healthcare professionals to act in controlling ways and may contribute to patients' angry responses (Gudjonsson et al. 2004). Patients are often undergoing procedures that threaten them and they may consequently feel vulnerable and react aggressively as a result (NHS Protect 2013). Another source of anger can be when personal beliefs in the form of rules are broken by others. We therefore need to strive to be aware of individual and cultural values and work with them to avoid frustration and upset.

People also can become angry when they feel that they have not been communicated with honestly or are misled about treatments and their outcomes. To prevent people's frustration escalating into anger or worse, health professionals need to ensure that they are communicating openly, honestly and frequently (NHS Protect 2013).

Some patients may appear or sound aggressive when they are not intending to be and the nurse must therefore use good judgement to clarify their behaviour in these instances. Nurses need to be aware of their own boundaries and capabilities when dealing with challenging or abusive situations.

Threats, uncertainty and disempowerment may predispose people to anger, and living with and being treated for any serious condition can be sufficiently threatening and disempowering (NHS Protect 2013).

Legal and professional issues

Nurses may be inclined to accept aggressive behaviour as part of the job (McLaughlin et al. 2009) due to being encouraged to be caring, compassionate and accepting of others. Despite this, nurses have the right to work without feeling intimidated or threatened and should not tolerate verbal or physical abuse, threats or assault. Personal comments, sarcasm and innuendo are all unacceptable.

Employers have a responsibility to adhere to Management of Health and Safety at Work Regulations (HM Government 2000, NHS Protect 2013). This involves providing a safe environment for people to work in and one that is free from threats and abuse. With any physical assault, the police should be involved.

Pre-procedural considerations

Assessment

Box 4.9 lists signs indicating that people may be angry. It is necessary to engage people sensitively and carefully to attempt to help them whilst maintaining a safe environment for all.

Evidence-based approaches

It is frequently possible to engage with and manage some of the underlying features without endangering anyone. People who are behaving aggressively probably do not normally act that way and may apologize when helped.

Talking down or de-escalation of situations where someone is being non-compliant can be achieved with careful assessment

Box 4.9 Warning signs that a patient is angry

- Tense, angry facial signs, restlessness and increased volume of speech
- Prolonged eye contact and a refusal to communicate
- Unclear thought process, delusions or hallucinations
- Verbal threats and reporting angry feelings

Box 4.10 Phrases that might help when talking with an angry person

- I can see that you are angry about this...
- I would like to help you try to sort this out, how can I do that?
- In order for me to help you, I need you to stop shouting.
- You are shouting at me and I can't help you until you stop.
- Please stop (unacceptable behaviour), you are making me and these other people quite frightened.
- Can you tell me what is making you so angry so that I might be able to help you sort it out?

Try to agree with the patient where possible (this can be a good way to defuse tensions).

- I can see how that would annoy you ... let's see what we can do about it.
- What might I/we do, for you to ... (comply with the rules/request)?

of the situation and skilful communication. NICE (2005) clinical guidelines on managing disturbed and violent behaviour recommend remaining calm when approaching someone and offering them choices. It is acknowledged, however, that there is little research indicating the correct procedure to follow. Box 4.10 suggests phrases that might help when talking with an angry person.

Pharmacological support

Short-term use of a benzodiazepine, for example diazepam or lorazepam, may be indicated. Assess this carefully; that is, do not assume that it is necessary. Once a situation is more under control, you can ask if the person feels less angry and whether they feel that they need further support. Suggesting this at the wrong time or insensitively may inflame the situation.

A psychiatrist may prescribe an antipsychotic medication for short-term use, for example risperidone.

Principles Table 4.9 Communicating with a person who is angry

Principle	Rationale
Remain calm.	
Verbally acknowledge the person's distress/anger and suggest you wish to help.	The person may respond positively and accept help (NHS Protect 2013, C).
Acknowledge issues that may be contributing, for example being kept waiting.	This helps the person feel that their concerns are understood. E
Consider what causes there may be, for example medication or disease (consider diabetes – hypo/hyperglycaemia), medical, circumstantial and so on.	Several factors might be influencing the behaviour. E
Consider safety – try to move to another area (ideally where you can sit down). If others might be intimidated or in danger, be clear about moving one of the parties away where practical, but do not endanger yourself in the process.	Maintain safety for all (NHS Protect 2013, C).
If a person's behaviour is hostile and intimidating, tell them you are finding their behaviour threatening and state clearly you wish them to stop/desist (see Box 4.10 for suggested phrases).	Some people may not be aware of the impact of their behaviour and will change it when it is pointed out that it is unacceptable (NHS Protect 2013, C).
Assess individual situations and make use of relatives or friends if they are present and can be of assistance in defusing the situation.	Sometimes people will listen more to a person who is close to them. E
Create some physical distance or summon assistance if the patient does not concur and continues to be threatening, abusive or passively non-compliant (e.g. refuses to move).	Maintaining safety for all. E
Warn the person that you will contact security staff/police if necessary – avoid threatening language. If possible, make a personal or practical appeal.	People need clear information about the consequences of their actions. E
Attempt to talk the individual down; that is, calm them down by remaining calm and professional yourself, keeping your voice at a steady pace and a moderate volume. Try to engage the person in conversation.	Your behaviour will have an impact on theirs (NHS Protect 2013, C).
Avoid personalizing the anger but do not accept unwarranted personal criticism.	If we personalize then we are likely to react in a way that exacerbates the situation but neither should you accept abuse. E
You may suggest walking with the patient to discuss issues but ensure you remain in a public/safe environment.	Changing the environment may help to recontextualize behaviour and movement channels agitation. E
The key communication skills discussed in the skills section will be helpful here but fundamentally you need to listen to what the grievance is, treat the person as an individual, preserve their dignity and attempt to help where you realistically can. Avoid passing the buck or blocking in another way.	People need to be heard and understood (NHS Protect 2013, C).

Principle	Rationale
If a patient is no longer abusive or threatening but is struggling to reduce their anger, they may benefit from some further psychological support or medication to help them feel calmer.	The short-term use of some medication may be beneficial. C
In rare and extreme circumstances where patients are violent and do not respond to de-escalation attempts and where the safety of other people is compromised, you must take immediate action by involving security and the police. If they are an ambulant outpatient, you need to ask them to leave if their behaviour is not acceptable.	Maintaining safety for all. E
Restraint and sedation may be required in some cases. Follow individual hospital security/emergency procedures in these instances.	Maintain the safety of the patient and staff members (NHS Protect 2013, C).
Document the incident according to the hospital incident reporting process.	So such incidents can be investigated.

Post-procedural considerations

The ideal outcome for an encounter with an angry, aggressive or threatening person is that safety is not compromised and the healthcare professional is able to talk the person down, helping them to express the reason why they are angry. Follow-up support should be offered to help stop the person repeating the same behaviour. However, people should also be made aware of potential sanctions if they are unable to comply, for example withdrawal of treatment and involvement of the police.

It can be distressing to be exposed to threatening or abusive people and it is good practice to seek a debriefing interview. This can help you and the institution reflect upon the experience and procedures in place to manage such situations. Check with your occupational health or human resources department to establish where you can access support facilities.

Delirium

Definition

Delirium is a distressing and underdiagnosed syndrome of acute alteration in mental state. The core clinical features that indicate a diagnosis of delirium are:

- impaired consciousness and attention
- disorientation, impaired recent memory, perceptual distortions, transient delusions
- psychomotor disturbances (hypo- or hyperactivity)
- disturbed sleep/wake cycle
- emotional disturbances (various) (ICD-10 1992).

Delirium can present in three forms.

- *Hypoactive delirium*: a subtype of delirium characterized by becoming withdrawn, quiet and sleepy.
- *Hyperactive delirium*: a subtype of delirium characterized by people who have heightened arousal and can be restless, agitated or aggressive.
- *Mixed*: with both hypoactive and hyperactive features.

Related theory

In most cases, delirium is caused by a general medical condition, intoxication or withdrawal of medication/substances which act upon the neurochemical balance of the brain (Ross 1991). Causative factors like infection, post-anaesthesia and medication (especially analgesics) need to be considered, particularly for sudden onset of delirium in the hospital environment.

The prevalence of delirium in hospital patients is between 20% and 50% (NICE 2010). Certain factors predispose to or are risk factors for developing delirium.

- Other serious illness such as uncontrollable cardiovascular or respiratory conditions, diabetes
- Multiple co-morbidities
- Older age
- Alcohol dependence syndrome
- Previous or existing other mental disorder, such as dementia
- Hypoalbuminaemia
- Infection
- Taking medications that affect the mind or behaviour
- Uncontrolled pain
- Taking high doses of analgesia (Irving et al. 2006)

Being an inpatient in a hospital environment can contribute to the development of delirium. The following factors can increase the risk.

- Patient not UK resident and/or English is not their first language.
- Changing clinical environment such as room or ward on a number of occasions.
- Absence of any means of gauging the time of day.
- Absence of family or other close friend.
- Catheterization.

The greater the number of risk factors present, the greater the likelihood of delirium developing (NICE 2010).

The disturbance can develop quickly and fluctuate during the course of a 24-hour period (DSM IV 1994). Environmental cues during the daytime act as stabilizing factors and this makes symptoms typically worse at night. The disturbance can resolve within hours/days or can last longer if co-existing with other problems like dementia. A patient's behaviour may change to indicate potential delirium before a full set of diagnostic symptoms is observable (Duppils and Wikblad 2004). There is considerable morbidity and mortality associated with delirium, delaying recovery and rehabilitation (Irving et al. 2006, NICE 2010). Recognizing and addressing delirium is important because of the distress it causes patients, families and staff (Lawlor et al. 2000). A marked feature of delirium is the variety and fluctuating nature of symptoms.

Evidence-based approaches

Nurses play a critical role in the prevention, early detection (Milisen et al. 2005) and management of delirium. Delirium is frequently

iatrogenic (i.e. caused by medical intervention) and hence can often be corrected once the causative factor has been identified.

Addressing the causative factors as part of good nursing and medical care will help prevent the development of delirium. This means ensuring hydration and nutritional requirements are met and any electrolyte imbalances are monitored and corrected.

Nurses need to be aware that patients over the age of 65 (especially those having anaesthesia) will be highly prone to developing delirium so need to be monitored carefully over a period of time to pick up any early signs. The effect of analgesia (especially opiates) also needs to be considered.

The emergence of delirium can also be significant at the end of life and significantly complicate care (Delgado-Guay et al. 2008). Terminal restlessness is a term often used to describe this agitated delirium in end-of-life care, where the causes may require specific management different from that of other types of delirium (Travis et al. 2001). A progressive shutdown of body organs in the last 2–3 days of life (Lawlor et al. 2000) leads to irresolvable systemic imbalances. The management of delirium in end-of-life care therefore shifts from a focus on reversing the cause to alleviating the symptoms. Nurses should avoid medicating symptoms unless this is in the patient's best interests.

Principles of care

Initial screening for any cognitive issues on admission is important to identify predictive factors and establish a baseline of cognitive functioning. Involving the family can be crucial to an accurate assessment where there are existing changes.

If risk factors are identified, nursing care for an individual with delirium should focus on minimizing hyperarousal from the environment.

- Minimize the frequency of moving the patient from one ward/bed/room to another.
- Ensure that there is cognitive stimulation – television is working, patient is in an environment with other patients.
- Access to means of determining the time of day, e.g. clock/can see a window.
- Have access to hearing aids/glasses, etc.
- Encourage friends/relatives/spiritual advisors (if appropriate) to visit.

And in addition, nursing care should include optimizing physical health for the patient to maintain mobility (if appropriate), hydration and nutrition, and prevent constipation and incontinence. This will take place in parallel to the medical management which should focus initially on attempting to establish the potential reversible causes. These will include:

- newly started medications
- changes in dosage
- opioid toxicity, withdrawal from opioids or alcohol
- use of corticosteroids
- metabolic imbalances or organ failure affecting the processing and excretion of drugs
- infections
- hypercalcaemia
- constipation.

Legal and professional issues

In the case of medium-term to longer-term delirium, another person may make decisions on the patient's behalf as long as this has been agreed as a part of a best interest assessment and the principles of the Mental Capacity Act have been applied. The best interest assessment must include the views of family or informal carers and the decision maker would generally be the lead clinician for the patient (Griffith and Tengnah 2008). However, if the patient has a Lasting Power of Attorney for welfare and this application has been registered with the Public Guardianship Office,

then the relevant person will be able to make decisions on the patient's behalf.

The Mental Capacity Act sets out principles for protection of liberty when caring for someone with reduced capacity. This is reliant upon accurate and suitable assessment of capacity and best interests which are well documented and reviewed.

Physical restraint

Wherever possible, nurses must attempt to create an environment where restraint is not going to be necessary. It is a rare requirement and all feasible steps to avoid the use of restraint must be explored. Any action taken must be the 'least harmful' intervention in the circumstance. The aim is to balance the patient's right to independence with their and others' safety. However, if physical restraint is necessary to maintain the safety of the patient, then it requires careful ethical consideration.

Restraint takes many forms and must be meticulously judged for the potential to benefit or harm an individual. The delirium diagnosis prevention and management guidelines (NICE 2010) advise that the use of physical restraint should be a last resort, where the patient is putting themselves or others at risk of harm and all other means of management and deflection have been employed. When physical restraint is employed, this should be for the shortest period possible and with use of minimum force to ensure the patient is not harmed.

'Control and Restraint' is a formal term relating to a specific process for which training is required and clear procedures are to be followed. This is outside the remit of this book. The level of force applied must be justifiable, appropriate, reasonable and proportionate to a specific situation and should be applied for the minimum possible amount of time.

If restraint is required, nurses must explain to the patient why they are doing what they are doing (regardless of the patient's perceived capacity) and reduce the negative impact upon the patient's dignity as much as possible.

Documentation

Delirium is under-reported in nursing and medical note taking (Irving et al. 2006). Documentation outlining the onset of behaviours and symptoms is instrumental in assisting the medical team to identify the cause and likely solution to the problem. The documentation of the assessment and subsequent care must be detailed and accurate.

Pre-procedural considerations

Pharmacological support

Once diagnosed, symptoms that do not respond to non-pharmacological interventions can be treated with prescribed medication, including sedatives, for example haloperidol (NICE 2010). As far as possible, benzodiazepines are avoided as a side-effect of these can be delirium (BNF 2014). However, they may be used if delirium is caused by alcohol withdrawal.

Use of medication for sedation in the end-stages of life needs individual consideration and the family must be involved and communicated with regularly.

It is worth noting that health professionals and family members can mistake the agitation of delirium for symptoms of pain. If opioids are increased as a result, there will be a potential worsening of the delirium (Delgado-Guay et al. 2008).

Non-pharmacological support

Creating an environment conducive to orientation is important wherever possible, for example a quiet well-lit environment, where normal routines take place. Nurses must help patients to maximize their independence through activity as mobilization is seen to assist with orientation (Neville 2006). Nursing interventions include creating a well-lit room with familiar objects, limited staff changes (possibly requiring one-to-one nursing care), reduced noise stimulation and the presence of family or familiar friends.

Principles Table 4.10 Communicating with a patient with delirium

Principle	Rationale
It is essential to ensure that aids for visual and hearing impairments are functional and are being used.	To maximize ability to communicate normally. E, C
Adjust environment to promote the patient's orientation, for example visible clock or calendar, photographs of family.	Maintain/promote orientation. E, C
Background noise should be kept to a minimum.	This can be very distracting for the patient. E, C
The healthcare professional should introduce themselves to the patient (do not assume they remember you). If possible, limit the number of individuals involved in care.	Promote consistency and reduce potential for confusion. E
Give simple information in short statements. Use closed questions.	Closed questions are less taxing and only require a yes or no answer. E
It is important to give explicit explanation of any procedures or activities carried out with the individual.	Maintain respect and dignity. E, C

Post-procedural considerations

Liaison with the patient's family is important so that they understand what is happening and what they can do to help. It must be recognized how distressing it can be to witness or spend time with a delirious member of the family. The family should therefore be given the opportunity to talk about their concerns and be updated with information about the cause and management.

Dementia

Definition

'Dementia is an umbrella term describing a syndrome' (Westerby and Howard 2011, p.44). There are four common types of dementia and Elkins (2012) suggests that the percentages of people who have the different types of dementia are as follows: Alzheimer's (60%), vascular (15–30%), Lewy body (4–20%) and frontotemporal (2%). Weatherhead and Courtney (2011, p.114) state that 'dementia is not a normal part of the aging process, but almost all types of dementia are progressive and incurable. Dementia does not exclusively affect older people and so younger people can be affected and it is not uncommon for people with Down's syndrome to develop dementia at an earlier age'.

Related theory

Dementia can be caused by a number of illnesses and manifests as a decline in multiple areas of functioning, most notably mental and social function and ability to carry out activities of daily living (Westerby and Howard 2011). The number of people in the UK living with dementia is thought to be around 820,000 (Alzheimer's Research UK 2014) and it is thought that one quarter of inpatient beds are occupied by people who have dementia (Alzheimer's Society 2009). Older patients who have not had a formal diagnosis of dementia may not in fact have dementia but have depression which manifests in a similar way to dementia, demonstrating the importance of obtaining a diagnosis (Westerby and Howard 2011).

Evidence-based approaches

De Vries (2013) suggests that the 'decline in communication ability for older people with dementia is usually progressive and gradual, with the condition affecting expressive and receptive language abilities' (p.30). It is thought that those in the caring profession avoid communication with people who have dementia and this can have a negative impact on the person's experience and result in behaviour which can be challenging (Jootun

and McGhee 2011). People who have dementia will frequently have word-finding difficulties so supporting communication can include finding suitable tools such as a communication book. The use of non-verbal skills such as simply allowing the person to point at what they want can help in the communication process. It is important to engage with the person with dementia and, although it may take more time, the results can be rewarding. Excluding or ignoring the patient can leave them feeling frustrated and angry (Tonkins 2011).

The use of family and carers is important as they may have a greater understanding of the verbal and non-verbal communication of the person with dementia. However, the involvement of family and carers should not exclude communication between the person with dementia and nurses; the person with dementia should be involved as much as possible in all communication relating to their care. As Jootun and McGhee (2011, p.41) suggest, it is important for the nurse to demonstrate sensitivity and to encourage the person to communicate in whichever way suits him or her the best.

Baillie et al. (2012) suggest that providing personal care to a person with dementia, if done sensitively, can help build on the relationship between them and the nurse. However, it is important to consider what the person with dementia might be experiencing. The person's reality may not be the same as the nurse's. The person with dementia may think they are at home and the nurse a family member.

Legal and professional issues

The principles of the Mental Capacity Act apply to all patients and the first principle of the Act, the presumption of capacity, also applies to patients who have dementia. A person's capacity is decision specific and, as such, a person with dementia may be able to make decisions as long as they can show that they understand the decision they are making and the risk associated with the decision. If a patient with dementia declines care or treatment, they should be treated as an adult with capacity unless an assessment of capacity has indicated they lack capacity to make the decision. If this is the case, a best interest decision must be made in consultation with the patient's family. Where the person has no family and the decision relates to medical treatment or about where they will be living, a referral must be made to the Independent Mental Capacity Advocacy Service.

For people with dementia who are in hospital or a care setting, consideration needs to be given to the Deprivation of Liberty Act. If the patient is unable to consent to being in hospital and there are restrictions on their liberty, they are not free to

leave if they wish to, so they may be being deprived of their liberty.

Pre-procedural considerations

Equipment
People who have dementia may need no additional equipment other than the skills of the nurse communicating with them.

However, tools such as communication cards or books that allow patients to point to images may be very useful, such as images of the toilet, shower and food and drink.

Assessment
Assessing the pain of a person who has dementia and communication difficulties can also be challenging and so using non-verbal pain assessment tools should ensure that the patient's pain is appropriately assessed.

Principles Table 4.11 Supporting communication for the person with dementia

Principle	Rationale
Be aware of what the patient's communication needs may be.	Knowing the patient's preferred style of communication or communication needs will enhance the patient's and nurse's experience.
Be aware of the patient's reality, orientating them and if necessary reinforcing this throughout the care intervention.	You may be speaking to a patient and they may not be able to understand the context.
Consider if the patient has other communication issues.	The patient may have a dementia but they may also have a hearing impairment and so they may understand what is being said but cannot hear what is being asked.
Consider the environment and the impact on the patient.	The patient may be distracted by the noise of a busy unit and finding a quieter space may help the communication process.
Avoid reinforcing a patient's reality when it is not real, and avoid telling them things that are not true.	Telling patient that a loved one, parent or husband has been dead for some years may be very distressing for the patient but so might telling them they are at home and they will see them later. Better to change the subject and orientate them to where they are.
Patients with dementia may need constant reorientation.	Due to anxiety and poor short-term memory, patients with dementia may forget what they have been told very quickly; for instance, when assisting with personal care or changing a dressing they may need to be reminded where they are.
Learn about the patient's past and occupation.	It is not uncommon for patients with dementia to behave as they did when they were in employment; for instance, a cleaner may want to go around the ward cleaning. These behaviours can give the patient a sense of value but can present risks.
Be aware of your body language and non-verbal communication; be open and approachable and be on the patient's level.	Patients with dementia may misinterpret non-verbal communication and this can cause them to become distressed or angry.
Use short simple sentences and avoid providing too many choices.	Patients with dementia may not recall everything that is being said, so shorter sentences will help; offering a choice of two at a time might be better than an entire list.
It is better to use closed rather than open-ended questions, such as 'Would you like a cup of tea?'	Open questions can make it difficult for the person to respond, as they may struggle to remember the words they need.
If a person with dementia is struggling to find a word, help them find a way around it.	The person with dementia can become very frustrated when trying to find a word and may decide to withdraw from the conversation.
When giving instruction to the patient with dementia, give one instruction at a time.	To help maximize the person's independence; supporting them to do a task by helping them with the sequencing is enabling.
Avoid interruption when the person with dementia is speaking.	Interrupting the person whilst they are speaking may result in them losing what they wanted to say and can cause frustration.

Acquired communication disorders

Definitions
Aphasia/dysphasia (terms can be used interchangeably) is an acquired communication disorder that impairs a person's ability to process language. It does not affect intelligence but does affect how someone uses language. Any injury to the brain has the potential to change a person's ability to speak, read, write and understand others.

Aphasia may be temporary or permanent. Aphasia does *not* include speech impairments caused by damage to the muscles involved with speech; that is dysarthria.
Dysarthria is a motor speech disorder. Neurological and muscular changes may cause difficulty in producing or sustaining the range, force, speed and co-ordination of the movements needed to achieve appropriate breathing, phonation, resonance and articulation for speech (Royal College of Speech and Language Therapists 2006). Speech may sound flat, slurred, nasal or have

a jerky rhythm; pitch, loudness and breath control can also be affected.

Dyspraxia of speech is different from dysarthria as it is not caused by muscle weakness or sensory loss but is a disorder of planning, initiating and sequencing purposeful/voluntary movement. Verbal expression may be hesitant with sound substitutions, for example saying 'tup of tea' for 'cup of tea'.

Dysphonia is a voice disorder and may be related to disordered laryngeal, respiratory and vocal tract function and reflect structural, neurological, psychological and behavioural problems as well as systemic conditions (Mathieson 2001).

Related theory

Language

It is now recognized that many areas of the brain are involved with language and cognitive processing and the complex relationship between structure and function is not fully understood. Impaired cognition is the most common deficit experienced by patients with primary brain tumours and has been reported to occur in up to 80% of cases (Mukand et al. 2001). Approximately 25% of patients with a primary brain tumour have a disturbance of language as part of their initial presentation (Recht et al. 1989).

The cause of cognitive and language impairment may be multifactorial and it may result from the location of the primary tumour, compression/oedema and/or as a consequence of treatment.

Cognitive and language impairments thus may not always have a direct relationship with the location of the primary brain tumour (Gaziano and Kumar 1999, Gehring et al. 2008, Scheibal et al. 1996).

Speech

Speech (dysarthria), voice (dysphonia) and swallowing (dysphagia) can be impaired by any brain tumours, involving the ventricular system, brainstem, cerebellum and cranial nerves (V, VII, IX, X, XI, XII), or by any tumour affecting the head and/or neck.

The brain is the organ of the body that is, above all others, linked with our sense of self. The importance of effective communication is considered at the beginning of this chapter and this need becomes more apparent with any communication disorder. Speech and language shape our thoughts, and language is necessary to make sense of or give meaning to our world. It is the currency of friendship (Parr et al. 1997) and is intrinsic and essential to our well-being. Its value and complexity may not become apparent until it is disrupted.

One of the key issues for patients with aphasia (disruption of language processing) is when we expect them to make sense of their disease, its treatment and management options. To

do this, they need to use the very medium that is damaged – language. This may have an obvious or more subtle impact upon how the patient's psychological, emotional and social needs are met.

When patients have difficulty communicating, their sense of identity can become fragile and may be further undermined when they are in hospital. Understandably, in this environment, the focus is on their medical diagnosis, prognosis, treatments and side-effects. Facilitating their communication strengths allows us to help them understand, as well as supporting, acknowledging and respecting their individual needs.

Barriers to communication

- *Poor memory*: delayed language processing can further compromise short-term memory problems.
- *Reduced concentration and short attention span*: acute post-surgical; during and after radiotherapy treatment to the brain.
- *Distractibility*: increased sensitivity to background noise or visual distractions.
- *Generalized fatigue*: already using extra energy to process language, it becomes too effortful to chat.

Evidence-based approaches

Communication is a neurological function and the speech and language therapist has a key role in the specialist assessment and management of disorders/disruptions to this vital function (Giordana and Clara 2006). Patients with diseases affecting their central nervous system require input from a well co-ordinated multiprofessional team (NICE 2006), to support their complex changing care needs throughout the patient pathway (NICE 2006, NSF 2005, RCP, BSRM, NCPCS 2008).

Pre-procedural considerations

Equipment

Communication aids

Communication aids are referred to as augmentive or alternative communication (AAC). AAC may range from basic picture charts or books to electronic aids and computer programs and may support communication when the patient presents with a severe dysarthria or a severe expressive and/or receptive aphasia. Box 4.11 provides suggestions to facilitate realistic expectations and successful use of AAC.

Patients with various forms of communication difficulty

The person with aphasia

Principles Table 4.12 Supporting communication for the person with aphasia

Principle	Rationale
Be aware of where the aphasic patient is within their disease trajectory.	
Be aware if the patient has impaired attention, concentration and/or memory.	This will affect what you say and how you check for understanding.
Minimize distractions, both visual and auditory.	Make it easier for both parties to concentrate.
Allow enough time, with a calm, friendly, encouraging approach.	Develop and maintain rapport.
Use a notebook to record key information.	This minimizes miscommunication particularly if the information is new or complex, the patient is anxious or their memory function is impaired.
Frequent signposting and checking of understanding.	To make sure the patient understands the purpose of the conversation.

(continued)

Principles Table 4.12 Supporting communication for the person with aphasia (*continued*)

Principle	Rationale
Talk directly to the patient and ask them what is/isn't helpful.	So that communication is as effective as possible.
Have a pen and paper for both the patient and healthcare professional to use during the conversation.	Writing or drawing can support what is being said.
Speech should be clear, slightly slower and of normal volume.	To ensure the patient has time to process what is being said.
Use straightforward language, avoiding jargon.	Medical terminology is inevitably long and complex but can be clearly written in the notebook for future reference.
Say one thing at a time and pause between 'chunks' of information.	To allow time for understanding and for questions.
Structure questions carefully and make use of closed questions.	Limit the need for complex expression.
Regularly check the patient's understanding.	To ensure they continue to be involved in the conversation and are respected.
Declare a change of topic clearly.	It can be harder for some patients to recognize when the topic has changed.
Be prepared for their and your frustration. You might have to come back to a topic at another time.	Abilities may fluctuate, so what helps one moment might not work another time.

Box 4.11 Suggestions to facilitate realistic expectations and successful use of augmentive or alternative communication

- An early referral to the speech and language therapist to assess the appropriateness of the use of AAC.
- With the addition of any aid (no matter how simple or sophisticated), communication becomes more complex and difficult as it involves another step in the process; that is, it changes from a two-way to a three-way process.
- Patients need to be motivated to use aids.
- The use of aids requires planning, extra concentration and time, listening, watching and interpretation by both patient and conversation partner.

The person with impaired speech (dysarthria)

The dysarthria may range from mild, slightly slurred or imprecise speech to being unintelligible (this is different from aphasia where language is not affected).

Principles Table 4.13 Supporting communication for the person with dysarthria

Principle	Rationale
Be encouraging but honest and open if you are having difficulty understanding.	This allows the patient to repeat things or express things in another way that may be more understandable.
Ask if they use any strategies to help their speech.	Patients may well know what helps most.
Encourage a slower rate of speech and regular pauses.	Ensure adequate breathing between words and phrases.
Find a quiet environment to speak.	Reduce distractions and make it easier to concentrate.
Allow more time than usual.	So the person doesn't feel rushed while they are finding the words they wish to communicate.
Have pen and paper to hand, and encourage writing when necessary.	To provide another medium of communication.

The person with impaired voice (dysphonia)

The dysphonia may fluctuate from a mild hoarseness to not being able to voice at all. Early referral to a speech and language therapist for assessment and advice on vocal hygiene may be required.

Principles Table 4.14 Supporting communication for the person with dysphonia

Principle	Rationale
Have pen and paper to hand, encourage writing when necessary.	Provide another medium of communication.
Encourage the patient to talk gently and avoid either shouting or whispering.	This can strain the voice.

Principle	Rationale
Avoid having to talk where there is background noise.	To reduce the necessity for the individual to strain their voice unnecessarily.
Face-to-face communication is preferable. Keep telephone calls to a minimum.	The patient will then also be able to use non-verbal communication to transmit their message.
Encourage regular sips of water.	To maintain hydration and keep the throat area moist.
Use closed questions and discourage lengthy responses to questions.	So the individual doesn't need to make lengthy responses to questions.
Discourage frequent throat clearing. Instead, encourage a firm swallow if possible or gentle throat clearing.	To minimize straining of the throat.
Be aware if the room atmosphere is dry (placing a bowl of water beside the radiator will help humidify/moisten the air).	A humid atmosphere is preferable to reduce local irritation.

The person who is blind or partially sighted

Sight loss may vary from mild to complete. Any sight loss is a significant issue when caring for patients. They will rely more on other senses, especially their hearing. Good communication practice is essential and you may need to be the eyes for the patient and relay information they are not aware of; for example, the patient's visitor has arrived and is waiting. It is important to be open about the visual impairment and identify the preferred

method(s) for each person. No single method will suit all. Even the same person might use different methods at different times and under different circumstances.

Blind and partially sighted people have the same information needs as everyone else and need accessible information in a suitable format such as large-print documents, Braille or audio information. Access to information facilitates informed decisions and promotes independence.

Principles Table 4.15 Communication with a person who is blind or partially sighted

Principle	Rationale
Always say who you are when you arrive.	Visual cues are not available to the blind or partially sighted.
In situations where there might be confusion as to who is being spoken to, use the patient's name or a light touch when you are addressing them.	As above.
Explain precisely where you are.	So people can orientate towards you.
Ensure glasses are clean and within reach.	
Clear and careful explanations and checking understanding verbally are essential.	We communicate a substantial essence of meaning non-verbally. Blind people therefore do not receive this information so it is harder to gain full understanding.
Indicate to a patient when you are leaving.	Normal cues are not available to the blind or partially sighted.

The person who is deaf or hard of hearing

As with blindness, the severity of the impairment will vary. If a hearing aid is used, make sure it is fitted and working. Remember that hearing aids amplify everything, even background noise. More severe hearing loss will not benefit from an aid and these patients might rely on lip reading and/or signing or writing.

Principles Table 4.16 Communicating with a person who is deaf or hard of hearing

Principle	Rationale
Find a suitable place to talk, somewhere quiet with no noise or distractions, with good lighting. Make sure that the light is not behind you.	So the person can clearly see your face, and lip reading and expression can contribute to understanding.
Be patient and allow extra time for the consultation/conversation.	It is likely to take longer than normal.
Depending on the purpose of the consultation, writing down a summary of the key points might be helpful.	This will ensure the person has a record of what is said in case they have misunderstood or misheard what is said.
If the person is wearing a hearing aid, ask if it is on and if they still need to lip read.	This is because at times individuals may turn their hearing aids off because they aren't functioning or the interference from background noise is painful. They can then forget to switch the hearing aid on again.

(continued)

Principles Table 4.16 Communicating with a person who is deaf or hard of hearing (*continued*)

Principle	Rationale
If an interpreter is required, always remember to talk directly to the person you are communicating with, not the interpreter.	This is respectful and confirms that it is them you are addressing.
Make sure you have the listener's attention before you start to speak.	Otherwise they may miss crucial information.
Contextualize the discussion by giving the topic of conversation first.	Signposting helps people understand.
Talk clearly but not too slowly, and do not exaggerate your lip movements.	Lip reading is easier for people when you talk fairly normally.
Use natural facial expressions and gestures and try to keep your hands away from your face.	Blocking your face will make understanding more difficult.
Use plain language; avoid waffling, jargon and unfamiliar abbreviations.	Plain language will be more easily understood.
Check that the person understands you. Be prepared to repeat yourself as many times as necessary.	Many people need to have information repeated to understand it.

Chapter 5

Elimination

Procedure guidelines

- 5.1** Care of a patient who is vomiting 135
- 5.2** Insertion of a nasogastric (NG) drainage tube 137
- 5.3** Removal of a nasogastric tube 138
- 5.4** Slipper bedpan use: assisting a patient 142
- 5.5** Commode use: assisting a patient 143
- 5.6** Penile sheath application 145
- 5.7** Urinary catheterization: male 151
- 5.8** Urinary catheterization: female 153
- 5.9** Urinary catheterization: intermittent self-catheterization patient guidance: male 156
- 5.10** Urinary catheterization: intermittent self-catheterization patient guidance: female 157
- 5.11** Urinary catheter bag: emptying 158
- 5.12** Urinary catheter removal 159
- 5.13** Commencing bladder irrigation 162
- 5.14** Care of the patient during bladder irrigation 164
- 5.15** Nephrostomy tube: weekly dressing and bag change 167
- 5.16** Nephrostomy tube: removal of locking pigtail drainage system 169
- 5.17** Continent urinary diversion stoma: self-catheterization 172
- 5.18** Enema administration 181
- 5.19** Suppository administration 184
- 5.20** Digital rectal examination 186
- 5.21** Digital removal of faeces 188
- 5.22** Stoma siting 193
- 5.23** Stoma bag change 195
- 5.24** Stoma bridge or rod removal 196

Overview

This chapter will provide an overview of elimination and is divided into four main sections. The first reviews normal elimination. The second examines altered urinary elimination, including penile sheaths, urinary catheterization, urinary diversions and bladder irrigation. The third section considers altered faecal elimination, including diarrhoea, constipation, enemas, suppositories, digital rectal examination and digital removal of faeces. The final section provides an overview of stoma care.

134

Normal elimination

This section reviews normal elimination processes including vomiting, urination and defaecation.

Vomiting

Definition

Vomiting is a co-ordinated reflex whereby the diaphragm contracts, resulting in changes in intrathoracic pressure causing the forceful expulsion of gastric or intestinal contents through the oral cavity (Bennett 2009, Campos de Carvalho et al. 2007, Kelly and Ward 2013). Vomiting, and the associated sensation of nausea, are significant and distressing symptoms that patients may experience as a result of either disease or treatment (Bennett 2009). Post-operative nausea and vomiting affects up to 30% of surgical patients (Abraham 2008). Around 70–80% of cancer patients receiving chemotherapy experience nausea and vomiting associated with their treatment (Richardson et al. 2007) while approximately 60% of patients with advanced cancer report nausea and 30% report vomiting (Davis and Walsh 2000). Nausea and vomiting is experienced by 17–49% of patients with advanced non-malignant disease, including heart disease and kidney failure (Kelly and Ward 2013) and Twycross et al. (2009) report that nausea and vomiting is experienced by up to 70% of patients in their last week of life.

Anatomy and physiology

The pathophysiology of nausea and vomiting is complex (Figure 5.1); two main centres within the brainstem are involved: the chemoreceptor trigger zone (CTZ) and the vomiting centre (Kelly and Ward 2013). Vomiting is ultimately controlled by the vomiting centre which receives input from a wide range of sources. Some of these inputs are directly connected to the vomiting centre but most are directed through the CTZ (Bennett 2009, Kelly and Ward 2013). The CTZ is an area of the brain that is not fully separated from the blood by the blood–brain barrier, allowing it to detect chemicals in the blood and cerebrospinal fluid and initiate vomiting where necessary. It is also stimulated by the vagus and vestibular nerves, which receive signals from the gut and inner ear respectively (Bennett 2009, Kelly and Ward 2013).

The causes of vomiting are often multifactorial and therefore thorough assessment of the risk factors, precipitating factors and alleviating factors is the key to identifying effective strategies for managing this symptom (Box 5.1).

Evidence-based approaches

Assessment

Assessment may either focus on risk factors in the case of post-operative nausea and vomiting, in order to prevent or minimize the symptom occurring, or identifying causative factors where patients are already experiencing the symptoms. Risk assessment tools for post-operative nausea and vomiting consider a range of factors relating to the patient themselves (e.g. gender, age, history of motion sickness, smoker), the surgical procedure

Figure 5.1 The emetic pathway. *Source:* Kelly and Ward (2013). Reproduced with permission from EMAP Publishing Ltd.

(e.g. duration, open versus laparoscopic, type of surgery) and the anaesthetic (e.g. type of agent, duration, premedication, use of opioids) (Hambridge 2013). In those patients who are already experiencing nausea and vomiting associated with other causes, a consistent and systematic approach should be used to determine the cause where possible and assess their symptoms (Kelly and Ward 2013).

Pharmacological and non-pharmacological approaches

Nausea and vomiting can be managed using pharmacological and non-pharmacological interventions. There are a range of non-pharmacological strategies available to manage nausea and vomiting. First, consideration needs to be given to any precipitating factors that can be controlled or removed, such as exposure to food smells, large meals or malodour. Complementary therapies, such as acupressure and acupuncture, may be used but the evidence base for their effectiveness is relatively weak (Abraham

Box 5.1 Common causes of vomiting

- Direct irritation of the throat, oesophagus, stomach or intestine (e.g. food poisoning).
- Anticipatory vomiting: situations which have previously been associated with vomiting.
- Sensory stimuli: strong smells or tastes, seeing others vomiting.
- Toxins: presence of drugs or other toxins (e.g. alcohol) in the bloodstream.
- Disruption of the inner ear: motion sickness, middle ear infections, physical trauma.
- Organic disease or conditions: migraines, certain tumours.
- Recent surgery: either as a direct result of surgery to the gut or surrounding organs or from the drugs used peri-operatively.
- Pregnancy.

Source: Adapted from Bennett (2009).

2008). Interventions including progressive muscle relaxation techniques (Campos de Carvalho et al. 2007) and hypnosis (Richardson et al. 2007) have been found to be effective in reducing nausea and vomiting associated with cancer chemotherapy but more research is required to establish the wider effectiveness of these approaches.

There is a wide variety of antiemetic drugs available, all of which act on one or more type of neuroreceptor, resulting in a central and/or peripheral effect. Bennett (2009) identifies nine categories of antiemetics, a summary of which can be found in Box 5.2. Table 5.1 summarizes the classification of drugs used to control nausea and vomiting.

Procedure guideline 5.1 Care of a patient who is vomiting

Essential equipment

- Clean gloves and apron
- 2 × vomit bowls
- Tissues/wipes
- Bowl of warm water, wipes, towel

Pre-procedure

Action	Rationale
1 Ensure the patient is in a safe place and position to avoid any unnecessary injury or fall.	To maintain patient safety. E
2 Put on clean gloves and an apron.	To ensure procedure is as clean as possible (Fraise and Bradley 2009, E).

Procedure

3 Close door/draw curtains around the patient's bed area.	To maintain privacy and dignity and avoid any unnecessary embarrassment for the patient (NMC 2015, C).
4 Provide the patient with a vomit bowl and tissues.	To reduce any risk of spillage and cross-infection (Fraise and Bradley 2009, E).
5 Remain with the patient.	To provide reassurance and maintain safety. E
6 Once the patient has stopped vomiting, remove used vomit bowl and offer warm water and towels for them to wash face and hands.	For infection prevention and control and patient comfort (Fraise and Bradley 2009, E).
7 Assist the patient to find a comfortable position and leave the second, clean vomit bowl with them.	To ensure comfort following the procedure. E
8 Take vomit bowl to the dirty utility (sluice) room and, where necessary, measure volume and note characteristics (colour, consistency and smell) of the vomit.	The characteristics of the vomit may help to determine the cause. E

Post-procedure

9 Dispose of contents safely and place vomit bowl in the washer/disposal unit.	For infection prevention and control (Fraise and Bradley 2009, E).
10 Remove disposable apron and gloves. Wash hands using soap and water.	For infection prevention and control (Fraise and Bradley 2009, E).
11 Record volume and any notable characteristics of the vomit in the patient's notes.	To maintain accurate documentation (NMC 2010, C).
12 Return to the patient and assess nausea and vomiting at regular intervals.	To monitor and maintain patient's safety. E

Insertion of a nasogastric drainage tube

For patients who are vomiting large amounts, it may be appropriate to insert a nasogastric drainage tube in order to make the patient more comfortable, avoid any unnecessary trauma, such as to wounds, from the retching associated with vomiting and to more effectively monitor fluid output.

Anticipated patient outcomes

The patient has a nasogastric drainage tube inserted comfortably and safely. The position is checked and it is confirmed that the tube is placed in the stomach.

Legal and professional issues

Those passing the nasogastric tube should have achieved competencies set by the local trust and be clear that the purpose of inserting the tube is for drainage of gastric contents only.

Pre-procedural considerations

Equipment

A wide-bore nasogastric drainage tube must be used for this procedure. This should not be confused with a fine-bore nasogastric

Box 5.2 Classes of antiemetics

Antihistamines

Antihistamines block the histamine H1 receptor and are widely used. The main side-effects are the sedative potential and anticholinergic side-effects (e.g. dry mouth, constipation). Cyclizine tends to be less sedating than other antihistamines and is commonly used as a first-line treatment for post-operative nausea and vomiting or motion sickness.

Dopamine antagonists

Act by blocking the dopamine D2 receptors in the chemoreceptor trigger zone. Some antipsychotic drugs, such as the phenothiazines, have a strong affinity for these receptors but also block D2 receptors elsewhere, leading to side-effects such as restlessness and tremors, which may limit their use as an antiemetic, particularly in very young or older patients (Bennett 2009). Metoclopramide and domperidone act on D2 receptors in the chemoreceptor trigger zone (CTZ) but also act on receptors in the gastrointestinal tract which can reduce abdominal bloating. There is a particular risk of neurological side-effects with longer-term use and higher doses (BNF 2014). Levomepromazine is a ‘broad-spectrum’ antiemetic, acting on a range of receptors, that also has sedating and analgesic effects and so is often used in the palliative care setting.

5-HT3 antagonists

These are regarded as highly effective antiemetics which block 5-HT3 receptors in the CTZ and the gastrointestinal tract. They are commonly used to prevent chemotherapy-induced nausea and vomiting.

Steroids

Dexamethasone, a corticosteroid, is recognized for its antiemetic effect (Warren and King 2008), and is often used in conjunction with other antiemetics, although its mechanism of action is not clear.

Other antiemetics

Other categories of antiemetic include benzodiazepines, which work in the central nervous system to inhibit the GABA neurotransmitter; anticholinergics, such as hyoscine hydrobromide which acts directly on the vomiting centre and cannabinoids which inhibit nausea and vomiting caused by substances that irritate the CTZ, although the precise mechanism of action is not clearly understood. Neurokinin-1 antagonists are a relatively new category of antiemetic acting on NK1 receptors in the CTZ which have been found to be most effective in the treatment of chemotherapy-induced nausea and vomiting when used in conjunction with an HT3 antagonist and dexamethasone (BNF 2014, Dikken and Wildman 2013).

Source: Adapted from Bennett (2009), BNF (2014).

tube that is used for the sole purpose of enteral feeding (see Chapter 7, Procedure guideline 7.10: Nasogastric intubation with tubes using an internal guidewire or stylet).

Specific patient preparation

The planned procedure should be discussed with the patient so they are aware of the rationale for insertion of a nasogastric tube. The decision to insert a nasogastric tube must be made by at least two healthcare professionals, including the senior doctor

Table 5.1 Classification of drugs used to control nausea and vomiting

Site/mode of action	Class	Example
Central nervous system		
Vomiting centre	Anticholinergic Antihistamine* 5-HT2 antagonist	Hyoscine hydrobromide, cyclizine, dimenhydrinate, phenothiazines, levomepromazine
Central nervous system	Neurokinin-1 antagonist	Aprepitant
Chemoreceptor trigger zone	Dopamine (D2) antagonist 5-HT3 antagonist	Haloperidol, phenothiazines, metoclopramide, domperidone, levomepromazine, granisetron, ondansetron, tropisetron
Cerebral cortex	Benzodiazepine Cannabinoid Corticosteroid	Lorazepam Nabilone Dexamethasone
Gastrointestinal tract		
Prokinetic	5-HT4 agonist Dopamine (D2) antagonist	Metoclopramide Metoclopramide, domperidone, levomepromazine
Antisecretory	Anticholinergic Somatostatin analogue	Hyoscine butylbromide Glycopyrronium Octreotide
Vagal 5-HT3 receptor blockade	5-HT3 antagonist	Granisetron, ondansetron, tropisetron
Anti-inflammatory	Corticosteroid	Dexamethasone
*Antihistamines and phenothiazines both have H1 receptor antagonistic and anticholinergic properties. Vomiting is a significant yet complex symptom that requires a multifactorial approach to assess, prevent and manage it effectively. Source: Adapted from Twycross and Back (2004).		

responsible for the patient’s care. Verbal consent for the procedure must be obtained from the patient.

Contraindications

Prior to performing this procedure, the patient’s medical and nursing notes should be consulted to check for potential complications. For example, anatomical alterations due to surgery, such as a flap repair, or the presence of a cancerous tumour can prevent a clear passage for the nasogastric tube, resulting in pain and discomfort for the patient and further complications. Patients who have recurrent retching or vomiting, swallowing dysfunction or are comatose have a high risk of placement error or migration of the tube so care must be taken when placing a nasogastric tube under these circumstances (NPSA 2011). The assessment of the patient, the risks and patient consent obtained should be clearly documented.

Procedure guideline 5.2 Insertion of a nasogastric (NG) drainage tube

Essential equipment

- Clean tray
- Receiver
- Nasogastric tube
- Drainage bag
- Tape
- Disposable gloves and apron
- Lubricating jelly
- Gauze squares
- 50 mL syringe

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Arrange a signal by which the patient can communicate if they want the nurse to stop, for example by raising their hand.
- 3 Assist the patient to sit in a semi-upright position in the bed or chair. Place a pillow behind their head for support. *Note:* The head should not be tilted backwards or forwards.
- 4 Using a small piece of tape, mark the distance to which the tube is to be passed by measuring the distance on the tube from the patient's earlobe to the bridge of the nose plus the distance from the earlobe to the bottom of the xiphisternum (the NEX measurement). See Chapter 7, Procedure guideline 7.10: Nasogastric intubation with tubes using an internal guidewire or stylet, **Action figure 4a,b**.
- 5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required. Put on disposable gloves and apron.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To maintain communication and minimize discomfort and trauma to the patient during the procedure. **E**
- To maintain a suitable position during the procedure to help correct insertion of the tube (Rollins 1997).
- To identify the length of tube that needs to be inserted to ensure it is in the correct position. **E**
- To ensure procedure is as clean as possible (Fraise and Bradley 2009, **E**).

Procedure

- 6 Check the nostrils are patent by asking the patient to sniff with one nostril closed. Repeat with the other nostril. To avoid any blockages or anatomical abnormalities. **E**
- 7 Lubricate about 15–20 cm of the tube with a thin coat of lubricating jelly that has been placed on a gauze swab. To make insertion of the tube easier. **E**
- 8 Ensure receiver is placed beneath the end of the tube. To prevent spillage and reduce risk of infection (Fraise and Bradley 2009, **E**).
- 9 Insert the proximal end of the tube into the clearer nostril and slide it backwards and inwards along the floor of the nose to the nasopharynx. If an obstruction is felt, withdraw the tube and try again in a slightly different direction or use the other nostril. To avoid unnecessary trauma to the nose and nasopharynx.
- 10 As the tube passes down into the nasopharynx, ask the patient to start swallowing. Offer sips of water. To help ensure that the tube passes easily into the oesophagus.
- 11 Advance the tube through the pharynx as the patient swallows until the tape-marked tube reaches the point of entry into the nostril (NEX measurement). If the patient shows signs of distress, for example gasping or cyanosis, remove the tube immediately. Reaching the NEX measurement on the tube indicates that it should have advanced far enough down the oesophagus to be correctly positioned in the stomach. If there are signs of respiratory distress this may indicate the tube is incorrectly positioned in the bronchus. **E**
- 12 Secure the tube to the nostril with adherent dressing tape, for example Elastoplast, or an adhesive nasogastric stabilization/securing device. If this is contraindicated, a hypoallergenic tape should be used. An adhesive patch (if available) will secure the tube to the cheek. To ensure the tube remains in the correct position. **E**
- 13 Use the syringe to gently aspirate any stomach contents and then attach the tube to a drainage bag. Aspiration and/or drainage of stomach contents or bile will indicate that the tube is in the correct position in the stomach.
- 14 Assist the patient to find a comfortable position. To ensure comfort following the procedure. **E**

Post-procedure

- 15 If unsure of the tube's position, the following method can be used to test it.

(continued)

Procedure guideline 5.2 Insertion of a nasogastric (NG) drainage tube (*continued*)

Action	Rationale
<p>pH Test</p> <p>Aspirate 0.5–1 mL of stomach contents and test pH on indicator strips (NPSA 2011).</p>	<p>A pH level of between 1 and 5.5 reflects the acidity of the stomach and so is unlikely to be pulmonary aspirates (Metheny and Meert 2004; NPSA 2011, C). If a pH of 6 or above is obtained, then a second person should retest.</p>
<p>16 Remove gloves and apron and dispose of all equipment safely. Wash hands using soap and water.</p>	<p>For infection prevention and control (Fraise and Bradley 2009, E).</p>
<p>17 Record the procedure, NEX measurement, length of visible portion of the tube from tip of nose and tip position in the patient's notes.</p>	<p>To maintain accurate documentation (NMC 2010, C).</p>

Removal of a nasogastric drainage tube

Prior to removal of a nasogastric drainage tube, the procedure should be explained to the patient and verbal consent obtained.

Procedure guideline 5.3 Removal of a nasogastric tube*Essential equipment*

- Clean gloves and apron
- Contaminated waste disposal bag
- Bowl of warm water and wipes

Pre-procedure

Action	Rationale
1 Explain the procedure to the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Assist the patient to sit in a semi-upright position in the bed or chair. Support the patient's head with pillows.	To allow for easy removal of tube. E
3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required. Apply apron and clean gloves.	Hands must be cleansed before patient contact to minimize cross-infections (Fraise and Bradley 2009, E).

Procedure

4 Remove any tape securing the nasogastric tube to the nose.	To assist in removal of nasogastric tube. E
5 Using a steady and constant motion, gently pull the tube until it has been completely removed.	To remove the nasogastric tube. E
6 Place the used nasogastric tube directly into the contaminated waste bag.	For infection prevention and control (Fraise and Bradley 2009, E).
7 Using warm water and wipes, clean the nose and face to remove any traces of tape.	To ensure patient comfort and dignity. E
8 Assist the patient to find a comfortable position.	To ensure comfort following the procedure. E

Post-procedure

9 Remove gloves and apron and dispose of all equipment safely. Wash hands using soap and water.	For infection prevention and control (Fraise and Bradley 2009, E).
10 Document removal of nasogastric tube in care plan and patient's notes.	To ensure adequate records and to enable continued care of patient (NMC 2010, C).

Urinary elimination**Definition**

Urinary elimination is the excretion of urine from the body (Thibodeau and Patton 2010).

Anatomy and physiology

The urinary tract (see Figure 5.2) consists of the two kidneys, two ureters, the bladder and urethra. The urinary system produces, stores and eliminates urine. The kidneys are responsible for excreting wastes such as urea and ammonium and for the

reabsorption of glucose and amino acids. They are involved with the production of hormones including calcitriol, renin and erythropoietin. The kidneys also have homeostatic functions, including the regulation of electrolytes, acid/base balance and blood pressure (Tortora and Derrickson 2011).

Each kidney excretes urine into a ureter, which arises from the renal pelvis on the medial aspect of each kidney. In adults, the ureters are approximately 25–30 cm long and 2–4 mm in diameter (Tortora and Derrickson 2011). The ureters are muscular tubes, which propel urine from the kidneys to the urinary bladder. They enter through the back of the bladder, running within the wall of the bladder for a few centimetres. Ureterovesical valves prevent the backflow of urine from the bladder to the kidneys.

The bladder sits on the pelvic floor and is a hollow, muscular, distensible organ which stores urine until it is convenient to expel it. Urine enters the bladder via the ureters and exits via the urethra. As the bladder fills, stretch receptors in the muscular wall signal the parasympathetic nervous system to contract the bladder, initiating the conscious desire to expel urine. In order for urine to be expelled, both the automatically controlled internal sphincter and the voluntary controlled external sphincter must be opened.

Urine leaves the bladder via the urethra. In females this lies in front of the anterior wall of the vagina and is approximately 3.8 cm long. In males it passes through the prostate and penis and is approximately 20 cm long (Tortora and Derrickson 2011).

Faecal elimination

Definition

Faecal elimination is the expulsion of the residues of digestion – faeces – from the digestive tract (Thibodeau and Patton 2010). The act of expelling faeces is called defaecation.

Figure 5.2 (a) Male and (b) female genitourinary tract.

Anatomy and physiology

This section will consider the normal structure and function of the bowel, which includes the small and large intestine (Figure 5.3).

Figure 5.3 The gastrointestinal tract. Source: Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

THE BRISTOL STOOL FORM SCALE

Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces ENTIRELY LIQUID

Figure 5.4 Bristol Stool Chart. *Source:* Reproduced by kind permission of Dr KW Heaton, Reader in Medicine at the University of Bristol. © 2000–2014, Norgine Group of Companies.

The small intestine begins at the pyloric sphincter of the stomach, coils through the abdomen and opens into the large intestine at the ileocaecal junction. It is approximately 6 m in length and is divided into three segments: the duodenum (25 cm), jejunum (2.5 m) and ileum (3.5 m) (Thibodeau and Patton 2010). The mucosal surface of the small intestine is covered with finger-like processes called

villi, which increase the surface area available for absorption and digestion. A number of digestive enzymes are also secreted by the small intestine (Tortora and Derrickson 2011). Movement through the small bowel is divided into two types, segmentation and peristalsis, and is controlled by the autonomic nervous system. Segmentation refers to the localized, concentric

contraction of the intestine, aided by constant lengthening and shortening of the villi, mixing the intestinal contents and bringing particles of food into contact with the mucosa for absorption. Once the majority of a meal has been absorbed through this process, intestinal content is then pushed along the small intestine by repeated peristaltic wave-like actions. Intestinal content usually remains in the small bowel for 3–5 hours (Tortora and Derrickson 2011).

The total volume of fluid, including ingested liquids and gastrointestinal secretions, that enters the small intestine daily is about 9.3 litres. The small intestine is responsible for absorbing around 90% of the nutrients, electrolytes and water within this volume by diffusion, facilitated diffusion, osmosis and active transport (Tortora and Derrickson 2011). Water is able to move across the intestinal mucosa in both directions, but is influenced by the absorption of nutrients and electrolytes. As various electrolytes and nutrients are actively transported out of the lumen, they create a concentration gradient, promoting water absorption, via osmosis, in order to maintain an osmotic balance between intestinal fluid and blood. This ultimately leads to only about 1 litre of effluent passing through into the colon (Thibodeau and Patton 2010, Tortora and Derrickson 2011).

From the ileocaecal sphincter to the anus, the colon is approximately 1.5–1.8 m in length and 4–6 cm in diameter. Its main function is to eliminate the waste products of digestion by the propulsion of faeces towards the anus. In addition, it produces mucus to lubricate the faecal mass, thus aiding its expulsion. Other functions include the absorption of fluid and electrolytes, including sodium and potassium, the storage of faeces and the synthesis of vitamins B and K by bacterial flora (Thibodeau and Patton 2010, Tortora and Derrickson 2011).

Faeces consist of the unabsorbed end-products of digestion, bile pigments, cellulose, bacteria, epithelial cells, mucus and some inorganic material. They are normally semi-solid in consistency and contain about 70% water (Tortora and Derrickson 2011). The colon absorbs about 2 litres of water in 24 hours, so if faeces are not expelled they will gradually become hard due to dehydration and more difficult to expel. If there is insufficient roughage (fibre) in the faeces, colonic stasis occurs, which leads to continued water absorption and further hardening of the faeces. Faeces will, therefore, vary in consistency, as illustrated in the Bristol Stool Chart (Figure 5.4).

The movement of faeces through the colon towards the anus occurs by mass peristalsis, a gastrocolic reflex initiated by the presence of food in the stomach, which begins at the middle of

the transverse colon and quickly drives the colonic contents into the rectum. This mass peristaltic movement generally occurs 3–5 times a day (Perdue 2005). In response to this stimulus, faeces move into the rectum (Norton 1996, Taylor 1997, Tortora and Derrickson 2011). This rectal distension triggers the desire to defaecate, also known as the ‘call to stool’.

Assisting the patient with elimination

Evidence-based approaches

Principles of care

Elimination is a sensitive issue and providing effective care and management for problems associated with it can be problematic. The difficulties associated with this can be minimized if the nurse seeks to respect the patient's dignity when carrying out procedures such as assisting them with using a bedpan or a commode.

Legal and professional issues

The privacy and dignity of the patient must be respected at all times (NMC 2015). It is essential that the procedure is explained clearly to the patient to ensure consent is obtained and patient co-operation is agreed. A moving and handling assessment is vital in order to establish if additional equipment such as a hoist is required.

Pre-procedural considerations

Equipment

Before commencing the procedure, ensure that appropriate equipment and staff are available for safe moving and handling of the patient and, depending on the patient's mobility, that either a bedpan or commode is available for immediate use (Figure 5.5, Figure 5.6).

Figure 5.5 Slipper bed pan.

Figure 5.6 Commode.

Pharmacological support

Incontinence-associated dermatitis (IAD) is a term used for skin breakdown resulting from exposure to urine or faeces and so is a common problem with either faecal and/or urinary incontinence (Doughty et al. 2012, Gray et al. 2007) and has been clearly differentiated from other forms of skin damage such as pressure ulcers or skin tears (Gray et al. 2012). Current nursing practice includes the use of a wide range of skin moisturizers and barrier creams with varying evidence about their efficacy or effectiveness (Gray et al. 2012). Ripley (2007) suggests that barrier products vary in

both properties and uses but they can be effective in promoting skin integrity when selected appropriately. The same author recommends the development of protocols to support effective use of such products. A review suggests that the use of barrier creams with a pH near to that of normal skin can be useful in prevention of skin problems (Beeckman et al. 2009, Geraghty 2011). Recommendations from a recent international consensus conference advocate a consistently applied skin regime for the prevention and treatment of IAD which includes gentle perineal cleansing, moisturization and application of a skin protectant, but suggest that further research is required (Doughty et al. 2012, Gray et al. 2012).

Procedure guideline 5.4 Slipper bedpan use: assisting a patient

Essential equipment

- Disposable apron and gloves
- Manual handling equipment as appropriate
- Slipper bedpan and paper cover
- Additional nurse if required to assist with manual handling
- Toilet paper
- Wash bowl, warm water, disposable wipes and a towel

Pre-procedure

Action

- 1 Carry out appropriate manual handling assessment prior to commencing procedure and establish whether an additional nurse or equipment such as a hoist is necessary.

Rationale

To maintain a safe environment. **E**

Procedure

- | | |
|--|---|
| 2 Take the equipment to the bedside and explain the procedure to the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 3 Wash hands, put on gloves and apron. | To ensure procedure is as clean as possible and minimize the risk of spreading infection (Fraise and Bradley 2009, E). |
| 4 Close door/draw curtains around the patient's bed area. | To maintain privacy and dignity and avoid any unnecessary embarrassment for the patient (NMC 2015, C). |
| 5 Remove the bedclothes and, providing there are no contraindications (e.g. if patient is on flat bedrest), assist the patient into an upright sitting position. | An upright, 'crouch-like' posture is considered anatomically correct for defaecation. Poor posture adopted while using a bedpan has been shown to cause extreme straining during defaecation. Patients should therefore be supported with pillows in order to achieve an upright position on the bedpan (Woodward 2012, E). |
| 6 Ask the patient to raise their hips/buttocks and insert the bedpan beneath the patient's pelvis, ensuring that the wide end of the bedpan is between the legs, and the narrow end is beneath the buttocks. | A slipper bedpan provides more comfort for a patient who is unable to sit upright on a conventional bedpan (Nicol 2008, E). |
| 7 Offer the patient the use of pillows and encourage them to lean forward slightly if possible. | To provide support and optimize positioning for defaecation (Woodward 2012, E).
To ensure that the patient is in optimum position for eliminating. E |
| 8 Once the patient is on the bedpan, encourage them to move their legs slightly apart and check to ensure that their positioning is correct. | To avoid any spillage onto the bedclothes and reduce risk of contamination and cross-infection. E |
| 9 Cover the patient's legs with a sheet. | To maintain privacy and dignity (NMC 2015, C). |
| 10 Ensure that toilet paper and call bell are within patient's reach and leave the patient, but remain nearby. | To maintain privacy and dignity (NMC 2015, C). |

11 When the patient has finished using the bedpan, remove it, replace the paper cover and bring washing equipment to the bedside. Assist the patient to clean perianal area using warm water and soap. Apply a small amount of barrier cream to the perineal/buttock area if appropriate.	Talcum powder should not be used and barrier creams should be applied sparingly, gently layered on in the direction of the hair growth rather than rubbed into the skin (Le Lievre 2002, E).
12 Offer a bowl of water or moistened wipes for the patient to clean their hands.	For infection prevention and control and patient comfort (Fraise and Bradley 2009, E).
13 Ensure bedclothes are clean, straighten sheets and rearrange pillows, assisting patient to a comfortable position. Ensure call bell is within reach of the patient.	For patient comfort. P
14 Take bedpan to the dirty utility (sluice) room and, where necessary, measure urine output and note characteristics and amount of faeces using the Bristol Stool Chart (Figure 5.4).	To monitor and evaluate patient's elimination patterns. E

Post-procedure

15 Dispose of contents safely and place bedpan in the washer/disposal unit.	For infection prevention and control (Fraise and Bradley 2009, E).
16 Remove disposable apron and gloves. Wash hands using soap and water.	For infection prevention and control (Fraise and Bradley 2009, E).
17 Record any urine output/bowel action in patient's documentation.	To maintain accurate documentation (NMC 2010, C).

Procedure guideline 5.5 Commode use: assisting a patient

Essential equipment

- Disposable apron and gloves
- Manual handling equipment as appropriate
- A clean commode with conventional bedpan inserted below seat
- Additional nurse if required
- Toilet paper
- Wash bowl, warm water, disposable wipes and a towel

Pre-procedure

Action	Rationale
1 Carry out appropriate manual handling assessment prior to commencing procedure and ensure that patient's weight does not exceed the maximum recommended for commode (see manufacturer's guidelines).	To maintain a safe environment. E
2 Wash hands, put on gloves and apron.	For infection prevention and control (Fraise and Bradley 2009, E).
3 Take the equipment to the bedside and explain the procedure to the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).

Procedure

4 Close door/draw curtains around the patient's bed area.	To maintain privacy and dignity and avoid any unnecessary embarrassment for the patient (NMC 2015, C).
5 Remove the commode cover. Assist the patient out of the bed/chair and onto the commode.	
6 Once seated, ensure the patient's feet are positioned directly below their knees and flat on the floor. The use of a small footstool and/or pillows may help to achieve a comfortable position.	An upright, crouching posture is considered anatomically correct for defaecation. Pillows and a footstool can provide support and optimize positioning for defaecation (Woodward 2012, E).
7 Cover the patient's knees with a towel or sheet.	To maintain privacy and dignity (NMC 2015, C).

(continued)

Procedure guideline 5.5 Commode use: assisting a patient (*continued*)

Action	Rationale
8 Ensure that toilet paper and call bell are within patient's reach and leave the patient, but remain nearby.	To maintain privacy and dignity (NMC 2015, C) and to prevent falls.
9 When the patient has finished using the commode, bring washing equipment to the bedside. Assist patient to clean perianal area using toilet paper and, where necessary, warm water and soap. Apply a small amount of barrier cream to the perineal/buttock area if appropriate.	Talcum powder should not be used and barrier creams should be applied sparingly, gently layered on in the direction of the hair growth rather than rubbed into the skin (Le Lievre 2002, E).
10 Offer a bowl of water for the patient to wash their hands.	For infection control and patient dignity (Fraise and Bradley 2009, E).
11 Assist the patient to stand and walk to bed/chair, ensuring that they are comfortably positioned. Ensure call bell is within reach of the patient.	For patient comfort. P
Post-procedure	
12 Replace cover on the commode and return to the dirty utility (sluice) room.	To reduce any risk of contamination or cross-infection (Fraise and Bradley 2009, E) and to avoid patient embarrassment (NMC 2015, C).
13 Remove pan from underneath the commode and, where necessary, measure urine output and note characteristics and amount of faeces using the Bristol Stool Chart (see Figure 5.4).	To monitor and evaluate patient's elimination patterns. E
14 Dispose of contents safely and place pan in the washer/disposal unit.	For infection prevention and control (Fraise and Bradley 2009, E).
16 Clean commode using Actichlor Plus solution and label commode according to local guidelines to indicate it has been cleaned.	
17 Remove disposable apron and gloves. Wash hands using bactericidal soap and water.	For infection control purposes (Fraise and Bradley 2009, E).
18 Record any urine output/bowel action in patient's documentation.	To maintain accurate documentation (NMC 2010, C).

Altered urinary elimination

This section first examines urinary incontinence and then reviews different approaches to its management. Surgical interventions and supportive care for altered urinary elimination will be considered, including insertion of nephrostomy tubes and urinary diversions.

Urinary incontinence

Related theory

Urinary incontinence is a worldwide problem affecting 13% of men and 14% of women aged 65–74 years (Nethercliffe 2012). Nurses will encounter patients with incontinence in most care settings, so it is important that they are aware of the issues surrounding this sensitive subject (Lay 2012).

Risk factors include the following.

- Age (Devore et al. 2012).
- Neurological conditions (MS or MDN, spinal cord injury) (Nethercliffe 2012).
- Surgical procedures (hysterectomy, pelvic surgery) (Stothers and Friedman 2011).
- Diabetes (Stothers and Friedman 2011).

- Higher body mass index (Devore et al. 2012).
- Physical trauma (childbirth) (Nethercliffe 2012).
- Menopause.
- Cystitis and UTI (Getliffe and Dolman 2007).
- Enlargement of the prostate – benign prostatic hyperplasia.
- Prostate surgery.
- Prostate cancer.

Evidence-based approaches – penile sheaths

Rationale

Penile sheaths are external devices made from a soft and flexible latex or silicone tubing which are applied over the penis to direct urine into a urinary drainage bag from where it can be conveniently emptied (Figure 5.7). A penile sheath is a soft flexible sleeve that fits over the penis with an anti-reflux bulbous end, which is able to attach to any standard urinary drainage bag (Kyle 2011a). They are used by men to manage urinary incontinence.

Penile sheaths (also known as conveys) are only to be considered once other methods of promoting continence have failed, as the promotion and treatment of incontinence should be the primary concern of the nurse (Pomfret 2002). They should be considered as a preferable alternative to other methods of continence control, such as pads which can quickly become sodden (Pomfret

Figure 5.7 Penile sheath.

2002) and cause skin problems, and catheters, which have several potential complications (Jahn et al. 2012).

Indications

Penile sheaths may be used to relieve incontinence when no other means is practicable or when all other methods have failed. Penile sheaths are associated with many common problems which are identified by Woodward (2007) and Wells (2008); these include difficulty in fitting, leaking, kinking, falling off, allergies and urinary tract infections.

Contraindications

Penile sheaths are contraindicated for men with very small or retracted penises, sensitive skin and allergies (Booth 2009, Wells 2008).

Pre-procedural considerations

Equipment

Silicone types are now preferred due to concerns about latex allergies (Booth and Lee 2005).

Sizing and fitting

As modern sheaths come in a variety of sizes and the correct size can be determined by measuring the girth of the penile shaft, one of the most important considerations is to move away from the mentality that one size fits all. The penis should be measured in the flaccid state (Potter 2007). Most devices come with a manufacturer's sheath sizing guide with different diameters cut into it, so that the correct size can be easily determined. Sheaths are available in a variety of different sizes, which generally increase in increments of 5–10 mm, and in either standard or short lengths (Robinson 2006). Silicone sheaths are advantageous as they are transparent, allowing the patient's skin to be observed and to breathe by allowing the transmission of water vapour and oxygen (Booth and Lee 2005).

The main methods of fixation in current use follow two different approaches. First, the sheaths can be self-adhesive, so that the sheath itself has a section along its length with adhesive on the internal aspect that sticks to the penile shaft as it is applied. The second method is a double-sided strip of hypoallergenic or foam material applied in a spiral around the penis (which increases the surface area of the condom adhered to the penis) and then the sheath is applied over the top. Newer devices have been developed which move away from the condom catheter-based system and employ a unique hydrocolloid 'petal' design which adheres only to a small area of the glans penis around the meatus, ensuring a comfortable and secure fit; these are ideal for men with a retracted penis (Wells 2008).

Procedure guideline 5.6 Penile sheath application

Essential equipment

- Bowl of warm water and soap
- Scissors or a disposable razor
- Clean disposable gloves and apron
- Drainage bag and stand or holder
- Selection of appropriate-sized penile sheaths
- Hypoallergenic tape or leg strap
- Bactericidal alcohol handrub
- Catheter leg bag

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives his valid consent (NMC 2013, C).
2 Screen the bed.	To ensure patient's privacy. To allow dust and airborne organisms to settle before the field is exposed (NMC 2015, C).
3 Prepare the trolley, placing all equipment required on the bottom shelf.	The top shelf acts as a clean working surface. E
4 Take the trolley to the patient's bedside, disturbing the screens as little as possible.	To minimize airborne contamination (Fraise and Bradley 2009, E).
5 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.	To reduce risk of infection (Fraise and Bradley 2009, E).
6 Put on a disposable plastic apron.	To reduce risk of cross-infection from micro-organisms on the uniform (Fraise and Bradley 2009, E).
7 Assist the patient into a comfortable position. The patient can lie on the bed in the supine position or sit on the edge of the bed.	To ensure the appropriate area is easily accessible. E

(continued)

Procedure guideline 5.6 Penile sheath application (continued)

Action	Rationale
Procedure	
8 Assist the patient to remove his underwear and ensure he has a sheet or disposable towels available and use to cover his thighs.	To maintain privacy and dignity (NMC 2015).
9 Position a disposable pad under the patient's buttocks and thighs.	To ensure urine does not leak onto bedclothes. E
10 Clean hands with a bactericidal alcohol handrub.	Hands may have become contaminated by handling the outer packs (Fraise and Bradley 2009, E).
11 Put on non-sterile gloves.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
12 With one hand retract the foreskin, if necessary, and with the other hand clean the penis with soap and water. Dry completely and reduce or reposition the foreskin.	To remove old adhesive and ensure sheath sticks to the skin. To prevent retraction and constriction of the foreskin behind the glans penis (paraphimosis) which may occur if this is not performed. E
13 Using the scissors or disposable razor, trim any excess pubic hair from around the base of the penis.	To prevent sheath from painfully pulling pubic hair when applied. E
14 Apply sheath following manufacturer's guidelines, ensuring that there is a space between the glans penis and the sheath. Squeeze the sheath gently around the penile shaft.	To prevent the sheath from rubbing the glans penis and causing discomfort and potential skin irritation and to ensure sheath has adhered to penis (Pomfret 2002, C).
15 Connect catheter bag and ensure tubing is not kinked.	To facilitate drainage of urine into catheter bag. E
16 Remove gloves and apron. Dispose of all waste and equipment in an orange plastic clinical waste bag and seal the bag.	Orange is the recognized colour for clinical waste (DEFRA 2005, C).
Post-procedure	
17 Provide any assistance the patient may need to dress, encouraging loose clothing where possible. Draw back the curtains once the patient is dressed.	To maintain the patient's dignity (NMC 2015, C) and to avoid any unnecessary kinking of the sheath or its tubing. E
18 Dispose of clinical waste bag in a larger bin.	To prevent environmental contamination (Fraise and Bradley 2009, E).
19 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • reasons for applying penile sheath • date and time of application • sheath type • length and size • manufacturer • any problems negotiated during the procedure • a review date to assess the need for reapplication. 	To provide a point of reference or comparison in the event of later queries (NMC 2010, C).

Problem-solving table 5.1 Prevention and resolution (Procedure guideline 5.6)

Problem	Cause	Action	Prevention
Leaking or backflow of urine under the sheath.	Penile sheath is the wrong size.	Remeasure penile shaft and select the correct size.	Measure penile shaft using the sizing tool.
Twisting or kinking of sheath.	Lack of care taken when applying, drainage tube unsecured.	Secure drainage bag to leg or stand.	Assess patient mobility before application and select suitable type and method of securing the drainage bag.
Difficulty fitting sheath to patient with retracted penis.	Anatomy of the patient.	Observe the penile length when the patient is sitting. If the length of the penis is less than 5 cm when sitting, use a hydrocolloid petal design sheath.	It may be that a penile sheath is not the most appropriate device in some cases.

Urinary catheterization

Evidence-based approaches

Rationale

Urinary catheterization is the insertion of a specially designed tube into the bladder using aseptic technique, for the purposes of draining urine, the removal of clots/debris and the instillation of medication. It is an invasive procedure and should not be undertaken without full consideration of the benefits and risks. The presence of a catheter can be a traumatic experience for patients and have huge implications for body image, mobility, pain and discomfort (Clifford 2000, RCN 2012a). Indwelling catheters are the primary source of urinary tract infections within acute care. It is essential that they are only used if clinically necessary (Murphy et al. 2014).

Indications

Urinary catheterization may be carried out for the following reasons.

- To empty the contents of the bladder, for example before or after abdominal, pelvic or rectal surgery, before certain investigations and before childbirth, if thought necessary.
- To determine residual urine.
- To allow irrigation of the bladder.
- To bypass an obstruction.
- To relieve retention of urine.
- To enable bladder function tests to be performed.
- To measure urinary output accurately, for example when a patient is in shock, undergoing bone marrow transplantation or receiving high-dose chemotherapy.
- To relieve incontinence when no other means is practicable.
- To avoid complications during the insertion of radioactive material (e.g. caesium into the cervix/uterus, brachytherapy for the prostate).

Legal and professional issues

Competencies

Nurses performing female and/or male urinary catheterization must have demonstrated the appropriate level of competency to carry out this procedure and be sure it is within their scope of professional practice in accordance with *The Code* (NMC 2015).

Pre-procedural considerations

Patients should be assessed individually as to the ideal time to change their catheters. The use of a catheter diary will help to ascertain a pattern of catheter blockages so changes can be planned accordingly.

Equipment: catheter selection

A wide range of urinary catheters is available, made from a variety of materials and with different design features. Careful assessment of the most appropriate material, size and balloon capacity will ensure that the catheter selected is as effective as possible, that complications are minimized and that patient comfort and quality of life are promoted (Nazarko 2010, Pomfret 1996, Robinson 2001). Types of catheter are listed in Table 5.2 and illustrated in Figure 5.8, together with their suggested use. Catheters should be used in line with the manufacturer's recommendations, in order to avoid product liability (Fraise and Bradley 2009, NHS Supply Chain 2008).

Balloon size

In the 1920s, Fredrick Foley designed a catheter with an inflatable balloon to keep it positioned inside the bladder. Balloon sizes vary from 2.5 mL for children to 30 mL. A 5–10 mL balloon is recommended for adults and a 3–5 mL balloon for children.

Table 5.2 Types of catheter

Catheter type	Material	Uses
Balloon (Foley) two-way catheter: two channels, one for urine drainage and second, smaller channel for balloon inflation	Latex, PTFE-coated latex, silicone elastomer coated, 100% silicone, hydrogel coated	Most commonly used for patients who require bladder drainage (short, medium or long term)
Balloon (Foley) three-way irrigation catheter: three channels, one for urine, one for irrigation fluid, one for balloon inflation	Latex, PTFE-coated latex, silicone, plastic	To provide continuous irrigation (e.g. after prostatectomy). Potential for infection is reduced by minimizing the need to break the closed drainage system (Mulhall et al. 1993)
Non-balloon (Nelaton) or Scotts, or intermittent catheter (one channel only)	PVC and other plastics	To empty bladder or continent urinary reservoir intermittently; to instil solutions into bladder

PTFE, polytetrafluoroethylene; PVC, polyvinylchloride.

Care should be taken to use the correct amount of water to fill the balloon because too much or too little may cause distortion of the catheter tip. This may result in irritation and trauma to the bladder wall, consequently causing pain, spasm, bypassing and haematuria. If underinflated, one or more of the drainage eyes may become occluded or the catheter may become dislodged. Overinflation risks rupturing the balloon and leaving fragments of it inside the bladder (Robinson 2001). Catheter balloons should only be inflated once; deflation/reinflation or topping up is not recommended by the manufacturers as distortion of the balloon may occur (Nazarko 2009, Robinson 2004).

Catheter balloons must be filled only with sterile water (Hart 2008). Tap water and 0.9% sodium chloride should not be used as salt crystals and debris may block the inflation channel, causing difficulties with deflation (Head 2006). Any micro-organisms which may be present in tap water can pass through the balloon into the bladder (Stewart 1998).

Figure 5.8 Catheter types.

Catheter size

Urethral catheters are measured in charrières (ch). The charrière is the outer circumference of the catheter in millimetres and is equivalent to three times the diameter. Thus a 12 ch catheter has a diameter of 4 mm. The bigger the catheter, the more the urethra is dilated. 12 ch is normally suitable for men and women (Nazarko 2012). The urethra is approximately 6 mm in diameter, this is equivalent to a size 16 ch catheter. This is useful to know as it has implications for patient comfort.

Potential side-effects of large-gauge catheters include:

- pain and discomfort
- pressure ulcers, which may lead to stricture formation
- blockage of paraurethral ducts
- abscess formation (Winn 1998)
- bypassing – urethral leakage.

The most important guiding principle is to choose the smallest size of catheter necessary to maintain adequate drainage (Robinson 2006). If the urine to be drained is likely to be clear, a 12 ch catheter should be considered. Larger gauge catheters may be necessary if debris or clots are present in the urine (Pomfret 1996, Winn 1998).

Length of catheter

There are three lengths of catheter currently available:

- female length: 23–26 cm
- paediatric: 30 cm
- standard length: 40–44 cm.

The shorter female length catheter is often more discreet and less likely to cause trauma or infections because movement in and out of the urethra is reduced. Infection may also be caused by the longer catheter looping or kinking (Pomfret 2002, Robinson 2001). In obese women or those in wheelchairs, however, the inflation valve of the shorter catheter may cause soreness by rubbing against the inside of the thigh, and the catheter is more likely to pull on the bladder neck; therefore, the standard length catheter should be used (Evans et al. 2001, Godfrey and Evans 2000, Pomfret 2004).

It is vital to stress that female catheters must not be used for male catheterization. This will cause trauma to the urethra as the balloon will be inflated inside it. It can cause haematuria, penile swelling, retention and impaired renal function. The NSPA have produced a rapid response report alerting clinical staff to the dangers of this (NSPA 2009).

Tip design

Several different types of catheter tip are available in addition to the standard round tip (Figure 5.9). Each tip is designed to overcome a particular problem.

- The *Tiemann-tipped catheter* has a curved tip with 1–3 drainage eyes to allow greater drainage. This catheter has been designed

to negotiate the membranous and prostatic urethra in patients with prostatic hypertrophy. It is recommended that these catheters are only inserted by a urology specialist.

- The *whistle-tipped catheter* has a lateral eye in the tip and eyes above the balloon to provide a large drainage area. This design is intended to facilitate drainage of debris, for example blood clots.
- The *Roberts catheter* has an eye above and below the balloon to facilitate the drainage of residual urine.

Catheter material

A wide variety of materials is used to make catheters. The key criterion in selecting the appropriate material is the length of time the catheter is expected to remain in place. Three broad time-scales have been identified.

- Short term (1–7 days), e.g. PVC and intermittent catheters.
- Short to medium term (up to 28 days), e.g. PTFE.
- Medium to long term (6–12 weeks), e.g. hydrogel and silicone coated.

The principal catheter materials are as follows.

Polyvinyl chloride (PVC)

Catheters made from PVC or plastic are quite rigid. They have a wide lumen, which allows a rapid flow rate, but their rigidity may cause some patients discomfort. They are mainly used for intermittent catheterization or post-operatively. They are recommended for short-term use only (Pomfret 1996).

Latex

Latex is a purified form of rubber and is the softest of the catheter materials. It has a smooth surface, with a tendency to allow crust formation. Latex absorbs water and consequently the catheter may swell, reducing the diameter of the internal lumen and increasing its external diameter (Pomfret 2002, Robinson 2001). It has been shown to cause urethral irritation and therefore should only be considered when catheterization is likely to be short term.

Hypersensitivity to latex has been increasing in recent years (Woodward 1997) and latex catheters have been the cause of some cases of anaphylaxis (Young et al. 1994). Woodward (1997) suggests that patients should be asked whether they have ever had an adverse reaction to rubber products before catheters containing latex are utilized.

Teflon (polytetrafluoroethylene [PTFE]) or silicone elastomer coatings

A Teflon or silicone elastomer coating is applied to a latex catheter to render the latex inert and reduce urethral irritation (Bell 2010). Teflon is recommended for short-term use and silicone elastomer-coated catheters are used for long-term catheterization.

All silicone

Silicone is an inert material which is less likely to cause urethral irritation. Silicone catheters are not coated and therefore have a wider lumen. The lumen of these catheters, in cross-section, is crescent or D-shaped, which may induce formation of encrustation (Pomfret 1996). Because silicone permits gas diffusion, balloons may deflate and allow the catheter to fall out prematurely. These catheters may be more uncomfortable as they are more rigid than the latex-cored types. All-silicone catheters are suitable for patients with latex allergies. Silicone catheters are recommended for long-term use.

Hydrogel coatings

Catheters made of an inner core of latex encapsulated in a hydrophilic polymer coating are commonly used for long-term catheterization. The polymer coating is well tolerated by the urethral mucosa, causing little irritation. Hydrogel-coated catheters become smoother when rehydrated, reducing friction with the

urethra. They are also inert and are reported to be resistant to bacterial colonization and encrustation (Woollons 1996). Hydrogel-coated catheters are recommended for long-term use.

Conformable catheter

Conformable catheters are designed to conform to the shape of the female urethra, and allow partial filling of the bladder. The natural movement of the urethra against the collapsible catheter is intended to prevent obstructions. They are made of latex and have a silicone elastomer coating. Conformable catheters are approximately 3 cm longer than conventional catheters for women.

Other materials

Research into new types of catheter materials is ongoing, particularly examining materials that resist the formation of biofilms (bacterial colonies that develop and adhere to the catheter surface and drainage bag) and consequently reduce the instances of urinary tract infections (Loveday et al. 2014).

Catheters coated with a silver alloy have been shown to prevent urinary tract infections (Schumm and Lam 2008). However, the studies that demonstrated this benefit were all small scale and a number of questions about the long-term effects of using such catheters, such as silver toxicity, need to be addressed. Arguria is a condition caused by the deposition of silver locally or systemically in the body, and can give rise to nausea, constipation and loss of night vision (Bardsley 2009, Loveday et al. 2014). There is some suggestion in the research that the use of silver alloy-coated catheters does reduce the onset of bacteriuria and may be beneficial when catheterization is in high-risk situations, for example diabetic and intensive care patients (Saint et al. 2000). However, research trials analysed by the Cochrane Collaboration (Schumm and Lam 2008) indicate that this asymptomatic bacteraemia was only seen in the first 5–7 days; after this, the catheter type made little difference (Loveday et al. 2014, Plowman et al. 2001).

Catheters coated with antibiotics such as gentamicin, rifampicin, nitrofurazone and nitrofuraxone have been investigated in the search to find a product that will reduce instances of catheter-associated urinary tract infections (CAUTI). They may have a role to play in the management of trauma patients; nitrofurazone-impregnated catheters were shown to reduce urinary infections when compared with standard catheters in a trial by Stensballe et al. (2007). Whether this effect would be present in non-trauma patients and in the management of patients with long-term catheters is unknown. However, issues such as antibiotic sensitivity or resistance have not been fully investigated or assessed (Schumm and Lam 2008).

The cost implications for routine use of these impregnated catheters would be huge for the NHS (Johnson et al. 2006). However, a recent review of impregnated catheters found that silver alloy (antiseptic)-coated or nitrofurazone-impregnated (antibiotic) urinary catheters do reduce infections in hospitalized adults, and siliconized catheters may reduce adverse effects in men, but the evidence is weak (Schumm and Lam 2008). Trials with a specific catheter may be appropriate on an individual patient basis when other types of catheter management of recurrent infections have failed.

Drainage bags

A wide variety of drainage systems is available. When selecting a system, consideration should be given to the reasons for catheterization, intended duration, the patient's wishes, and infection control issues.

Urine drainage bags should only be changed according to clinical need; that is, when that catheter is changed or if the bag is leaking, or at times dictated by the manufacturer's instructions, for example every 5–7 days (Loveday et al. 2014). Urine drainage bags positioned above the level of the bladder and full bags cause urine to reflux, which is associated with infection. Therefore bags should always be positioned below the level of the bladder to maintain an unobstructed flow and be emptied appropriately.

Figure 5.10 Urinary catheter bag, standard.

Urine drainage bags should be hung on suitable stands to avoid contact with the floor. In situations when dependent drainage is not possible, the system should be clamped until dependent drainage can be resumed (Kunin 1997). When emptying drainage bags, clean separate containers should be used for each patient and care should be taken to avoid contact between the drainage tap and the container (Loveday et al. 2014).

Urine drainage bags are available in a wide selection of sizes ranging from the large 2 litre bag, which is used more commonly in non-ambulatory patients and overnight, to 350–750 mL leg bags (Figure 5.10, Figure 5.11). There are also large drainage bags that incorporate urine-measuring devices, which are used when very close monitoring of urine output is required (Figure 5.12).

There are a number of different styles of drainage bags, from the body-worn 'belly bags' (Pomfret 2007) to the standard leg-worn bags. They allow patients greater mobility and can be worn under the patient's own clothes and therefore are much more discreet, helping to preserve the patient's privacy and dignity. Shapes vary from oblong to oval and some have cloth backing for greater comfort when in contact with the skin. Others are ridged to encourage an even distribution of urine through the bag, resulting in better conformity to the leg. The length of the inlet tube also varies (direct, short, long and adjustable length) and the intended position on the leg, that is thigh, knee or lower leg, determines which length is used (Robinson 2006, 2008). The patient should be asked to identify the most comfortable position for the bag (Pomfret 2007). The majority of drainage bags are fitted with an antireflux valve to prevent the backflow of urine into the bladder (Madedo and Roodhouse 2009). Several different tap designs exist and patients must have the manual dexterity to operate the mechanism (Robinson 2008). Most leg bags allow for larger 1–2

Figure 5.11 Urinary catheter leg bag.

Figure 5.12 Urinary catheter bag with urometer.

litre bags to be connected via the outlet tap, to increase capacity for night-time use.

It is advised to maintain a closed system of drainage to limit infection, but long-term catheter users may opt to wear a urinary drainage bag attached to their leg bag for larger capacity. Such changes disrupt the closed system but are essential to improve quality of life (Ostaszkievicz and Patterson 2012).

A variety of supports is available for use with these bags, including sporran waist belts, leg holsters, knickers/pants and leg straps (Doherty 2006).

Leg straps

The use of thigh straps (e.g. Simpla G-Strap) and other fixation devices (e.g. Bard StatLock, Comfasure, Clinimed CliniFix) helps to immobilize the catheter and thus reduce the trauma potential to the bladder neck and urethra (Eastwood 2009). It is particularly appropriate for men, due to the longer length and weight of the tube being used; however, some women may also find the extra support more comfortable. Guidance from the Royal College of Nursing (RCN 2012a) and NHS Scotland (NHSQIS 2004) reiterates the importance of catheter tetherage to promote patient comfort and to limit the potential complications of catheter migration and subsequent need for recatheterization. The application of these devices is not without potential complications; for example, restriction of the circulation to the limb may give rise to deep vein thrombosis while tension and traction to the urethra can cause trauma and necrosis, especially in men (Bierman and Carigan 2003).

Catheter valves

Catheter valves, which eliminate the need for drainage bags, are also available. The valve allows the bladder to be emptied intermittently and is particularly appropriate for patients who require long-term catheterization, as they do not require a drainage bag.

Catheter valves are only suitable for patients who have good cognitive function, sufficient manual dexterity to manipulate the valve and an adequate bladder capacity. It is important that catheter valves are released at regular intervals to ensure that the bladder does not become overdistended. These valves must not be used on patients following surgical procedures to the prostate or bladder, as pressure caused by the distending bladder may cause perforation or rupture; in most of these instances the urethral catheter is only required for a short period of time and free drainage is the preferred method. As catheter valves preclude free drainage, they are unlikely to be appropriate for patients with uncontrolled detrusor overactivity, ureteric reflux or renal impairment (Fader et al. 1997). Catheter valves are designed to fit with linked systems so it is possible for patients to connect to a drainage bag. This may be necessary when access to toilets may be limited, for example overnight or on long journeys.

Catheter valves are recommended to remain *in situ* for 5–7 days, which corresponds with most manufacturers' recommendations (Woodward 2013). More research is needed into the advantages and disadvantages of catheter valves.

Pharmacological support

Anaesthetic lubricating gel

The use of anaesthetic lubricating gels is well recognized for male catheterization, but there is some controversy over their use for female catheterization. In male patients the gel is instilled directly into the urethra and then external massage is used to move the gel down its length, unless a conforming gel such as Instillagel is used and then this is not necessary. In female patients, the anaesthetic lubricating gel or plain lubricating gel is applied to the tip of the catheter only, if it is used at all.

These differences in practice imply that catheterization is a painful procedure for men but is not so for women. This assumption is not based on any empirical or biological evidence. Other than the differences in length and route, the male and female

urethra are very similar except for the presence of lubricating glands in the male urethra (Tortora and Derrickson 2011).

A study by Chung et al. (2007) showed that women who had lubricating gel prior to catheterization reported lower pain scores than those who did not. The use of anaesthetic gel also dilates the urethral folds, making insertion easier for the professional. There is a need for caution with the use of lidocaine in the elderly, those with cardiac dysrhythmias and those with sensitivity to the drug, as there is a danger of injury to the urothelial lining of the urethra

during the procedure, allowing systemic absorption of the drug (BNF 2014).

Trauma can occur during catheterization, which in turn can increase the risk of infection. Using single-use lubrication gels with antiseptic properties can reduce these risks (BNF 2014, Loveday et al. 2014). Since there is a lack of research to clarify the efficacy of lubricating gels, practice must be based on the research evidence that is available and the physiology and anatomy of the urethra.

Procedure guideline 5.7 Urinary catheterization: male

Essential equipment

- Sterile pack containing gallipots, receiver, gauze swabs, disposable towels
- Disposable pad
- 0.9% sodium chloride
- Bactericidal alcohol handrub
- Hypoallergenic tape or leg strap for tethering
- Sterile gloves
- Sterile water
- Selection of appropriate catheters
- Syringe and needle (as required to obtain a urine sample)
- Sterile anaesthetic lubricating jelly
- Disposable plastic apron
- Universal specimen container
- Drainage bag and stand or holder
- Clean towel or similar

Pre-procedure

Action

1 Explain and discuss the procedure with the patient.

2 Screen the bed.

3 Prepare the trolley, placing all equipment required on the bottom shelf.

4 Take the trolley to the patient's bedside, disturbing the screens as little as possible.

5 Assist the patient to get into the supine position with the legs extended on the bed.

6 Remove underpants or pyjama trousers and use a towel to cover the patient's thighs and genital area.

7 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.

8 Put on a disposable plastic apron.

Rationale

To ensure that the patient understands the procedure and gives his valid consent (NMC 2013, **C**).

To ensure patient's privacy. To allow dust and airborne organisms to settle before the sterile field is exposed (Fraise and Bradley 2009, **E**).

The top shelf acts as a clean working surface. **E**

To minimize airborne contamination (Fraise and Bradley 2009, **E**).

To ensure the appropriate area is easily accessible. **E**

To maintain patient's dignity and comfort (NMC 2015, **C**).

To reduce risk of infection (Fraise and Bradley 2009, **E**).

To reduce risk of cross-infection from micro-organisms on uniform (Fraise and Bradley 2009, **E**).

Procedure

9 Open the outer cover of the catheterization pack and slide the pack onto the top shelf of the trolley.

10 Using an aseptic technique, open the sterile/catheter pack. Pour 0.9% sodium chloride into gallipot. Open an appropriately sized catheter onto the sterile field.

11 Remove cover from the patient's genital area, maintaining the patient's privacy, and position a disposable pad under the patient's buttocks and thighs.

12 Clean hands with a bactericidal alcohol handrub.

13 Put on sterile gloves.

14 On the sterile field, place the catheter into the sterile receiver.

15 Place a sterile towel across the patient's thighs.

To prepare equipment. **E**

To reduce the risk of introducing infection into the bladder (NICE 2012, **C**).

To ensure urine does not leak onto bedclothes. **E**

Hands may have become contaminated by handling the outer packs (Fraise and Bradley 2009, **C**).

To reduce risk of cross-infection (NICE 2012, **C**).

To create a sterile field. **E**

(continued)

Procedure guideline 5.7 Urinary catheterization: male (continued)

Action	Rationale
16 With one hand, wrap a sterile topical swab around the penis. Use this to retract the foreskin, if necessary, and with the other hand clean the glans penis with 0.9% sodium chloride or sterile water.	To reduce the risk of introducing infection to the urinary tract during catheterization. E
17 Insert the nozzle of the lubricating jelly into the urethra. Squeeze the gel into the urethra, remove the nozzle and discard the tube. Massage the gel along the urethra using the barrel of the syringe.	Adequate lubrication helps to prevent urethral trauma. Use of a local anaesthetic minimizes the discomfort experienced by the patient (Bardsley 2005, P).
18 Squeeze the penis and wait approximately 5 minutes.	To prevent anaesthetic gel from escaping. To allow the anaesthetic gel to take effect. E
19 With one hand hold the penis firmly behind the glans, raising it until it is almost totally extended. Maintain this hold of the penis until the catheter is inserted and urine flowing.	This manoeuvre straightens the penile urethra and facilitates catheterization (Stoller 2004, P). Maintaining a grasp of the penis prevents contamination and retraction of the penis.
20 With the free hand, place the receiver containing the catheter between the patient's legs. Take the catheter and insert it into the penis for 15–25 cm until urine flows.	The male urethra is approximately 18 cm long (Bardsley 2005, P).
21 If resistance is felt at the external sphincter, increase the traction on the penis slightly and apply steady, gentle pressure on the catheter. Ask the patient to cough gently.	Some resistance may be due to spasm of the external sphincter. Coughing gently helps to relax the external sphincter. E
22 When urine begins to flow, advance the catheter almost to its bifurcation.	Advancing the catheter ensures that it is correctly positioned in the bladder. E
23 Gently inflate the balloon according to the manufacturer's direction, having ensured that the catheter is draining properly beforehand.	Inadvertent inflation of the balloon in the urethra causes pain and urethral trauma (Getliffe and Dolman 2007, E).
24 Withdraw the catheter slightly and attach it to the drainage system.	To ensure that the balloon is inflated and the catheter is secure. E
25 Support the catheter, if the patient desires, either by using a specially designed support, for example Simpla G-Strap, or by taping the catheter to the patient's leg. Ensure that the catheter does not become taut when patient is mobilizing or when the penis becomes erect. Ensure that the catheter lumen is not occluded by the fixation device or tape.	To maintain patient comfort and to reduce the risk of urethral and bladder neck trauma. Care must be taken in using adhesive tapes as they may interact with the catheter material (Fillingham and Douglas 2004, E ; Pomfret 1996, P).
26 Ensure that the glans penis is clean and dry and then extend the foreskin.	Retraction and constriction of the foreskin behind the glans penis (paraphimosis) may occur if this is not done (Pomfret 2002, E).
Post-procedure	
27 Assist the patient to replace underwear and pyjamas and replace bed cover. Ensure that the area is dry.	If the area is left wet or moist, secondary infection and skin irritation may occur (Pomfret 2002, E).
28 Measure the amount of urine.	To be aware of bladder capacity for patients who have presented with urinary retention. To monitor renal function and fluid balance. It is not necessary to measure the amount of urine if the patient is having the urinary catheter routinely changed (Pomfret 2002, E).
29 If required, take a urine specimen for laboratory examination (see Chapter 11: Observations).	For further information, see Chapter 11, Procedure guideline 11.7 Urinalysis: reagent strip procedure.
30 Dispose of equipment including apron and gloves in an orange plastic clinical waste bag and seal the bag before moving the trolley.	To prevent environmental contamination. Orange is the recognized colour for clinical waste (DH 2005, C).
31 Draw back the curtains.	
32 Dispose of clinical waste bag in a larger bin.	To prevent environmental contamination (Fraise and Bradley 2009, E).
33 Wash hands thoroughly with bactericidal soap and water.	To reduce risk of infection (Fraise and Bradley 2009, E).

34 Record information in relevant documents; this should include:

- reasons for catheterization
- date and time of catheterization
- catheter type, length and size
- amount of water instilled into the balloon
- batch number
- manufacturer
- any problems negotiated during the procedure
- a review date to assess the need for continued catheterization or date of change of catheter.

To provide a point of reference or comparison in the event of later queries (NMC 2010, **C**).

Procedure guideline 5.8 Urinary catheterization: female

Essential equipment

- Sterile catheterization pack containing gallipots, receiver, gauze swabs, disposable towels
- Bactericidal alcohol handrub
- Hypoallergenic tape or leg strap for tethering
- Sterile water
- Syringe and needle
- Disposable plastic apron
- Drainage bag and stand or holder
- Clean towel or similar cover
- Disposable pad
- Sterile gloves
- Selection of appropriate catheters
- Sterile anaesthetic lubricating jelly
- Universal specimen container

Pre-procedure

Action

1 Explain and discuss the procedure with the patient.

2 Screen the bed.

3 Prepare the trolley, placing all equipment required on the bottom shelf. (See also 'Equipment: catheter selection'.)

4 Take the trolley to the patient's bedside, disturbing screens as little as possible.

5 Remove patient's underwear. Assist patient to get into the supine position with knees bent, hips flexed and feet resting about 60 cm apart.

6 Place a towel over the patient's thighs and genital area.

7 Ensure that a good light source is available.

8 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.

9 Put on a disposable apron.

Rationale

To ensure that the patient understands the procedure and gives her valid consent (NMC 2015, **C**).

To ensure patient's privacy. To allow dust and airborne organisms to settle before the sterile field is exposed (Fraise and Bradley 2009, **E**).

To reserve top shelf for clean working surface. **E**

To minimize airborne contamination (Fraise and Bradley 2009, **C**).

To enable genital area to be seen. **E**

To maintain the patient's dignity and comfort (NMC 2015, **C**).

To enable genital area to be seen clearly. **E**

To reduce risk of cross-infection (Fraise and Bradley 2009, **E**).

To reduce risk of cross-infection from micro-organisms on uniform (Bardsley and Kyle 2008, **E**; Fraise and Bradley 2009, **E**).

Procedure

10 Open the outer cover of the catheterization pack and slide the pack on the top shelf of the trolley.

11 Using an aseptic technique, open sterile pack. Then open appropriately-sized catheter and place on sterile field.

12 Remove towel, maintaining the patient's privacy, and position a disposable pad under the patient's buttocks.

13 Clean hands with a bactericidal alcohol handrub.

14 Put on sterile gloves.

15 Place sterile towels under the patient's buttocks.

To prepare equipment. **E**

To reduce risk of introducing infection into the urinary tract. **E**

To ensure urine does not leak onto bedclothes. **E**

Hands may have become contaminated by handling of outer packs, and so on (Fraise and Bradley 2009, **C**).

To reduce risk of cross-infection (NICE 2012, **C**).

To create a sterile field. **E**

(continued)

Procedure guideline 5.8 Urinary catheterization: female (continued)

Action	Rationale
16 Using gauze swabs, separate the labia minora so that the urethral meatus is seen. One hand should be used to maintain labial separation until catheter is inserted and urine flowing.	This manoeuvre provides better access to the urethral orifice and helps to prevent labial contamination of the catheter. E
17 Clean around the urethral orifice with 0.9% sodium chloride using single downward strokes.	Inadequate preparation of the urethral orifice is a major cause of infection following catheterization. To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
18 Place a small amount of the lubricating jelly/anaesthetic gel onto the tip of the catheter.	Adequate lubrication helps to prevent urethral trauma. Use of a local anaesthetic minimizes the patient's discomfort (Baston 2011; Woodward 2005, P).
19 Place the catheter, in the sterile receiver, between the patient's legs.	To provide a temporary container for urine as it drains. E
20 Introduce the tip of the catheter into the urethral orifice in an upward and backward direction. Advance the catheter until 5–6 cm has been inserted.	The direction of insertion and the length of catheter inserted should relate to the anatomical structure of the area. E
21 If there is no urine present, remove the catheter gently and start procedure again. If urine is present, advance the catheter 6–8 cm.	This prevents the balloon from becoming trapped in the urethra.
22 Inflate the balloon according to the manufacturer's directions, having ensured that the catheter is draining adequately.	Inadvertent inflation of the balloon within the urethra is painful and causes urethral trauma (Getliffe and Dolman 2007, P).
23 Withdraw the catheter slightly and connect it to the drainage system.	To ensure that the balloon is inflated and the catheter is secure. E
24 Support the catheter, if the patient desires, either by using a specially designed support, for example Simpla G-Strap, or by taping the catheter to the patient's leg. Ensure that the catheter does not become taut when patient is mobilizing. Ensure that the catheter lumen is not occluded by the fixation device or tape.	To maintain patient comfort and to reduce the risk of urethral and bladder neck trauma. Care must be taken in using adhesive tapes as they may interact with the catheter material (Pomfret 1996, P).

Post-procedure

25 Assist the patient to replace underwear and pyjamas and replace bed cover. Ensure that the area is dry.	If the area is left wet or moist, secondary infection and skin irritation may occur (Pomfret 2002, E).
26 Measure the amount of urine.	To be aware of bladder capacity for patients who have presented with urinary retention. To monitor renal function and fluid balance. It is not necessary to measure the amount of urine if the patient is having the urinary catheter routinely changed (Pomfret 2002, E).
27 If required, take a urine specimen for laboratory examination (see Chapter 11: Observations).	For further information, see Chapter 11, Procedure guideline 11.7 Urinalysis: reagent strip procedure.
28 Dispose of equipment including apron and gloves in an orange plastic clinical waste bag and seal the bag before moving the trolley.	To prevent environmental contamination. Orange is the recognized colour for clinical waste (DH 2005, C).
29 Draw back the curtains.	
30 Dispose of clinical waste bag in a larger bin.	To prevent environmental contamination (Fraise and Bradley 2009, E).
31 Wash hands thoroughly with bactericidal soap and water.	To reduce risk of infection (Fraise and Bradley 2009, E).
32 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • reasons for catheterization • date and time of catheterization • catheter type, length and size • amount of water instilled into the balloon • batch number and manufacturer • any problems negotiated during the procedure • a review date to assess the need for continued catheterization or date of change of catheter. 	To provide a point of reference or comparison in the event of later queries (NMC 2010, C).

Suprapubic catheterization

Evidence-based approaches

Rationale

Suprapubic catheterization is the insertion of a catheter through the anterior abdominal wall into the dome of the bladder. The procedure is performed under general or local anaesthesia, using a percutaneous system (Robinson 2008). The National Patient Safety Agency (NPSA 2009) published a rapid response report stating that the insertion of a suprapubic catheter should be undertaken by experienced urology staff using ultrasound imaging. Pre-procedural considerations are those indicated when preparing a patient for a radiological intervention.

Indications

Suprapubic catheterization does offer some advantages over urethral catheterization (Rigby 2009). The risk of patients developing urinary tract infection is reduced, as the bacterial count on the abdominal skin is less than around the perineal and perianal areas, although bacteriuria and encrustation still occur in susceptible patients (Simpson 2001). Urethral integrity is retained and it allows for the resumption of normal voiding after surgery. Clamping the suprapubic catheter allows urethral voiding to occur, and the clamp can be released if voiding is incomplete. Pain and catheter-associated discomfort are reduced. Patient satisfaction is increased as, for some, their level of independence is increased and sexual intercourse can occur with fewer impediments (Fillingham and Douglas 2004).

Indications for the use of suprapubic catheters over indwelling catheters include the following.

- Post-operative drainage of urine after lower urinary tract and bowel surgery.
- Management of neuropathic bladders.
- Long-term conditions, for example multiple sclerosis (MS) or spinal cord injuries.
- People with long-term catheters – to minimize the risk of urethral infections or urethral damage (NPSA 2009).

However, there are a number of risks and disadvantages associated with suprapubic catheterization.

- Bowel perforation and haemorrhage at the time of insertion.
- Infection, swelling, encrustation and granulation at insertion site.
- Pain, discomfort or irritation for some patients.
- Bladder stone formation and possible long-term risk of squamous cell carcinoma.
- Urethral leakage (Addison and Mould 2000).

Post-procedural considerations

Care of a suprapubic catheter is the same as for a urethral catheter. Immediately following insertion of a suprapubic catheter, aseptic technique should be employed to clean the insertion site (Robinson 2008). Keyhole dressings around the insertion site may be required if secretions soil clothing, but they are not essential. Once the insertion site has healed (7–10 days), the site and catheter can be cleaned during bathing using soap, water and a clean cloth (Fillingham and Douglas 2004).

Intermittent catheterization

Some patients need a catheter long term to empty their bladder. This is often managed by teaching them intermittent self-catheterization. This involves a person passing a catheter into their bladder to drain urine and then removing it immediately when the bladder is empty (Logan 2012).

Patients who may need to do this include those who are unable to empty their bladder (with a residual of 150 mL or more). This

could be due to a number of factors including urethral or meatal strictures or prostatic issues such as benign prostatic hypertrophy or prostate cancer (Logan 2012).

Intermittent self-catheterization can also be used short term, for the management of post-operative voiding, for example, following surgery for stress incontinence (Rantell 2012).

Evidence-based approaches

Indications

Patients suitable for intermittent self-catheterization include those:

- with a bladder capable of storing urine without leakage between catheterizations
- who can comprehend the technique
- with a reasonable degree of dexterity and mobility to position themselves for the procedure and manipulate the catheter
- who are highly committed to carrying out the procedure at least six times a day (Nazarko 2012).

This procedure may be required by patients who have undergone continent reconstruction to manage initial post-operative incontinence. Patients with a Mitrofanoff reconstruction will need to perform this procedure for life.

Intermittent self-catheterization (ISC) is not a new technique, although it has become noticeably more popular in recent years. The procedure involves the episodic introduction of a catheter into the bladder to remove urine. After this the catheter is removed, leaving the patient catheter free between catheterizations. In hospital, this should be a sterile procedure because of the risks of hospital-acquired infection. However, in the patient's home a clean technique may be used (Lapides et al. 2002, Newman and Wilson 2011). Catheterization should be carried out as often as necessary to stop the bladder becoming overdistended and to prevent incontinence (Bennett 2002). How frequent this is, depends on the individual. It is common practice for patients to reuse catheters after cleaning them (Nazarko 2012).

The advantages of intermittent catheterization over indwelling urethral catheterizations include improved quality of life, as patients are free from bulky pads or indwelling catheters and drainage bags, greater patient satisfaction and greater freedom to express sexuality. In addition, urinary tract complications are minimized and normal bladder function is maintained (Wright 2009).

There are challenges to intermittent catheterization. Patients need to have an understanding of their anatomy, an understanding of what is causing their voiding problems and they need to know how intermittent catheterization works (Logan 2012).

There are several physical and psychological barriers to ISC.

- Physical barriers include poor eyesight, reduced mobility or reduced dexterity.
- Psychological barriers include anxiety about ISC, fear of pain or discomfort, concern regarding sexual function, lack of understanding and cultural concerns (Shaw et al. 2008).

Nurses can help with these anxieties by empowering patients through teaching and knowledge. They can make a difference by supporting the patient within practice and continuously when they are discharged into the community (Nazarko 2012).

Pre-procedural considerations

Equipment

Nelaton catheters are generally used to carry out intermittent self-catheterizations (see Figure 5.9). These catheters are available in standard, female and paediatric lengths and in charrière

sizes 6–24; as they are not left in the bladder, they do not have a balloon (Winder 1995). They are normally manufactured from plastic but there is also a non-PVC, chlorine-free catheter available. Some Nelaton catheters are coated with a lubricant which is activated by soaking the catheter in water for a short while; others are packaged with a lubricant gel which coats the catheter as it slides out of the packaging (these catheters are for single use only). Lubricated Nelaton catheters are also available with an

integral drainage bag, useful when toilet facilities are unavailable or the environment is not conducive to performing a clean procedure safely or comfortably.

Uncoated catheters, which require separate lubrication, may be reused by a single patient for up to a week, but the catheter must be rinsed in running water and properly dried after use; between uses, it should be kept in a clean bag or container (Barton 2000, Lapides et al. 2002).

Procedure guideline 5.9 Urinary catheterization: intermittent self-catheterization patient guidance: male

Essential equipment

- Lubricating gel
- Appropriately sized catheter. If carrying out this procedure in hospital, a new catheter must be used every time
- Suitable container (clean jug or receiver) if required
- Mirror if required

Pre-procedure

Action	Rationale
1 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.	To prevent infection (Fraise and Bradley 2009, E).
2 Stand in front of a toilet or a low bench with a suitable container, such as a jug or bottle if it is easier. Standing in front of a mirror is helpful for patients with a large abdomen.	To catch urine. E For ease of observation.

Procedure

3 Clean the glans penis with water. If the foreskin covers the penis, it will need to be held back during the procedure.	To reduce risk of infection (Fraise and Bradley 2009, E).
4 Open catheter packaging or container. If using an uncoated catheter, a water-soluble lubricating gel may be applied to the surface of the catheter. If using a coated catheter, pre-soak it in water to activate the slippery coating.	To prepare catheter and to ease insertion (Barton 2000, E).
5 Hold penis, with the non-dominant hand, upwards towards the stomach.	To prevent trauma to the penoscrotal junction. E
6 Hold the catheter with the dominant hand, being careful not to touch the part of the catheter entering the body, and gently insert it into the opening of the urethra. Advance the catheter into the bladder. There will be a change of feeling as the catheter passes through the prostate gland and into the bladder. It may be a little sore on the first few occasions only. If there is any resistance, do not continue. Withdraw the catheter and contact a nurse or doctor.	To reduce the risk of introducing an infection (Fraise and Bradley 2009, E). The prostate gland surrounds the urethra just below the neck of the bladder and consists of much firmer tissue. This can enlarge and cause an obstruction, especially in older men. E
7 Drain the urine into the toilet or suitable container. When the urine stops flowing, slowly remove the catheter, halting if more urine starts to flow.	To ensure that the bladder is completely emptied.
8 Before removing the catheter from the urethra, put a finger over the funnel end of the catheter and then remove the catheter from the urethra.	To trap urine in the catheter and prevent spillage on to clothing or the floor. E
9 Hold the catheter over the toilet or suitable container and remove finger from the funnel end to release the trapped urine.	
10 If using a coated catheter, dispose of the catheter in a suitable receptacle. If the catheter is uncoated and is to be reused, wash through with tap water. Allow to drain, then dry the outside of the catheter. Store in a dry container (as per manufacturer's instructions). These catheters may be used for 5–7 days.	To prevent environmental contamination. To remove urine. To reduce the risk of infection.
11 Wash hands with soap and water.	To reduce the risk of infection.

Procedure guideline 5.10 Urinary catheterization: intermittent self-catheterization patient guidance: female**Essential equipment**

- Mirror
- Lubricating gel
- Appropriately sized catheter. If carrying out this procedure in hospital, a new catheter must be used every time
- Suitable container (clean jug or receiver)

Pre-procedure

Action	Rationale
1 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
2 Take up a comfortable position, depending on mobility (e.g. sitting on toilet; standing with one foot placed on toilet seat).	To facilitate insertion of intermittent catheter. E

Procedure

3 Wash genitalia, from front to back, with soap and water, then dry.	To reduce the risk of introducing infection (Fraise and Bradley 2009, E).
4 Open catheter packaging or container. If using an uncoated catheter, a water-soluble lubricating gel may be applied to the surface of the catheter. If using a coated catheter, pre-soak it in water to activate the slippery coating.	To prepare catheter and to ease insertion (Barton 2000, E).
5 Find the urethral opening above the vagina. A mirror can be used to help identify it. Gently insert the catheter into the urethra, taking care not to touch the part of the catheter entering the body.	To reduce the risk of introducing infection (Fraise and Bradley 2009, E).
6 Drain the urine into the toilet or suitable container. When the urine stops flowing, slowly remove catheter, halting if more urine starts to flow.	To ensure that the bladder is completely emptied.
7 Before removing the catheter from the urethra, put a finger over the funnel end of the catheter and then remove the catheter from the urethra.	To trap urine in the catheter and prevent spillage on to clothing or the floor. E
8 Hold the catheter over the toilet or suitable container and remove finger from the funnel end to release the trapped urine.	To prevent spillage on to clothing or the floor.

Post-procedure

9 If using a coated catheter, dispose of it in a suitable receptacle.	To prevent environmental contamination.
If the catheter is uncoated and is to be reused, wash through with tap water.	To remove urine.
Allow to drain, then dry the outside of the catheter.	To reduce risk of infection.
Store in a dry container (as per manufacturer's instructions). These catheters may be used for 5–7 days.	
10 Wash hands with soap and water.	To reduce the risk of infection.

Problem-solving table 5.2 Prevention and resolution (Procedure guidelines 5.7, 5.8, 5.9, 5.10)

Problem	Cause	Prevention	Action
Urethral mucosal trauma.	Incorrect size of catheter. Procedure not carried out correctly or skilfully. Movement of the catheter in the urethra.		Recatheterize the patient using the correct size of catheter. Check the catheter support and apply or reapply as necessary.
	Trauma to the urethral tissue due to rapid insertion of catheter.		Nurse may need to remove the catheter and wait for the urethral mucosa to heal.

(continued)

Problem-solving table 5.2 Prevention and resolution (Procedure guidelines 5.7, 5.8, 5.9, 5.10) (*continued*)

Problem	Cause	Prevention	Action
Patient has a vasovagal attack.	This is caused by the vagal nerve being stimulated so that the heart slows down, leading to a syncope faint.		Lie the patient down in the recovery position (see Chapter 9: Respiratory care, Figure 9.48 Recovery position). Inform doctors.
Male			
Paraphimosis.	Failure to extend the foreskin after catheterization or catheter toilet.		Always retract the foreskin. Clean and dry around the foreskin.
Female			
No drainage of urine.	Incorrect identification of external urinary meatus.	Ensure sufficient light to observe the area. Review the female anatomy prior to the procedure.	Check that catheter has been sited correctly. If catheter has been wrongly inserted in the vagina, leave it in position to act as a guide, re-identify the urethra and catheterize the patient. Remove the inappropriately sited catheter.
Difficulty in visualizing the urethral orifice.	This can be due to vaginal atrophy and retraction of the urethral orifice.		The index finger of the 'dirty' hand may be inserted in the vagina, and the urethral orifice can be palpated on the anterior wall of the vagina. The index finger is then positioned just behind the urethral orifice. This then acts as a guide, so the catheter can be correctly positioned (Jenkins 1998).

Procedure guideline 5.11 Urinary catheter bag: emptying*Essential equipment*

- Alcohol wipe
- Disposable gloves
- Container (jug or urine bottle)
- Paper towel to cover the jug

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and put on disposable gloves.	To reduce risk of cross-infection (Fraiese and Bradley 2009, E).

Procedure

3 Open the catheter valve. Allow the urine to drain into the jug.	To empty drainage bag and accurately measure volume of contents. E
4 Close the outlet valve and clean it with an alcohol wipe.	To reduce risk of cross-infection (Fraiese and Bradley 2009, E).
5 Cover the jug and dispose of contents in the sluice, having noted the amount of urine if this is requested for fluid balance records.	To reduce risk of environmental contamination (DEFRA 2005, C).
6 Wash hands with bactericidal soap and water.	To reduce risk of infection (Fraiese and Bradley 2009, E).

Procedure guideline 5.12 Urinary catheter removal

Essential equipment

- Dressing pack containing sterile towel, gallipot, swab or non-linting gauze
- Needle and syringe for urine specimen, specimen container
- Disposable gloves and apron
- Syringe for deflating balloon

Pre-procedure

Action	Rationale
1 Catheters are usually removed early in the morning.	So that any retention problems can be dealt with during the day. E
2 Explain procedure to the patient and inform them of potential post-catheter symptoms, such as urgency, frequency and discomfort, which are often caused by irritation of the urethra by the catheter.	So that patient knows what to expect, and can plan daily activity.
3 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and put on disposable gloves.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).

Procedure

4 If a specimen is required, clamp below the sampling port until sufficient urine collects. Take a catheter specimen of urine using the sampling port.	To obtain an adequate urine sample and to assess whether postcatheter antibiotic therapy is needed (Fraise and Bradley 2009, E).
5 Wearing gloves, use saline-soaked gauze to clean the meatus and catheter, always swabbing away from the urethral opening. <i>Note:</i> in women, never clean from the perineum/vagina towards the urethra.	To reduce risk of infection (Fraise and Bradley 2009, E). To help reduce the risk of bacteria from the vagina and perineum contaminating the urethra. E
5 Release leg support.	For easier removal of catheter. E
6 Having checked volume of water in balloon (see patient documentation), use syringe to deflate balloon.	To confirm how much water is in the balloon. To ensure balloon is completely deflated before removing catheter. E
7 Ask patient to breathe in and then out; as patient exhales, gently (but firmly with continuous traction) remove catheter. Male patients should be warned of discomfort as the deflated balloon passes through the prostate gland.	To relax pelvic floor muscles. E It is advisable to extend the penis as per the process for insertion to aid removal. E

Post-procedure

8 <i>Male:</i> clean meatus and make the patient comfortable. <i>Female:</i> clean area around the genitalia and make the patient comfortable.	To maintain patient comfort and dignity. E
9 Encourage patient to exercise and to drink 2–3 litres of fluid per day.	To prevent urinary tract infections. E
10 Dispose of equipment including apron and gloves in an orange plastic clinical waste bag.	To prevent environmental contamination. Orange is the recognized colour for clinical waste (DEFRA 2005, C).
11 Wash hands thoroughly with bactericidal soap and water.	To reduce risk of infection (Fraise and Bradley 2009, E).
12 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • reasons for catheterization • date and time of catheterization • catheter type, length and size • amount of water instilled into the balloon • batch number and manufacturer • any problems negotiated during the procedure • a review date to assess the need for continued catheterization or date of change of catheter. 	To provide a point of reference or comparison in the event of later queries (NMC 2010, C).

Complications

Infections

Catheterization carries an infection risk. Catheter-associated infections are the most common hospital-acquired infection, accounting for 40% of all hospital infections (Andreessen et al. 2012).

160

Key areas have been identified as having a direct link with the development of urinary tract infection.

- Assessing the need for catheterization and the length of time the catheter is *in situ* (Nazarko 2007). The risk of developing a catheter-associated infection increases with the length of time that a catheter is *in situ* (Bernard et al. 2012).
- Selection of the most appropriate type of catheter and drainage system to be used.
- The aseptic conditions and process by which the catheter is inserted and maintained as a closed drainage system.
- Training and competence of the person performing the procedure and those undertaking the aftercare, that is, patients, relatives and health professionals. Patient education is essential in preventing catheter-associated infections. Adequate information and teaching for patients may help to reduce infection if they can care for their catheters with good hygiene.

The maintenance of a closed drainage system is central in reducing the risk of catheter-associated infection. It is thought that micro-organisms reach the bladder by two possible routes: from the urine in the drainage bag or via the space between the catheter and the urethral mucosa (Ostaszkiwicz and Patterson 2012). To reduce the risk of infection, it is important to keep manipulation of the closed system to a minimum; this includes unnecessary emptying, changing the drainage bags or taking samples (Ostaszkiwicz and Patterson 2012). There is now an integral catheter and drainage bag available to reduce the number of potential disconnection sites and infection risk. Before handling catheter drainage systems, hands must be decontaminated and a pair of clean non-sterile gloves should be worn (Loveday et al. 2014). All urine samples should only be obtained via the specially designed sampling ports using an aseptic technique.

Urinary tract infections (male): meatal cleaning

Cleaning the urethral meatus, where the catheter enters the body, is a nursing procedure intended to minimize infection of the urinary tract for men (DH 2003, Magnall and Watterson 2006). Studies examining the use of a variety of antiseptic, antimicrobial agents or soap and water found that there was no reduction in bacteriuria when using any of these preparations for meatal cleaning compared to routine bathing or showering (Loveday et al. 2014). Further studies support the view that vigorous meatal cleaning is unnecessary and may compromise the integrity of the skin, thus increasing the risk of infection (Leaver 2007, Saint and Lipsky 1999). Therefore it is recommended that routine daily personal hygiene with soap and water (NICE 2012) is all that is needed to maintain meatal hygiene (Loveday et al. 2014, Pomfret 2004). Nursing intervention is necessary if there is a poor standard of hygiene or a risk of contamination (Gilbert 2006); removal of a smegma ring, where the catheter meets the meatus, is important to prevent ascending infections and meatal trauma (Wilson 2005).

A urinary tract infection (UTI) may be introduced during catheterization because of faulty aseptic technique, inadequate urethral cleaning or contamination of catheter tip. UTI may be introduced via the drainage system because of faulty handling of equipment, breaking the closed system or raising the drainage bag above bladder level, causing urine reflux.

If a UTI is suspected, a catheter specimen of urine must be sent for analysis. The patient should be encouraged to have a fluid intake of 2–3 litres a day. Medical staff should be informed if the problem persists so that antibiotics can be prescribed.

Table 5.3 details other complications that may arise if a patient is catheterized.

Bladder irrigation

Definition

Bladder irrigation is the continuous washing out of the bladder with sterile fluid, usually 0.9% normal saline (Ng 2001). Three-way catheters are used to wash out the bladder (Moslemi and Rajaei 2010).

Evidence-based approaches

Rationale

Indications

Bladder irrigation is performed to prevent the formation and retention of blood clots, for example following prostatic surgery such as transurethral resection of bladder tumour (TURBT) or transurethral resection of prostate (TURP). Other indications include irrigation for the delivery of pharmacological agents, irrigation for candida cystitis, prevention of haematuria following chemotherapy or surgical procedures (Moslemi and Rajaei 2010). On rare occasions bladder irrigation is performed to remove heavily contaminated material from a diseased urinary bladder (Cutts 2005, Fillingham and Douglas 2004, Scholtes 2002).

Principles of care

There are a number of risks associated with bladder irrigation (including introducing infection) and the procedure should not be undertaken lightly (McCarthy and Hunter 2001, NICE 2012). Prior to taking a decision to use bladder maintenance solutions, patients should be assessed. The guiding principle for effective catheter management always involves addressing the individual needs of the patient (Godfrey and Evans 2000). Assessment of all aspects of catheter care and irrigation should be undertaken, including:

- patient activity and mobility (catheter positioning, catheter kinking)
- diet and fluid intake
- standards of patient hygiene
- patient's and/or carer's ability to care for the catheter (Ng 2001, Rew 2005).

An important aspect of management for patients in whom a clear pattern of catheter history can be established is the scheduling of catheter changes prior to likely blockages (Yates 2004). In patients in whom no clear pattern emerges, or for whom frequent catheter changes are traumatic, acidic bladder washouts can be beneficial in reducing catheter encrustations (McCarthy and Hunter 2001, Yates 2004). The administration of catheter maintenance solutions to eliminate catheter encrustation can also be timed to coincide with catheter bag changes (every 5–7 days) so that the catheter system is not opened more than necessary (Yates 2004).

Pre-procedural considerations

Equipment

Catheters used for irrigation

A three-way urinary catheter must be used for irrigation in order that fluid may simultaneously be run into, and drained out from, the bladder (Cutts 2005, Ng 2001). A large-gauge catheter (16–24) is often used to accommodate any clot and debris which may be present. This catheter is commonly passed in theatre when irrigation is required, for example after prostatectomy (Forristal and Maxfield 2004). Occasionally, if a patient is admitted with a heavily contaminated bladder, for example blood clots, bladder irrigation

Table 5.3 Complications of catheterization

Problem	Cause	Suggested action
Inability to tolerate indwelling catheter	Urethral mucosal irritation Psychological trauma Unstable bladder Radiation cystitis	Nurse may need to remove the catheter and seek an alternative means of urine drainage Explain the need for and the functioning of the catheter
Inadequate drainage of urine	Incorrect placement of a catheter Kinked drainage tubing Blocked tubing, for example pus, urates, phosphates, blood clots	Resite the catheter Inspect the system and straighten any kinks If a three-way catheter, such as a Foley, is in place, irrigate it. If an ordinary catheter is in use, milk the tubing in an attempt to dislodge the debris, then attempt a gentle bladder washout. Failing this, the catheter will need to be replaced; a three-way catheter should be used if the obstruction is being caused by clots and associated haematuria
Fistula formation	Pressure on the penoscrotal angle	Ensure that correct strapping is used
Penile pain on erection	Not allowing enough length of catheter to accommodate penile erection	Ensure that an adequate length is available to accommodate penile erection
Formation of crusts around the urethral meatus	Increased urethral secretions collect at the meatus and form crusts, due to irritation of urothelium by the catheter (Fillingham and Douglas 2004)	Correct catheter toilet
Leakage of urine around catheter	Incorrect size of catheter Incorrect balloon size Bladder hyperirritability	Replace with the correct size, usually 2 ch smaller Select catheter with 10 mL balloon Use Roberts tipped catheter As a last resort, bladder hyperirritability can be reduced by giving diazepam or anticholinergic drugs (Nazarko 2009)
Unable to deflate balloon	Valve expansion or displacement Channel obstruction	Check the non-return valve on the inflation/deflation channel. If jammed, use a syringe and needle to aspirate by means of the inflation arm above the valve Obstruction by a foreign body can sometimes be relieved by the introduction of a guidewire through the inflation channel Inject 3.5 mL of dilute ether solution (diluted 50/50 with sterile water or 0.9% sodium chloride) into the inflation arm Alternatively, the balloon can be punctured suprapubically using a needle under ultrasound visualization Following catheter removal, the balloon should be inspected to ensure it has not disintegrated, leaving fragments in the bladder <i>Note:</i> steps above should be attempted by or under the directions of a urologist. The patient may require cystoscopy following balloon deflation to remove any balloon fragments and to wash the bladder out
Dysuria	Inflammation of the urethral mucosa	Ensure a fluid intake of 2–3 litres per day. Advise the patient that dysuria is common but will usually be resolved once micturition has occurred at least three times. Inform medical staff if the problem persists
Retention of urine	May be psychological	Encourage the patient to increase fluid intake. Offer the patient a warm bath. Inform medical staff if the problem persists

Figure 5.13 Closed urinary drainage system with provision for intermittent or continuous irrigation.

may be started on the ward. If the patient has a two-way catheter, this must be replaced with a three-way type (Scholtes 2002).

It is recommended that a three-way catheter is passed if frequent intravesical instillations of drugs or antiseptic solutions are prescribed and the risk of catheter obstruction is not considered to be very great. In such cases, the most important factor is minimizing the risk of introducing infection and maintaining a closed urinary drainage system, which the three-way catheter allows (Figure 5.13).

Pharmacological support

The agent most commonly recommended for irrigation is 0.9% sodium chloride which should be used in every case unless an alternative solution is prescribed. 0.9% sodium chloride is isotonic so it does not affect the body's fluid or electrolyte levels, enabling large volumes of the solution to be used as necessary (Cutts 2005). In particular, 2-litre bags of 0.9% sodium chloride

are available for irrigation purposes. It has been proposed that sterile water should never be used to irrigate the bladder as it can be readily absorbed by osmosis (Addison 2000). However, a study has demonstrated that sterile water is a safe irrigating fluid for TURP (Moharari et al. 2008).

Although not a common complication, absorption of irrigation fluid can occur during bladder irrigation. This can produce a potentially critical situation, as absorption leads to electrolyte imbalance and circulatory overload. Absorption is most likely to occur in theatre where glycine irrigation fluid, devoid of sodium or potassium, is forced under pressure into the prostatic veins (Forristal and Maxfield 2004). The 0.9% sodium chloride cannot be used during surgery as it contains electrolytes which interfere with diathermy (Forristal and Maxfield 2004). However, the risk of absorption still remains while irrigation continues post-operatively. For this reason, it is important that fluid balance is monitored carefully during irrigation (Scholtes 2002).

Procedure guideline 5.13 Commencing bladder irrigation

Essential equipment

- Sterile dressing pack and sterile gloves
- Chlorhexidine antiseptic solution
- Bactericidal alcohol handrub
- Clamp
- Disposable irrigation set
- Infusion stand

- Sterile jug
- Absorbent sheet
- Clean gloves and apron

Medicinal products

- Sterile irrigation fluid

Pre-procedure**Action****Rationale**

- | | |
|--|---|
| 1 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Screen the bed. Ensure that the patient is in a comfortable position, allowing the nurse access to the catheter. | For the patient's privacy and to reduce the risk of cross-infection (Fraise and Bradley 2009, E). |

Procedure

- | | |
|---|--|
| 3 Perform the procedure using an aseptic technique. | To minimize the risk of infection (Fraise and Bradley 2009, E). |
| 4 Open the outer wrappings of the pack and put it on the top shelf of the trolley. | To prepare equipment. E |
| 5 Insert the end of the irrigation giving set into the fluid bag and hang the bag on the infusion stand. Allow fluid to run through the tubing so that air is expelled. | To prime the irrigation set so that it is ready for use. Air is expelled in order to prevent discomfort from air in the patient's bladder. E |
| 6 Clamp the catheter and place absorbent sheet under the catheter junction. | To prevent leakage of urine through the irrigation arm when the spigot is removed. E
To contain any spillages. |
| 7 Clean hands with a bactericidal alcohol handrub. Put on clean gloves. | To minimize the risk of cross-infection (Fraise and Bradley 2009, E). |
| 8 Place a sterile paper towel under the irrigation inlet of the catheter and remove the spigot. | To create a sterile field. To prepare catheter for connection to irrigation set (Scholtes 2002, E). |
| 9 Discard the spigot and gloves. | To prevent reuse and reduce risk of cross-infection (Fraise and Bradley 2009, E). |
| 10 Put on sterile gloves. Clean around the end of the irrigation arm with sterile low-linting gauze and an antiseptic solution. | To remove surface organisms from gloves and catheter and to reduce the risk of introducing infection into the catheter (Fraise and Bradley 2009, E). |
| 11 Attach the irrigation giving set to the irrigation arm of the catheter. Keep the clamp of the irrigation giving set closed. | To prevent overdistension of the bladder, which can occur if fluid is run into the bladder before the drainage tube has been unclamped (Scholtes 2002, E). |
| 12 Release the clamp on the catheter tube and allow any accumulated urine to drain into the catheter bag. Empty the urine from the catheter bag into a sterile jug. | Urine drainage should be measured before commencing irrigation so that the fluid balance may be monitored more accurately (Scholtes 2002, E). |
| 13 Discard the gloves. | These will be contaminated, having handled the catheter bag (Fraise and Bradley 2009, E). |
| 14 Set irrigation at the required rate and ensure that fluid is draining into the catheter bag. | To check that the drainage system is patent and to prevent fluid accumulating in the bladder. C |

Post-procedure

- | | |
|--|--|
| 15 Make the patient comfortable, remove unnecessary equipment and clean the trolley. | To reduce the risk of cross-infection (Fraise and Bradley 2009, E). |
| 16 Wash hands. | To reduce the risk of cross-infection (Fraise and Bradley 2009, E). |
| 17 Check blood results 8–12 hours after irrigation has been commenced. | To ensure reabsorption has not occurred. |
| 18 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • reason for irrigation • date and time irrigation commenced • volume, colour and characteristics of urine output. | To provide a point of reference or comparison in the event of later queries (NMC 2010, C). |
| 19 Ensure an accurate fluid balance is commenced and maintained throughout irrigation (Figure 5.14 provides an example of a bladder irrigation chart). | |

Problem-solving table 5.3 Prevention and resolution (Procedure guideline 5.13)

Problem	Possible cause	Prevention	Suggested action
Fluid retained in the bladder when the catheter is in position.	Fault in drainage apparatus, for example: kinked tubing blocked catheter. Overfull drainage bag. Catheter clamped off.	Empty the drainage bag every 4 hours.	Straighten the tubing. 'Milk' the tubing. Wash out the bladder with 0.9% sodium chloride using an aseptic technique. Empty the drainage bag. Unclamp the catheter.
Distended abdomen related to an overfull bladder during the irrigation procedure.	Irrigation fluid is infused at too rapid a rate. Fault in drainage apparatus.	Monitor fluid drainage rate every 15 minutes.	Slow down the infusion rate. Check the patency of the drainage apparatus.
Leakage of fluid from around the catheter.	Catheter slipping out of the bladder. Catheter too large or unsuitable for the patient's anatomy.		Insert the catheter further in. Decompress balloon fully to assess the amount of water necessary. Refill balloon until it remains <i>in situ</i> , taking care not to overfill beyond safe level (see manufacturer's instructions). If leakage is profuse or catheter is uncomfortable for the patient, replace with one of smaller size.
Patient experiences pain during the lavage or irrigation procedure.	Volume of fluid in the bladder is too great for comfort. Solution is painful to raw areas in the bladder.		Reduce the fluid volume within the bladder. Inform the doctor. Administer analgesia as prescribed.
Retention of fluid with or without distended abdomen, with or without pain.	Perforated bladder.		Stop irrigation. Maintain in recovery position. Call medical assistance. Monitor vital signs. Monitor patient for pain, tense abdomen.

Procedure guideline 5.14 Care of the patient during bladder irrigation

Essential equipment

- Gloves and apron
- Bactericidal alcohol handrub
- Clean jug

Medicinal products

- Sterile irrigation fluid

Procedure

Action	Rationale
1 Adjust the rate of infusion according to the degree of haematuria. This will be greatest in the first 12 hours following surgery (average fluid input is 6–9 litres during the first 12 hours, falling to 3–6 litres during the next 12 hours). The aim is to obtain a drainage fluid which is rosé in colour. Check the bags of irrigation fluid regularly and renew as required.	To remove blood from the bladder before it clots and to minimize the risk of catheter obstruction and clot retention (Scholtes 2002, E).
2 Check the volume in the drainage bag frequently when infusion is in progress, and empty bags before they reach their capacity, for example half-hourly or hourly, or more frequently as required.	To ensure that fluid is draining from the bladder and to detect blockages as soon as possible; also to prevent overdistension of the bladder and patient discomfort.
3 Annotate the fluid balance chart accurately. The fluid balance of all patients having bladder irrigation must be closely monitored.	So that urine output is known and any related problems, for example renal dysfunction, may be detected quickly and easily. E

Patient name:			Hospital no:		
(A) Date and time	(B) Volume put up	(C) Volume run in	(D) Total volume out	(E) Urine	(F) Urine running total
10/7/14					
10.00	2000				
10.30			700		
11.10			850		
11.40		2000	600

Figure 5.14 Bladder irrigation chart.

Post-procedural considerations

Documentation

Bladder irrigation recording chart

The bladder irrigation recording chart (see Figure 5.14) is designed to provide an accurate record of the patient's urinary output during the period of irrigation. Record the time (column A) and the fluid volume in each bag of irrigating solution (column B) as it is put up.

When the irrigating fluid has all run from the first bag into the bladder, record the original volume in the bag in column C. Record the corresponding time in column A. Do not attempt to estimate the fluid volume run-in while a bag is in progress as

this will be inaccurate. If, however, a bag is discontinued, the volume run-in can be calculated by measuring the volume left in the bag and deducting this from the original volume. This should be recorded in column C (Scholtes 2002).

The catheter bag should be emptied as often as is necessary, the volume being recorded in column D and the corresponding time in column A. The catheter bag must also be emptied whenever the bag of irrigating fluid is empty, and the volume recorded in column D.

When each bag of fluid has run through, add up the total volume drained by the catheter in column D, and write this in red. Subtract from this the total volume run-in (column C) to find the urine output ($D - C = E$). Write this in column E. Draw a line across the page to indicate that this calculation is complete and continue underneath for the next bag.

Nephrostomy tubes

Related theory

The nephrostomy tube is a pigtail drain inserted under fluoroscopic, ultrasonographic or computed tomography (CT) guidance, with a local anaesthetic, usually by an interventional radiologist. The procedure involves the passing of a needle and guidewire, followed by a pigtail drain, through the skin, subcutaneous tissue, muscle layers and the renal parenchyma into the renal pelvis (Grasso and Taylor 1996). The drain is attached to a drainage bag and the system is secured to the skin with a suture and a drain fixation dressing (Figure 5.15).

The percutaneous nephrostomy diverts urine away from the ureter and bladder into an externalized drainage bag (Hohenfeller and Santucci 2010). The nephrostomy can be unilateral, with a tube and drainage bag on one side and the other kidney continuing to drain through the ureter into the bladder. Alternatively, bilateral tubes may be inserted, with a tube and drainage bag on each side and with minimal urine draining through the ureters into the bladder.

In most cases a nephrostomy is temporary and will be removed when the obstruction has resolved, the obstruction can be bypassed with a stent or the therapeutic intervention has been completed. Rarely, a nephrostomy will be a permanent or semi-permanent solution when bypassing the obstruction is not possible or when it is inadvisable.

Evidence-based approaches

Rationale

The decision to perform a percutaneous nephrostomy is taken by the patient's medical/surgical team in discussion with the radiologist. Indications for a nephrostomy include:

- relief of urinary obstruction (the most common reason for insertion, characterized by any of the following: rising creatinine, acute renal failure, loin pain, nausea and vomiting, fever, urosepsis)
- urinary diversion (for example, following a ureteral injury, ureteral fissure/fistula, haemorrhagic cystitis)
- access for therapeutic interventions (for example, stone removal, access for antegrade stent insertion, removal of foreign body such as a broken ureteric stent, delivery of medications, ureteral biopsy)
- diagnostic testing (for example, antegrade pyelography or a ureteral perfusion test) (Dagli and Ramchandani 2011, Ramchandani et al. 2003).

Figure 5.15 Nephrostomy tube.

The medical/surgical team will be guided by the urologist when making the decision as a retrograde stent insertion or ureteroscopy may be alternatively indicated for the patient. In general, a retrograde approach is preferred as it has a lower associated morbidity and when a retrograde approach is possible for the patient, a nephrostomy is contraindicated.

Other contraindications include:

- coagulation conditions that increase the tendency to bleed
- anticoagulant use (Patel et al. 2012).

Principles of care

The principles of care for a patient with a nephrostomy tube are similar to those for a patient with an indwelling catheter. Accurate measurement of urine output from each of the indwelling tubes is required and should be recorded separately (usually marked Left/Right/Urethral) and with a total output also recorded.

Good wound site care is essential to avoid exit site infection. Flushing of the nephrostomy should be avoided where possible to avoid introducing infection and potentially causing pyelonephritis. Where flushing of the nephrostomy tube is required, this should be performed by appropriately trained staff with 5 mL of 0.9% sodium chloride using an aseptic technique.

Anticipated patient outcomes

Whether the nephrostomy is short or long term, it is anticipated that the patient will have an uneventful episode of care. The nephrostomy tube will continue to drain urine without occlusion, the patient will remain free from infection and their fluid balance will be maintained.

Legal and professional issues

The nurse looking after the patient must have an understanding of the principles, anatomy and indications for a nephrostomy tube. All staff managing a patient with a nephrostomy tube should be appropriately trained and working within their scope of practice. If formal competencies are required at the place of employment, these must be met prior to managing the patient's care.

Removal of the nephrostomy tube should be performed by a trained member of staff and under the instruction of the medical/surgical team (see Procedure guideline 5.16: Nephrostomy tube: removal of locking pigtail drainage system). If there is a stent *in situ*, the nephrostomy tube should be removed under X-ray or ultrasound guidance to avoid misplacement of the ureteric stent.

Pre-procedural considerations

If this is a long-term nephrostomy, the patient and/or carer should be taught to change both the drain site dressing and the drainage bag on a regular basis. If self-care and independence are not possible, the patient should be referred to the community nursing team.

The recommended dressing is one that supports the nephrostomy tube to prevent accidental tugging and also secures the tube to the patient's skin. There are several drain-specific types available including Drain-Guard, Drain-Fix and OPSITE Post-Op Visible drain dressing. When selecting the dressing, it is important to consider the comfort factor for the patient as the dressing is directly on the patient's back when lying down and sitting against a chair.

To perform the dressing change and drainage bag change, the patient will need to be sitting upright on a stool, couch or a bed with their back facing towards you. The dressing change and drain removal are best performed from behind, so preparing the patient well and good communication are essential. If the patient is unable to sit upright, then positioning the patient on their side in the bed is an alternative with the patient's back facing towards you. Again the procedure is performed from behind the patient.

Post-procedural considerations and complications

In between bag changes, the nephrostomy bag should be emptied when it becomes three-quarters full (see Procedure guideline 5.11: Urinary catheter bag: emptying). Where appropriate, the patient or carer should be taught how to do this.

If the kidney has been obstructed the patient may enter a phase of diuresis. This is characterized by high-volume outputs from the nephrostomy tube (polyuria). Close monitoring of the patient's fluid balance and vital signs is required. The patient's intake (intravenous or oral) should closely match the output. A closely monitored and adjusted fluid balance will prevent deterioration in the patient's condition associated with rapid fluid loss.

The patient is at risk of pyelonephritis from the foreign body puncturing the kidney. The patient should be monitored for signs of infection/sepsis, for example loin pain, elevated temperature, fever/chills, purulent urine output or deterioration in their vital signs. A urine specimen should be taken when infection is suspected. In such cases, medical advice should be sought and the patient treated accordingly. Ensuring the drain site remains clean and dry is essential to prevent infection and flushing of the nephrostomy tube should be avoided. Drainage bags should be changed every 5–7 days. Ensure good hand hygiene when handling the drain and exit site and when emptying the drainage bag. Nephrostomy tubes should be changed every 3 months.

Procedure guideline 5.15 Nephrostomy tube: weekly dressing and bag change

Essential equipment

- 0.9% sodium chloride
- Drainage bag and leg straps (with appropriate connector if needed)
- Non-sterile gloves
- Dressing pack with gauze
- Disposable plastic apron
- Drain fixation dressing (e.g. Drain Fix, Drain-Guard or OPSITE Post-Op Visible drain dressing)
- Bactericidal alcohol handrub
- Blunt disposable clamps
- Alcohol (chlorhexidine) wipe
- Adhesive remover
- Micropore tape

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives his/her valid consent (NMC 2013, C).
2 Screen the bed.	To ensure patient privacy. To allow dust and airborne organisms to settle before the field is exposed (NMC 2015, E).
3 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.	To reduce risk of infection (Fraise and Bradley 2009, E).
4 Put on a disposable plastic apron.	To reduce risk of cross-infection from micro-organisms on uniform/clothing (Fraise and Bradley 2009, E).
5 Prepare the trolley, placing all equipment required on the bottom shelf.	The top shelf acts as a clean working surface.
6 Take the trolley to the patient's bedside, disturbing screens as little as possible.	To minimize airborne contamination (Fraise and Bradley 2009, E).
7 Assist the patient onto the edge of the bed/trolley sitting in an upright position with their back exposed.	To enable access to the nephrostomy site. E

Procedure

8 Keeping the drain secure with one hand, carefully remove existing drain fixation dressing and inspect incision site. Check suture remains intact.	To assess skin for signs of infection, inflammation and overgranulation. The suture should remain intact to ensure the drain remains secure. E
9 Pour a small amount of adhesive remover onto a gauze square. Keeping the drain secure with one hand, use the adhesive remover to remove any dressing residue from the drain tubing (check manufacturer's guidance to ensure this is safe for use on a drain).	Removing the sticky residue from the tubing minimizes the risk of infection. E
10 Clean hands with soap and water and a bactericidal alcohol handrub.	Hands may have become contaminated by handling the outer packs and the old dressing (Fraise and Bradley 2009, E).
11 Put on non-sterile gloves.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
12 Clean the drain site with 0.9% sodium chloride, working from the drain outwards. Gently remove any encrustation. Allow the site to dry.	This is performed at least weekly to reduce micro-organisms present and to remove exudate, blood and wound debris from around the site and the device, which may be a medium for bacterial growth, and also to prevent overgranulation (NICE 2012; RCN 2011, C).

(continued)

Procedure guideline 5.15 Nephrostomy tube: weekly dressing and bag change (*continued*)

168

Action	Rationale
13 When the site is dry, apply a sterile drain fixation dressing according to the manufacturer's guidelines (e.g. Drain Fix or OPSITE Post-Op Visible drain dressing). 'Window frame' the edges of the dressing to prevent it rucking up by using surgical tape around each edge of the dressing.	To improve security of the nephrostomy drain and enable patient mobility. E
14 Clean hands with soap and water and a bactericidal alcohol handrub.	Hands may have become contaminated by handling the outer packs and the old dressing (Fraise and Bradley 2009, E).
15 Gently clamp nephrostomy tube using blunt disposable clamps.	To prevent leakage of urine. E
16 Disconnect the drainage bag, and connector if attached, from the nephrostomy tube.	This is performed every 5–7 days or according to manufacturer's guidelines. E
17 Clean connector hub with alcohol-impregnated chlorhexidine wipe.	To minimize risk of infection. E
18 Apply new sterile drainage bag, and connector if required, to the nephrostomy tube, being careful not to touch the hubs and unclamp the drain. Urine should begin to flow.	To enable clean passage of urine and to minimize contamination from bacteria within the drainage bag (Pellowe and Pratt 2004; Pomfret 2006). E
19 Apply leg strap or waist strap according to patient preference to secure the bag to the patient. Be careful to ensure that the tube is not taut nor pulling at the exit site.	To enable independent mobility and maintain patient dignity. To maintain tube security. E
Post-procedure	
20 Dispose of waste in an orange plastic clinical waste bag and seal the bag before moving the trolley.	To prevent environmental contamination. Orange is the recognized colour for clinical waste (DEFRA 2005, C).
21 Draw back the curtains once the patient has been covered.	To maintain the patient's dignity (NMC 2015, C).
22 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • date and time of procedure • procedure/s performed • dressing and bag type used • condition of skin • any problems/concerns during procedure • any swabs/samples taken during the procedure (e.g. exit site swab or urine sample) • any referrals made following the procedure • a review date for next dressing/bag change. 	To provide a point of reference or comparison in the event of later queries (NMC 2010, C).

Problem-solving table 5.4 Prevention and resolution (Procedure guideline 5.15)

Problem	Cause	Action	Prevention
Wound site infection.	Foreign body puncturing the skin.	Monitor patient for signs of infection, e.g. purulent discharge, exit site erythema, pain/itching, elevated temperature. Send swab for MC&S when indicated. Seek medical advice. Treat patient according to medical advice.	Maintain good exit site care. Change dressing and check site at least every 7 days. Ensure good hand hygiene.
Nephrostomy tube falls out.	Locking mechanism on drain has failed. Retaining suture has become loose. Drain fixation dressing has fallen off.	Seek urgent medical assistance. Nephrostomy tube will need to be replaced by physician.	Ensure that all the elements securing the nephrostomy are well situated. Check the locking mechanism on the drain is in the 'lock' or 'drain' position. Check the retaining suture is intact during weekly dressing changes. Be careful to correctly apply and secure the drain fixation dressing.
Nephrostomy tube stops draining.	No urine output. Blocked tube. Kinked tube.	Check patient's vital signs and seek urgent medical assistance if patient is unwell. Ensure there are no kinks in the tube that have occluded flow of urine and straighten tube. If the tube may be blocked with debris, flush tube with 5 mL NaCl using aseptic technique to unblock.	Monitor urine output and vital signs. Escalate concerns to the medical team. Carefully secure the drain and tubing to prevent kinking.

Procedure guideline 5.16 Nephrostomy tube: removal of locking pigtail drainage system

Essential equipment

- Sterile dressing pack containing gallipots or an indented plastic tray, low-linting swabs and/or medical foam, disposable forceps, gloves, sterile field, disposable bag
- Scissors or stitch cutter (refer to patient notes for directions if dressing in place)
- Key or alternative device to unlock the pigtail drain
- Sterile absorbent dressing to place over drainage site
- 0.9% sodium chloride solution

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient and gain their consent.	To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, C ; Walker 2007, C). Another member of staff may be needed to reassure the patient during the procedure.
2 Check the patient's medical notes to confirm which nephrostomy tube is to be removed. Once confirmed, establish the number and site(s) of sutures (both internal and external).	To ensure only documented drains are removed. To ensure all non-absorbable sutures are removed prior to attempting removal.
3 Offer the patient analgesia as per chart.	To promote comfort (NMC 2015, C).
4 If the patient has a ureteric stent <i>in situ</i> , removal of the nephrostomy should be done under X-ray or ultrasound guidance.	To ensure that the ureteric stent does not become misplaced during removal.

Procedure

5 Perform procedure using aseptic technique. Clean the drain site, using 0.9% sodium chloride.	To reduce risk of infection (Fraise and Bradley 2009, E).
6 If the drain is sutured in place, hold the knot of the suture with metal forceps and gently lift upwards.	To facilitate removal. E Plastic forceps tend to slip against nylon sutures. To allow space for the scissors or stitch cutter to be placed underneath. E
7 Cut the shortest end of the suture as close to the skin as possible and remove the suture.	To minimize cross-infection by allowing the suture to be liberated from the drain without drawing the exposed part through tissue (Pudner 2010, E).
8 Disconnect drainage bag from stopcock. Using the 'key' or alternative items that fit in the slot of the stopcock, rotate the stopcock counter-clockwise exactly 180° to the 'unlocked' position. <i>Note:</i> After rotating the retention stopcock 180° to lock the pigtail during placement, you must rotate the stopcock counter-clockwise 180° to unlock it prior to catheter removal.	
9 Warn the patient of the pulling sensation they will experience and reassure throughout.	To promote comfort and co-operation (Walker 2007, E). Another member of staff may be needed to reassure the patient during the procedure.
10 Loosening up of the drain should be done if possible, especially for a drain that has been in for some time. This can be done by gently rotating the drain to loosen it from the embedded tissue.	To minimize pain and reduce trauma. E Drains that have been left in for an extended period will sometimes be more difficult due to tissue growing around the tubing (Walker 2007, E).
11 With one gloved hand, place a finger on each side of the drain exit site, exerting gentle pressure to stabilize the skin around the drain. Using the other hand, take a firm grasp of the drain as close to the skin as possible and gently pull to start removing it. Steady gentle traction should be used to remove the drain rather than sudden jerky movements. If there is resistance, ensure that other gloved hand is still exerting gentle pressure around the drain exit site.	Firm grasp for shortest length of time should be done to minimize patient discomfort. This is especially important for supple drains such as those made from silicone or rubber which can stretch for some distance, then suddenly break free, causing undue pain to the patient.
12 Once removed, the drain should be inspected to ensure that it is intact. The end of the drain should be clean cut and not jagged.	This clean appearance ensures that the whole drain has been removed. E If you have any doubt that the drain is intact, the surgeons should be contacted to inspect the drain before disposal.

(continued)

Procedure guideline 5.16 Nephrostomy tube: removal of locking pigtail drainage system (continued)

Action	Rationale
13 Cover the drain site with a sterile dressing and tape securely.	To prevent infection entering the drain site. E
14 If the site is inflamed or there is a request for the tip to be sent to microbiology, cut it cleanly, using sterile scissors, and send it in a sterile pot and send a wound swab of the exit site.	To recognize and treat suspected infection (Fraise and Bradley 2009, E ; Walker 2007, E).
Post-procedure	
15 Dispose of used drainage system in clinical waste bag.	To ensure safe disposal. E
16 Observe drain site for signs of haematoma, urinoma or infection.	
17 Record information in relevant documents; this should include: <ul style="list-style-type: none"> • date and time of procedure • procedure/s performed • any problems/concerns during procedure • any swabs/samples taken during the procedure (e.g. exit site swab or urine sample) • any referrals made following the procedure. 	To provide a point of reference or comparison in the event of later queries (NMC 2010, C).

Surgical urinary diversions**Definition**

A urinary diversion is a surgically created system for removing urine from the body when either the bladder or urethra is either non-existent or no longer viable.

Evidence-based approaches**Rationale**

Invasive bladder cancer is the most common condition for which urinary diversions are performed. Other conditions that may lead to urinary diversion include:

- pelvic cancers, for example gynaecological cancers, sarcoma
- congenital abnormalities, for example bladder extrophy
- neuropathic bladder, a condition where the nerve impulses do not reach the bladder as the result of an underlying disease or injury, for example myelomeningocele
- trauma
- irreparable fistula
- interstitial cystitis
- radiation fibrosis
- intractable incontinence (Taylor 2005).

There are two main types: a urostomy, which is an incontinent diversion where the urine is stored in a body-worn pouch, and continent urinary diversions. Continent urinary diversions differ in that a system is created to collect and store urine before it is removed from the body.

The main aim in selection of urinary diversion is to provide patients with a diversion which gives the lowest potential for complications and the best quality of life and, for those patients with cancer, the best cancer control (Parekh et al. 2006).

Indications

A urinary diversion is formed to:

- eliminate urine from the body if the lower urinary tract is defective or absent
- preserve the upper urinary tract

- avoid metabolic disturbance
- store the urine either internally or externally until convenient to empty.

Continent diversions:

- store an adequate volume of urine at low pressure
- offer patients a choice of urinary diversion
- improve or maintain the individual's body image, psychological and social well-being by removing the necessity of wearing external devices, for example urostomy pouch or incontinence pads (Leaver 2002).

Principles of care

Patients are selected carefully for urinary diversion, particularly for the continent types of diversions. Patients' general levels of health, co-morbidities, renal and hepatic function are all taken into consideration when deciding on the type of urinary diversion. Intestinal disease such as Crohn's disease, urinary stress incontinence, bladder cancer involving the bladder neck or prostatic urethra and previous pelvic radiotherapy are contraindications for continent diversion and will dictate the types of diversions offered to patients (Hautmann et al. 2006, Meyer et al. 2005).

Patients undergoing continent diversions must be motivated towards self-care, those needing to self-catheterize must be dextrous enough to manipulate Nelaton catheters, and good anal sphincter control is a must for those undergoing a rectal bladder.

Encouraging patients' independence in living with a urinary diversion is a key aim of care. Practical help, advice and support are employed in encouraging patients to continue with all necessary activities of daily living.

Methods of urinary diversion

Urinary diversions may be divided into two main types.

- Incontinent diversions, whereby urine is stored in an external body-worn appliance, for example ileal conduit, colonic conduit, cutaneous ureterostomy.
- Continent diversions where urine is stored in an internal pouch, for example Mitrofanoff, Mainz, orthotopic neobladder.

Incontinent diversions

An ileal conduit is the most common form of urostomy; the colon (colonic conduit) may also be used. Urostomy comes from the Greek words *uros* meaning urine and *stoma* meaning mouth or opening (Nazarko 2008).

A section of bowel is isolated, along with its mesentery vessels, and the remaining ends of the bowel are anastomosed to restore continuity. The isolated section is mobilized, the proximal end is closed and the ureters, once resected from the bladder, are implanted at this end. The distal end is brought out onto the surface of the abdominal wall and everted to form a spout (Figure 5.16), as in an ileostomy (Fillingham and Fell 2004). Urine from a urostomy will contain mucus from the bowel used in its construction (Taylor 2005).

A cutaneous ureterostomy is another form of incontinent diversion, whereby the ureters are brought out onto the abdominal wall together (one stoma) or separately (two stomas). This may be a permanent or temporary procedure, and may be used for patients with poor renal function and when less extensive abdominal surgery is indicated. Stomas formed in this way are often small and flush to the abdomen. They are prone to stenosis and it is often difficult to maintain a leak-proof appliance (Fillingham and Fell 2004).

Continent diversions

All continent diversions consist of three components.

- A reservoir to store urine, which may be the bladder itself, an augmented bladder or one made completely out of ileum or colon.
- A continence mechanism to retain urine in the reservoir, which may be an existing valve or sphincter, such as the ileocaecal valve, urethral sphincter or anal sphincter. A valve may also be constructed using the same tissue used to construct the reservoir, such as a flutter valve created by the intussusception of a segment of bowel or a flap valve created by tunnelling a narrow tube between muscle and mucosal layers of the reservoir (Leaver 2002).
- A channel or tunnel to let the urine out, which may be formed by utilizing other tube/tunnel-like structures such as the appendix, ureter, urethra or fallopian tube. Alternatively, a segment of ileum or colon can be used (Leaver 2002).

Figure 5.17 Continent urinary diversion.

There are three main types of continent diversion: continent cutaneous diversion, rectal bladder and orthotopic neobladder.

Continent cutaneous diversion

There are a number of different types of continent cutaneous diversions which differ in construction, using different structures to form the reservoir and the tunnel, and different techniques to create the continence mechanism. The outcomes for patients and the nursing care involved are essentially similar in most cases. The most commonly performed procedure of this type in the UK is arguably the Mitrofanoff (Leaver 1996) (Figure 5.17).

In this type of diversion, urine drains into the urinary reservoir constructed from bowel or bladder through the ureters. One end of the tissue used to construct the channel is buried in a submuscular tunnel in the bladder, forming an obstructing flap valve. The other end is brought to the surface of the abdominal wall to form a continent stoma. As the bladder fills with urine, more pressure is put on the valve, causing it to become even more obstructed. A catheter is passed into the stoma along the channel, through the valve and into the bladder when the patient wants to empty their bladder (Leaver 1996). Patients can self-catheterize into the continent urinary stoma every 4–6 hours to empty the urine reservoir (Figure 5.18).

*Pre-procedure***Action****Rationale**

- | | |
|---|---|
| 1 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Collect all equipment necessary for the procedure. | To ensure all the equipment required is easily available. E |
| 3 Take the equipment to the toilet, bathroom or screened bed area. Ensure there is a good light and a full-length mirror. | To ensure the patient's privacy. To ensure patient can see the stoma clearly. E |
| 4 The equipment should be arranged on a clean surface and within easy reach for the procedure. | To reduce the risk of contamination by surface bacteria. So the equipment is easily available. E |
| 5 The patient needs to remove any inhibiting clothing. | To ensure the patient can examine the stoma. E |
| 6 The patient should wash their hands with soap and water, then dry them. | To ensure the hands are clean (Fraise and Bradley 2009, E). |

Procedure

- | | |
|---|--|
| 7 The patient should look at the stoma, if necessary with the aid of a hand or full-length mirror. | To look for mucus and swelling around the stoma. E |
| 8 The patient should wipe away any mucus with a tissue soaked in warm water and gently pat dry. | To ensure the opening of the stoma is clear and mucus does not block the catheter during insertion into the stoma. E |
| 9 If a lubricated catheter is to be used, follow manufacturer's guidelines. If not, lubricate the tip of the catheter with water-soluble lubricant. | To act as a lubricant to allow the catheter to enter the urinary reservoir without causing internal trauma. E |
| 10 Ensure the untipped end of the catheter is in a receiver, such as a jug, bowl or toilet. | To ensure the urine goes into a bowl and not onto the patient. E |
| 11 The patient can either use a mirror to guide the tube into the opening of the stoma or feel the opening with two fingers slightly apart with the stoma between. | To act as a guide to pass the catheter into the continent urinary stoma. E |
| 12 Insert the catheter gently into the stoma, following the pathway inside (usually towards the middle of the abdomen) until urine starts to flow, then insert tube a further 4–6 cm to reduce risk of contamination. | The direction of insertion and the diameter of catheter inserted depend on the type, size and shape of continent urinary stoma. E
To negotiate continence device. E |
| 13 When all the urine has stopped flowing, advance the catheter to ensure the bladder is completely empty. Slowly remove the catheter using a rotating action. If urine starts flowing again, wait until it stops before removing the catheter any further. | To ensure complete emptying of the urinary reservoir. The rotating action reduces the suction effect and pain due to friction (Leaver 1996, C). It may dislodge any debris or mucus blocking the tube and allow the urine to flow (Leaver 1996). |
| 14 Remove the tube. Cover the end of the catheter with a finger just before it is removed from the tunnel. Hold the catheter over the receptacle before removing the finger. | To trap urine in the catheter and stop it leaking on to the patient (Colley 1998, E).
To allow complete drainage of the tube. |

Post-procedure

- | | |
|---|--|
| 15 Dispose of the catheter in an orange bin disposal bag. | To ensure safe disposal (DEFRA 2005, C). |
| 16 Cover the stoma with a non-adherent dressing and secure with skin-protective tape. | To prevent mucus staining the patient's clothing. E |
| 17 The patient should wash their hands with soap and water, and then dry them. | To remove any urine on the hands. |
| 18 The patient can then dress, collect equipment and dispose of any soiled dressings. | To prevent cross-infection (Fraise and Bradley 2009, E). |

Altered faecal elimination

This section focuses on altered faecal elimination, including diarrhoea and constipation, and considers a range of pharmacological and non-pharmacological strategies to manage these conditions. Also reviewed in this section is the care required to support a patient with a bowel stoma.

Diarrhoea

Definition

The term diarrhoea originates from the Greek for 'to flow through' (Bell 2004) and can be characterized according to its onset and duration (acute or chronic) or by type (e.g. secretory, osmotic or malabsorptive). Diarrhoea can also be defined in terms of stool frequency, consistency, volume or weight (Metcalf 2007). The World Health Organization (2014) defines diarrhoea as the passage of three or more loose stools per day, or more frequent than is normal for the individual.

Related theory

Diarrhoea is a serious global public health problem, in particular in low-income and middle-income countries due to poor sanitation. There are almost 1.7 billion cases of diarrhoeal disease each year, with many people dying (WHO 2014). The disease pathogens are most commonly transmitted via the faecal–oral route (Ejemot-Nwadiaro et al. 2008). Diarrhoea should be classified according to time (acute or chronic) and the characteristics of the stools (see Bristol Stool Chart, Figure 5.4) (Baldi et al. 2009).

Acute diarrhoea

Acute diarrhoea is very common, usually self-limiting, generally lasting less than 2 weeks and often requires no investigation or treatment (Hall 2010, Shepherd 2000). Causes of acute diarrhoea include:

- dietary indiscretion (eating too much fruit, alcohol misuse)
- allergy to food constituents
- infective:
 - travel associated
 - viral
 - bacterial (usually associated with food)
 - antibiotic related.

One of the most common causes of acute diarrhoea in the adult population worldwide is viral gastroenteritis resulting from norovirus. Its low infectious dose, resistance to extreme temperatures as well as many household cleaning products, along with viral shedding, before and after symptoms are apparent, have resulted in this virus being prolific during colder months and becoming widely known as the winter vomiting bug (Krenzer 2012).

Chronic diarrhoea

Chronic diarrhoea generally lasts longer than 2–4 weeks (Metcalf 2007) and may have more complex origins. Chronic causes can be divided as follows (Thomas et al. 2003).

- *Colonic*: colonic neoplasia, ulcerative colitis and Crohn's disease, microscopic colitis.
- *Small bowel*: small bowel bacterial overgrowth, coeliac disease, Crohn's disease, Whipple's disease, bile acid malabsorption, disaccharidase deficiency, mesenteric ischaemia, radiation enteritis, lymphoma, giardiasis.
- *Pancreatic*: chronic pancreatitis, pancreatic carcinoma, cystic fibrosis.
- *Endocrine*: hyperthyroidism, diabetes, hypoparathyroidism, Addison's disease, hormone-secreting tumours.
- *Other causes*: laxative misuse, drugs, alcohol, autonomic neuropathy, small bowel resection or intestinal fistulas, radiation enteritis.

Pre-procedural considerations

Assessment

The cause of diarrhoea needs to be identified before effective treatment can be instigated. This may include clinical investigations such as stool cultures for bacterial, fungal and viral pathogens or a more formal medical evaluation of the gastrointestinal tract (Kornblau et al. 2000).

Ongoing nursing assessment is essential for ensuring individualized management and care. The lack of a systematic approach to assessment and poor documentation cause problems in effective management of diarrhoea (Cadd et al. 2000, Smith 2001). Nurses need to be aware of contributing factors and be sensitive to patients' beliefs and values in order to provide holistic care. A comprehensive assessment is therefore essential and should include the following.

- History of onset, frequency and duration of diarrhoea: patient's perception of diarrhoea is often related to stool consistency (Metcalf 2007).
- Consistency, colour and form of stool, including the presence of blood, fat and mucus. Stools can be graded using a scale such as the Bristol Stool Chart (see Figure 5.4), where diarrhoea would be classified as types 6 or 7 (Longstreth et al. 2006).
- Associated symptoms: pain, nausea, vomiting, fatigue, weight loss or fever.
- Physical examination: check for gaping anus, rectal prolapse and prolapsed haemorrhoids (Nazarko 2007).
- Recent lifestyle changes, emotional disturbances or travel abroad.
- Fluid intake and dietary history, including any cause-and-effect relationships between food consumption and bowel action.
- Regular medication, including antibiotics, laxatives, oral hypoglycaemics, appetite suppressants, antidepressants, statins, digoxin or chemotherapy (Nazarko 2007).
- Effectiveness of antidiarrhoeal medication (dose and frequency).
- Significant past medical history: bowel resection, pancreatitis, pelvic radiotherapy.
- Hydration status: evaluation of mucous membranes and skin turgor.
- Perianal or peristomal skin integrity: enzymes present in faecal fluid can cause rapid breakdown of the skin (Nazarko 2007).
- Stool cultures for bacterial, fungal and viral pathogens: to check for infective diarrhoea (Pellatt 2007). Treatment may not be commenced until results are available except if the patient has been infected by *Clostridium difficile* in the past.
- Blood tests: full blood count, urea and electrolytes, liver function tests, vitamin B₁₂, folate, calcium, ferritin, erythrocyte sedimentation rate (ESR) and C-reactive protein.
- Patient's preferences and own coping strategies including non-pharmacological interventions and their effectiveness (Cadd et al. 2000, Chelvanayagam and Norton 2004, King 2002, Kornblau et al. 2000).

All episodes of acute diarrhoea must be considered potentially infectious until proven otherwise. The risk of spreading the infection to others can be reduced by adopting universal precautions such as wearing of gloves, aprons and gowns, disposing of all excreta immediately and, ideally, nursing the patient in a side room with access to their own toilet (King 2002). Advice should always be sought from the infection control team. At this stage nursing care should also include educating patients about careful hand washing.

Diarrhoea can have profound physiological and psychosocial consequences for a patient. Severe or extended episodes of diarrhoea may result in dehydration, electrolyte imbalance and malnutrition. Patients not only have to cope with increased frequency of bowel movement but may have abdominal pain, cramping, proctitis and anal or perianal skin breakdown. Food aversions may develop or patients may stop eating altogether as they anticipate subsequent

diarrhoea following intake. Consequently, this may lead to weight loss and malnutrition. Fatigue, sleep disturbances, feelings of isolation and depression are all common consequences for those experiencing diarrhoea. The impact of severe diarrhoea should not be underestimated; it is highly debilitating and may cause patients on long-term therapy to be non-compliant, resulting in a potentially life-threatening problem (Kornblau et al. 2000).

Once the cause of diarrhoea has been established, management should be focused on resolving the cause and providing physical and psychological support for the patient. Most cases of chronic diarrhoea will resolve once the underlying condition is treated, for example drug therapy for Crohn's disease or dietary management for coeliac disease. Episodes of acute diarrhoea, usually caused by bacteria or viruses, generally resolve spontaneously and are managed by symptom control and the prevention of complications (Shepherd 2000).

Pharmacological support

The treatment for diarrhoea depends on the cause.

Antimotility drugs

Antimotility drugs such as loperamide or codeine phosphate may be useful in some cases, for example in blind loop syndrome and radiation enteritis. These drugs reduce gastrointestinal motility to relieve the symptoms of abdominal cramps and reduce the frequency of diarrhoea (Shepherd 2000). It is important to rule out any infective agent as the cause of diarrhoea before using any of these drugs, as they may make the situation worse by slowing the clearance of the infective agent.

Antibiotics

In the case of bacterial diarrhoea, treatment with antibiotics is recommended only in patients who are very symptomatic and show signs of systemic involvement (Metcalf 2007). Not uncommonly, *Salmonella* can become resistant to commonly used antimicrobial agents such as amoxicillin (Metcalf 2007). When dealing with antibiotic-associated diarrhoea, most patients will notice a cessation of their symptoms with discontinuation of the antibiotic therapy. If diarrhoea persists, it is important to exclude pseudomembranous colitis by performing a sigmoidoscopy and sending a stool for cytotoxin analysis. However, over recent years there has been increasing evidence supporting the use of probiotics in cases of diarrhoea associated with antibiotics (McFarland 2007). Researchers believe that probiotics restore the microbial balance in the intestinal tract previously destroyed by inciting antibiotics (Hickson et al. 2007). There are a variety of probiotic products available and their effectiveness appears to be related to the strain of bacteria causing the diarrhoea (Avadhani and Miley 2011, Hickson et al. 2007, McFarland 2007).

Fluid replacement

The prevention and/or correction of dehydration is the first step in managing an episode of diarrhoea. Adults normally require 1.5–2 L of fluid in 24 hours. The person who has diarrhoea will require an additional 200 mL for each loose stool. Dehydration can be corrected by using intravenous fluids and electrolytes or by oral rehydration solutions. The extent of dehydration dictates whether a patient can be managed at home or will need to be admitted to hospital (Nazarko 2007). Nursing care should also include monitoring signs or symptoms of electrolyte imbalance, such as muscle weakness and cramps, hypokalaemia, tachycardia and hypernatraemia (Metcalf 2007).

Non-pharmacological support

Maintaining dignity

Preserving the patient's privacy and dignity is essential during episodes of diarrhoea. The nurse has an important role in minimizing the patient's distress by adjusting language and using terms that are appropriate to the individual to reduce embarrassment

(Smith 2001) and by listening to the patient's preferences for care (Cadd et al. 2000). Additionally, the use of deodorizers and air fresheners to remove the smell caused by offensive diarrhoea contributes to the person's dignity. Stoma deodorants are thought to be more effective and samples can be obtained from company representatives (Nazarko 2007).

Skin care

It is important that the patient has easy access to clean toilet and washing facilities and that requests for assistance are answered promptly. Skin care is also essential to prevent bacteria present in faecal matter from destroying the skin's cellular defences and causing skin damage. This is particularly important with diarrhoea since it has high levels of faecal enzymes that come into contact with the perianal skin (Gray et al. 2012, Le Lievre 2002, Ripley 2007). The anal area should be gently cleaned with warm water immediately after every episode of diarrhoea. Frequent washing of the skin can alter the pH and remove protective oils from the skin. Products aimed at maintaining healthy peristomal skin should be used to protect perianal skin in patients with diarrhoea (Nazarko 2007). Soap should be avoided, unless it is an emollient, to avoid excessive drying of the skin and gentle patting of the skin is preferred for drying to avoid friction damage. Talcum powder should not be used and barrier creams should be applied sparingly, gently layered on in the direction of the hair growth rather than rubbed into the skin (Le Lievre 2002). The use of incontinence pads should be carefully considered in a person with severe episodes of diarrhoea. This particular material does not absorb fluid stools, protect the skin from damage or contain smells.

Faecal collection devices may leak with movement, so are most useful for patients who are cared for in bed (Nazarko 2007, Wilson 2008). This type of device is fitted over the anus and fluid stools drain into a drainage bag similar to a drainable stoma bag. It is imperative that such devices are fitted by appropriately trained, competent healthcare professionals and that both local policies and manufacturer's instructions are followed to ensure this equipment is used in an appropriate and safe manner (Rees and Sharpe 2009) (Figure 5.19).

Diet

A diet rich in fibre, or 'roughage', can cause diarrhoea. In such cases individuals should be advised to reduce their intake of foods including cereals, fruit and vegetables and space it out over the day (Nazarko 2007). Chilli and other spices can irritate the bowel and should be avoided. Sorbitol (artificial sweetener), beer, stout and high doses of vitamins and minerals should also be avoided.

Faecal incontinence

Faecal incontinence is a clinical symptom associated with diarrhoea (Nazarko 2007) which has been defined as the uncontrolled passage of solid or liquid faeces at socially inappropriate times and places (Kenefick 2004). When it is not possible to treat the cause of the diarrhoea, a care plan should be created to manage incontinence and prevent complications (NICE 2007).

Factors that can contribute to the development of faecal incontinence include (Nazarko 2007):

- damage or weakness of the anal sphincter: obstetric damage, haemorrhoidectomy, sphincterotomy or degeneration of the internal anal sphincter muscle
- severe diarrhoea
- faecal loading (impaction): immobility, lack of fluids
- neurological conditions: spinal cord injury, Parkinson's disease
- cognitive deficits.

Diarrhoea can potentially disrupt a person's well-being. Community nurses and hospital-based specialist nurses have an essential role in supporting those affected by this condition. Diagnosis, treatment and management of diarrhoea and potential

Figure 5.19 Faecal management system. *Source:* Reproduced with permission from ConvaTec Ltd.

faecal incontinence can take place at home where individuals are more familiar with the environment.

Constipation

Definition

Constipation results when there is a delayed movement of intestinal content through the bowel. It has been described as persistently difficult, infrequent or incomplete defaecation, which may or may not be accompanied by hard, dry stools (Norton 2006). Constipation is a subjective disorder, being perceived differently by different people owing to the wide variety of bowel habits among healthy people (Woodward 2012). Consequently, there is a lack of consensus amongst both healthcare professionals and the general public as to what actually constitutes constipation (Kyle 2011b, Norton 2006, Perdue 2005).

Anatomy and physiology

The rectum is very sensitive to rises in pressure, even of 2–3 mmHg, and distension will cause a perineal sensation with a

subsequent desire to defaecate. A co-ordinated reflex empties the bowel from mid-transverse colon to the anus. During this phase the diaphragm, abdominal and levator ani muscles contract and the glottis closes. Waves of peristalsis occur in the distal colon and the anal sphincter relaxes, allowing the evacuation of faeces (Tortora and Derrickson 2011). The stimulus to defaecate varies in individuals according to habit, and if a decision is made to delay defaecation, the stimulus disappears and a process of retro-peristalsis occurs whereby the faeces move back into the sigmoid colon (Perdue 2005). If these natural reflexes are inhibited on a regular basis, they are eventually suppressed and reflex defaecation is inhibited, resulting in such individuals becoming severely constipated.

Related theory

It has been estimated that up to 27% of a given population experience constipation (Longstreth et al. 2006) with an average prevalence across Europe of 17.1% (Peppas et al. 2008).

Constipation occurs when there is either a failure of colonic propulsion (slow colonic transit) or a failure to evacuate the rectum (rectal outlet delay) or a combination of these problems (Norton 2006, Woodward 2012).

The management of constipation depends on the cause and there are numerous possible causes, with many patients being affected by more than one causative factor (Figure 5.20). While constipation is not life-threatening, it does cause a great deal of distress and discomfort. Particularly, constipation can be associated with abdominal pain or cramps, feelings of general malaise or fatigue and feelings of bloatedness. Nausea, anorexia, headaches, confusion, restlessness, retention of urine, faecal incontinence and halitosis may also be present in some cases (Fritz and Pitlick 2012, Kyle 2011b).

The effective treatment of constipation relies on the cause being identified by thorough assessment. Constipation can be categorized as primary or secondary (Perdue 2005). Primary constipation has no pathological cause (RCN 2012b). Factors that lead to the development of primary, or idiopathic, constipation are extrinsic or lifestyle related and include:

- an inadequate diet (low fibre)
- poor fluid intake
- a lifestyle change
- ignoring the urge to defaecate.

Secondary constipation is attributed to another disorder, whether this be metabolic, neurological or psychological; there is an identifiable cause for the constipation (RCN 2012). Examples of disease processes that may result in secondary constipation include anal fissures, colonic tumours, irritable bowel syndrome or conditions such as Parkinson's disease. Constipation may also result as a side-effect of certain medications, such as opioid analgesics (RCN 2012b, Woodward 2012).

Bowel obstruction and ileus

Bowel obstruction occurs when the passage of contents through the bowel lumen is inhibited, either by mechanical (anatomical) or non-mechanical causes. The alternative term 'ileus' is sometimes used to describe the failure of passage of intestinal contents in the absence of any mechanical obstruction (Morton and Fontaine 2013).

Intestinal obstructions are caused by a physical narrowing or internal blockage of the gut lumen, extrinsic compression of the bowel, or a disruption or failure in motility. In cancer patients, malignant bowel obstruction can be either partial or complete, with acute or gradual onset of symptoms (Letizia and Norton 2003).

Obstruction can occur at a single site or, in the case of disseminated intra-abdominal disease, such as intra-abdominal carcinomatosis, in multiple sites (Lynch and Sarazine 2006). Intestinal obstruction is a potentially devastating complication for

Figure 5.20 Classification of constipation.

the patient, with a vast number of possible clinical causes, and is a condition which can rapidly progress to cause life-threatening problems (Shih et al. 2003). Intestinal obstruction precipitates a cascade of pathophysiological events which lead to complex and unpleasant symptoms. Thoughtful nursing assessment and evaluation, and meticulous symptom control, can make an important contribution to improving the experience of the patient in bowel obstruction.

Evidence-based approaches

Assessment

Taking a detailed history from the patient is pivotal in establishing the appropriate treatment plan. It is therefore of vital importance that nurses adopt a proactive preventive approach to the assessment and management of constipation. Kyle et al. (2005a, 2011b) have developed, refined and tested a constipation risk

assessment tool, now known as the Norgine Risk Assessment Tool (NRAT). This assesses a range of risk factors that appear consistently within relevant literature on the development of constipation, including:

- nutritional intake/recent changes in diet
- fluid intake
- immobility and lack of exercise
- medication, for example analgesics, antacids, iron supplements, tricyclic antidepressants
- toileting facilities, for example having to use shared toilet facilities, commodes or bedpans
- medical conditions, for example inflammatory bowel disease, irritable bowel syndrome, colorectal cancer, diabetes and neurological conditions such as multiple sclerosis or muscular dystrophy.

In addition to the identification of these risks/contributing factors, it is important to take a careful history of a patient's bowel habits, taking particular note of the following.

- Any changes in the patient's usual bowel activity. How long have these changes been present and have they occurred before?
- Frequency of bowel action.
- Volume, consistency and colour of the stool. Stools can be graded using a scale such as the Bristol Stool Chart (see Figure 5.4) where constipation would be classified as types 1 or 2 (Longstreth et al. 2006).
- Presence of mucus, blood, undigested food or offensive odour.
- Presence of pain or discomfort on defaecation.
- Use of oral or rectal medication to stimulate defaecation and its effectiveness.

A digital rectal examination (DRE) can also be performed, providing the nurse has received suitable training or instruction to perform it competently. This procedure can be used to assess the contents of the rectum and anal sphincter tone and to identify conditions which may cause discomfort such as haemorrhoids, anal fissures or rectal prolapse (Hinrichs et al. 2001, Kyle 2011c, Peate 2003, RCN 2012b). See 'Digital rectal examination' below for further information.

Additional investigations such as an abdominal X-ray may be necessary to exclude bowel obstruction (Christer et al. 2003, Kyle et al. 2005a, Thompson et al. 2003).

Over recent years, international criteria (the Rome Criteria) have been developed and revised (Longstreth et al. 2006) which can help to more accurately and consistently define constipation. According to the Rome III Criteria, an individual who is diagnosed with constipation should report having at least two of the following symptoms within the last 3 months where those symptoms began at least 6 months prior to diagnosis (Longstreth et al. 2006, Norton 2006).

- Straining for at least 25% of the time.
- Lumpy or hard stool for at least 25% of the time.
- A sensation of incomplete evacuation for at least 25% of the time.
- A sensation of anorectal obstruction or blockage for at least 25% of the time.
- Manual manoeuvres used to facilitate defaecation at least 25% of the time (e.g. manual evacuation).
- Less than three bowel movements a week.
- Loose stools are rarely present without the use of laxatives.

The myth that daily bowel evacuation is essential to health has persisted through the centuries. It is thought that less than 10% of the population have a bowel evacuation daily (Getliffe and Dolman 2007). This myth has resulted in laxative abuse becoming one of the most common types of drug misuse in the Western

world. The annual cost to the NHS of prescribing medications to treat constipation is in the region of £45 million (DH 2005).

Given that there is such a wide normal range, it is important to establish the patient's usual bowel habit and the changes that may have occurred. Many patients are too embarrassed to discuss bowel function and will often delay reporting problems, despite the sometimes severe impact these symptoms have on their quality of life (Cadd et al. 2000). Generally complaints will be either that the patient has diarrhoea or is constipated. These should be seen as symptoms of some underlying disease or malfunction and managed accordingly. The nurse's priority is to effectively assess the nature and cause of the problem, to help find appropriate solutions and to inform and support the patient. This requires sensitive communication skills to dispel embarrassment and ensure a shared understanding of the meanings of the terms used by the patient (Smith 2001).

Pharmacological support

Laxatives

Laxatives can be defined simply as substances that cause evacuation of the bowel by a mild action (Mosby 2006). A laxative with a mild or gentle effect is also known as an aperient and one with a strong effect is referred to as a cathartic or purgative. Purgatives should be used only in exceptional circumstances, that is, where all other interventions have failed, or when they are prescribed for a specific purpose. The aim of laxative treatment is to achieve comfortable rather than frequent defaecation and, wherever possible, the most natural means of bowel evacuation should be employed, with preference given to use of oral laxatives where appropriate (Perdue 2005). The many different laxatives available may be grouped into types according to the action they have (Table 5.4, Table 5.5).

Bulk-forming laxatives

Bulk-forming agents work by increasing the amount of fibre and therefore water retained in the colon, increasing faecal mass and stimulating peristalsis (Peate 2003, Woodward 2012). Ispaghula husk (Isogel, Regulan) and sterculia (Normacol) both trap water in the intestine by the formation of a highly viscous gel which softens faeces, increases weight and reduces transit time. These agents need plenty of fluid in order to work (2–3 litres per day), so their appropriateness for older patients should be questioned (Hinrichs et al. 2001, Perdue 2005). They also take a few days to exert their effect (Woodward 2012) so are not suitable to relieve acute constipation. Furthermore, bulk-forming laxatives are contraindicated in some patients, including those who have bowel

Table 5.4 Types of laxative

Type of laxative	Example	Brand names and sources
Bulk producers	Dietary fibre Mucilaginous polysaccharides Methylcellulose	Bran, wholemeal bread, Fybogel (ispaghula), Normacol (sterculia)
Stool softeners	Synthetic surface active agents, liquid paraffin	Agarol, Dioctyl, Petrolager, Milpar
Osmotic agents	Sodium, potassium and magnesium salts	Magnesium sulphate, milk of magnesia, lactulose
Stimulant laxatives	Sodium picosulphate, glycerine	Senna, Senokot, bisacodyl, Dulcolax, co-danthrusate, Picolax, glycerol

Table 5.5 Classification of laxatives

Type of laxative	How it works	Name of drug	Special notes for patients
Bulk forming	These drugs act by holding onto water so the stool remains large and soft and encourages the gut to move	Fybogel	This is to be avoided if patients bowel activity is not normal or their fluid intake is limited
Stimulant	Will cause water and electrolytes to accumulate in the bowel and will stimulate the bowel to move	Senna tablet/liquid Bisacodyl tablet/suppositories	This group of drugs is to be avoided if the bowel is not moving very well as they can cause abdominal cramps
Mixed stimulant and softener	2-in-1 preparations	Co-danthramer liquid and capsules available Docusate tablets	This drug may cause the urine to change colour Mild stimulant
Softeners	Attract and retain water in the bowel	Milpar (liquid paraffin and magnesium hydroxide) Docusate Arachis oil enema	If the patient is allergic to nuts, tell the nurse or doctor as an arachis oil enema should be avoided
Osmotic	Act in the bowel by increasing stimulation of fluid secretion and movement in the bowel	Lactulose Movicol Phosphate enema Microlax enema	Can cause bloating, excess wind and abdominal discomfort
5-HT ₄ receptor agonists (prokinetic agents)	Enhance gut motility by mimicking the effects of serotonin on the gut wall	Prucalopride	This is not a laxative. It causes an increase in gut motility resulting in an increase in bowel movement
Peripheral opioid receptor antagonists	Bind to peripheral opioid receptors and so reverse opioid-induced constipation	Methylnaltrexone bromide	This is a subcutaneous injection that is only given in advanced stages of illness, in consultation with a specialist palliative care team, where oral laxatives can no longer be taken by mouth

obstruction, faecal impaction, acute abdominal pain and reduced muscle tone, or those who have had recent bowel surgery.

Increasing the bulk may produce side-effects including flatulence and bloating (Woodward 2012), worsen impaction, lead to increased colonic faecal loading or even intestinal obstruction and in some cases may increase the risk of faecal incontinence. Other potentially harmful effects include malabsorption of minerals, calcium, iron and fat-soluble vitamins, and reduced bioavailability of some drugs.

Stool softeners

Stool-softening preparations, such as docusate sodium and glycerol (glycerine) suppositories, act by lowering the surface tension of faeces which allows water to penetrate and soften the stool (Hinrichs et al. 2001, Peate 2003).

Liquid paraffin acts as a lubricant as well as a stool softener by coating the faeces and allowing easier passage. However, its use should be avoided as there are a number of problems associated with this preparation. It interferes with the absorption of fat-soluble vitamins and can also cause skin irritation and changes to the bowel mucosa, while accidental inhalation of droplets of liquid paraffin may result in lipid pneumonia (BNF 2014).

Overall, there is little evidence to support the use of stool softeners and so this group of laxatives are no longer recommended in the treatment of constipation (Woodward 2012).

Osmotic laxatives

Osmotic laxatives, such as lactulose or macrogols (polyethylene glycol), increase the amount of water within the large bowel either

through osmosis or by retaining the water they were administered with (BNF 2014). Lactulose is a semi-synthetic disaccharide which draws water into the bowel through osmosis, resulting in a looser stool. However, it can be metabolized by colonic bacteria which not only reduces the osmotic effect but also produces gas which can result in abdominal cramps and flatulence, thereby causing discomfort as well as delaying the osmotic effect by as much as 3 days (BNF 2014, Woodward 2012). By contrast, polyethylene glycol is an inert polymer that is iso-osmotic and binds to water molecules, so acts by retaining the water it is diluted with when administered (BNF 2014, Woodward 2012). Both lactulose and polyethylene glycol are commonly used in the treatment of constipation. In a recent Cochrane review, it was recommended that polyethylene glycol is used in preference to lactulose (Lee-Robichaud et al. 2010) as it resulted in more frequent bowel motions, softer stools and a reduced need for additional laxative product.

Magnesium and phosphate preparations also exert an osmotic effect on the gut. They have a rapid effect, so fluid intake is important as patients may experience diarrhoea and dehydration. These preparations should be avoided in elderly patients and those with renal or hepatic impairment (BNF 2014).

Stimulant laxatives

Laxatives including bisacodyl, dantron and senna stimulate the nerve plexi in the gut wall, increasing peristalsis and promoting the secretion of water and electrolytes in the small and large bowel to improve stool consistency (Peate 2003, Rogers 2012, Woodward 2012). Stimulant laxatives can cause abdominal cramping,

particularly if the stool is hard, and so a stool softener may be recommended for use in combination with this group of drugs (BNF 2014, Connolly and Larkin 2012). Other adverse effects with high doses of stimulant laxatives include electrolyte disturbances in frail older people and loose stools (Rogers 2012, Woodward 2012).

Preparations containing dantron are restricted to certain groups of patients, such as the terminally ill, as some studies on rodents have indicated a potential carcinogenic risk (BNF 2014). Dantron preparations should be avoided in incontinent patients, especially those with limited mobility, as prolonged skin contact may cause irritation and excoriation (BNF 2014).

5-HT₄ receptor agonists (prokinetic agents)

5-HT₄ receptor agonists are not laxatives but enhance gut motility by mimicking the effects of serotonin on the gut wall. Serotonin is usually released when the gut mucosa is stimulated following a meal and its attachment to 5-HT₄ receptors triggers a co-ordinated contraction and relaxation of the gut smooth muscle known as the peristaltic wave. Prokinetic agents, such as prucalopride, mimic this action, thereby increasing peristalsis and increasing stool frequency (Rogers 2012, Woodward 2012).

Peripheral opioid receptor antagonists

Methylnaltrexone bromide is a parenteral preparation which is administered by subcutaneous injection. It is a peripherally acting selective antagonist of opioid binding to the mu-receptor, thus reversing peripherally mediated opioid-induced constipation. As this preparation does not cross the blood-brain barrier, it does not interfere with the centrally mediated analgesic effects of opioids (Connolly and Larkin 2012, Rogers 2012, Thomas et al. 2008, Toner and Claros 2012). The indications for use are opioid-induced constipation in patients with advanced illness receiving palliative care and who are unable to take oral laxatives. It is necessary to exclude bowel obstruction prior to their use and they should be used under the advice of a palliative care team (Connolly and Larkin 2012).

Non-pharmacological support

Diet

Dietary manipulation may help to resolve mild constipation, although it is much more likely to help prevent constipation from recurring. Increasing dietary fibre increases stool bulk, which in turn improves peristalsis and stool transit time (Rogers 2012). The current recommended daily intake of dietary fibre for an adult is 18 g (British Nutrition Foundation 2012).

There are two types of fibre: insoluble fibre is contained in foods such as wholegrain bread, brown rice, fruit and vegetables and soluble fibre is contained in foods such as oats, pulses, beans and lentils. It is recommended that fibre should be taken from a variety of both soluble and insoluble foods and eaten at times spread throughout the day (Denby 2006, Food Standards Agency 2006). Care should be taken to increase dietary fibre intake gradually as bloating and abdominal discomfort can result from a sudden increase, particularly in the older person and those with slow-transit constipation (Getliffe and Dolman 2007, Rogers 2012).

Dietary changes need to be made in combination with other lifestyle changes. There is little evidence to support the benefit of increasing fluid intake for constipation, but there is arguably a benefit in encouraging people to drink the recommended daily fluid intake of at least 2.0 litres (Fritz and Pitlick 2012, Rogers 2012). There is a need for further studies to examine the role of dietary manipulation in the management of constipation, particularly the function of dietary fibre and fluid intake.

Positioning

Patients should be advised not to ignore the urge to defaecate and to allow sufficient time for defaecation. It is important that the correct posture for defaecation is adopted; crouching or a 'crouch-like' posture is considered anatomically correct (Denby

2006, Woodward 2012) and the use of a footstool by the toilet may enable patients to adopt a better defaecation posture (Getliffe and Dolman 2007, NICE 2007, RCN 2012b, Woodward 2012) (Figure 5.21). The use of the bedpan should always be avoided if possible as the poor posture adopted while using one can cause extreme straining during defaecation.

Exercise

Where possible, patients should be encouraged to increase their level of exercise; physical activity has been found to have a positive effect on peristalsis, particularly after eating (Thompson et al. 2003). Therapies such as homeopathy and reflexology can also be utilized (Getliffe and Dolman 2007).

Other treatments

Biofeedback is a behaviour modification technique that encourages bracing of the abdominal wall and relaxation of the pelvic floor muscles to achieve effective defaecation. It is reported to be effective in 70% of patients (Koch et al. 2008), but more so in people who have a problem with evacuation rather than slow transit constipation (Rao et al. 2010, Rogers 2012, Woodward 2012).

Rectal irrigation is being increasingly offered as a treatment for chronic constipation, particularly where biofeedback has not worked, as well as faecal incontinence. It involves instilling lukewarm water into the rectum using a rectal catheter with the aim of ensuring the rectum, sigmoid and descending colon are emptied of faeces (Rogers 2012, Woodward 2012).

Overall, lifestyle changes and laxatives (see Table 5.4) are the most commonly used treatments for constipation. In general, laxatives should be used as a short-term measure to help relieve an episode of constipation as long-term use can perpetuate constipation and create dependence, and Emmanuel (2004) suggests that they lose their effect over time. The development of newer aperients broadens the treatment options, particularly for those patients with chronic constipation that has not responded to lifestyle modification or traditional laxatives.

Enemas

Definition

An enema is the administration of a substance in liquid form into the rectum, either to aid bowel evacuation or to administer medication (Higgins 2006) (Figure 5.22).

Evidence-based approaches

Rationale

Indications

Enemas may be prescribed for the following reasons.

- To clean the lower bowel before surgery, X-ray examination of the bowel using contrast medium or endoscopy examination.
- To treat severe constipation when other methods have failed.
- To introduce medication into the system.
- To soothe and treat irritated bowel mucosa.
- To decrease body temperature (due to contact with the proximal vascular system).
- To stop local haemorrhage.
- To reduce hyperkalaemia (calcium resonium).
- To reduce portal systemic encephalopathy (phosphate enema).

Contraindications

Enemas are contraindicated under the following circumstances.

- In paralytic ileus.
- In colonic obstruction.
- Where the administration of tap water or soap and water enemas may cause circulatory overload, water intoxication,

Correct position for opening your bowels

Figure 5.22 Enema.

mucosal damage and necrosis, hyperkalaemia and cardiac arrhythmias.

- Where the administration of large amounts of fluid high into the colon may cause perforation and haemorrhage.
- Following gastrointestinal or gynaecological surgery, where suture lines may be ruptured (unless medical consent has been given).
- Frailty.
- Proctitis.
- The use of microenemas and hypertonic saline enemas in patients with inflammatory or ulcerative conditions of the large colon.
- Recent radiotherapy to the lower pelvis unless medical consent has been given (Davies 2004).

Legal and professional issues

Enema administration must be performed by a practitioner with the appropriate knowledge and skills and where it is within their scope of professional practice to carry out this procedure.

Pre-procedural considerations

Evacuant enemas

An evacuant enema is a solution introduced into the rectum or lower colon with the intention of it being expelled, along with faecal matter and flatus, within a few minutes. The osmotic activity increases the water content of the stool so that rectal distension follows and induces defaecation by stimulating rectal motility.

The following solutions are often used.

- Phosphate enemas with standard or long rectal tubes in single-dose disposable packs. Although these are often used for bowel clearance before X-ray examination and surgery, there is little evidence to support their use due to the associated risks and contraindications. Davies (2004) and Bowers (2006) highlight the risk of phosphate absorption resulting from pooling of the enema due to lack of evacuation and also the risk of rectal injury caused by the enema tip. Studies have found that if evacuation does not occur, patients may suffer from hypovolaemic shock, renal failure and oliguria. When using this type of enema, it is vital that good fluid intake is encouraged and maintained.
- Dioctyl sodium sulphosuccinate 0.1% and sorbitol 25% in single-dose disposable packs are used to soften impacted faeces.
- Sodium citrate 450 mg, sodium alkylsulphoacetate 45 mg and ascorbic acid 5 mg in single-dose disposable packs.

Retention enemas

A retention enema is a solution introduced into the rectum or lower colon with the intention of being retained for a specified period of time. Two types of retention enema have been most commonly used: arachis oil enemas (which are contraindicated in patients with nut allergies) and prednisolone enemas. These work by penetrating faeces, increasing the bulk and softness of stools. Classified as stool softeners, there is little evidence to support the use of this group of laxatives in the treatment of constipation (Woodward 2012).

All types of enemas need to be prescribed and checked against the prescription before administration. It is essential that the implications and procedure are fully explained to the patient, so as to relieve anxiety and embarrassment.

Procedure guideline 5.18 Enema administration

Essential equipment

- Disposable incontinence pad
- Disposable apron and gloves
- Rectal tube and funnel (if not using a commercially prepared pack)
- Solution required or commercially prepared enema
- Gauze squares
- Commode or bedpan if required
- Lubricating gel

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

(continued)

Procedure guideline 5.18 Enema administration (*continued*)

Action	Rationale
2 Wash hands.	For infection prevention and control (Fraise and Bradley 2009, E).
3 Draw curtains around the patient or close the door to ensure privacy.	To avoid unnecessary embarrassment and to promote dignified care (NMC 2015, C).
4 Allow patient to empty bladder first if necessary.	A full bladder may cause discomfort during the procedure (Higgins 2006, E).
5 Ensure that a bedpan, commode or toilet is readily available.	In case the patient feels the need to expel the enema before the procedure is completed. P

Procedure

6 Warm the enema to room temperature by immersing in a jug of hot water.	Heat is an effective stimulant of the nerve plexi in the intestinal mucosa. An enema at room temperature or just above will not damage the intestinal mucosa. The temperature of the environment, the rate of fluid administration and the length of the tubing will all have an effect on the temperature of the fluid in the rectum (Higgins 2006, E).
7 Assist the patient to lie on the left side, with knees well flexed, the upper knee higher than the lower one, and with the buttocks near the edge of the bed.	This allows ease of passage into the rectum by following the natural anatomy of the colon. In this position, gravity will aid the flow of the solution into the colon. Flexing the knees ensures a more comfortable passage of the enema nozzle or rectal tube (Higgins 2006, E).
8 Place a disposable incontinence pad beneath the patient's hips and buttocks.	To reduce potential infection caused by soiled linen. To avoid embarrassing the patient if the fluid is ejected prematurely following administration. P
9 Wash hands and put on disposable gloves.	For infection prevention and control (Fraise and Bradley 2009, E).
10 Place some lubricating gel on a gauze square and lubricate the nozzle of the enema or the rectal tube.	This prevents trauma to the anal and rectal mucosa which reduces surface friction (Higgins 2006, E).
11 Expel excessive air from the enema and introduce the nozzle or tube slowly into the anal canal while separating the buttocks. (A small amount of air may be introduced if bowel evacuation is desired.)	The introduction of air into the colon causes distension of its walls, resulting in unnecessary discomfort for the patient. The slow introduction of the lubricated tube will minimize spasm of the intestinal wall (evacuation will be more effectively induced due to the increased peristalsis). C
12 Slowly introduce the tube or nozzle to a depth of 10.0–12.5 cm.	This will bypass the anal canal (2.5–4.0 cm in length) and ensure that the tube or nozzle is in the rectum. C
13 If a retention enema is used, introduce the fluid slowly and leave the patient in bed with the foot of the bed elevated by 45° for as long as prescribed.	To avoid increasing peristalsis. The slower the rate at which the fluid is introduced, the less pressure is exerted on the intestinal wall. Elevating the foot of the bed aids retention of the enema by the force of gravity. C
14 If an evacuant enema is used, introduce the fluid slowly by rolling the pack from the bottom to the top to prevent backflow, until the pack is empty or the solution is completely finished.	The faster the rate of flow of the fluid, the greater the pressure on the rectal walls. Distension and irritation of the bowel wall will produce strong peristalsis which is sufficient to empty the lower bowel (Higgins 2006, E).
15 If using a funnel and rectal tube, adjust the height of the funnel according to the rate of flow desired.	The forces of gravity will cause the solution to flow from the funnel into the rectum. The greater the elevation of the funnel, the faster the flow of fluid. E
16 Clamp the tubing before all the fluid has run in.	To avoid air entering the rectum and causing further discomfort. E
17 Slowly withdraw the tube or nozzle.	To avoid reflex emptying of the rectum. E
18 Dry the patient's perineal area using gauze squares.	To promote patient comfort and avoid excoriation. P
19 Ask the patient to retain the enema for 10–15 minutes before evacuating the bowel.	To enhance the evacuant effect. C
20 Ensure that the patient has access to the nurse call system, is near to the bedpan, commode or toilet, and has adequate toilet paper.	To enhance patient comfort and safety. To minimize the patient's embarrassment. P

Post-procedure

21 Remove and dispose of equipment, gloves and apron.	
22 Wash hands.	For infection prevention and control (Fraise and Bradley 2009, E).
23 Record in the appropriate documents that the enema has been given, its effects on the patient and its results (colour, consistency, content and amount of faeces produced), using the Bristol Stool Chart (see Figure 5.4).	To monitor the patient's bowel function (Gill 1999, C).
24 Observe patient for any adverse reactions.	To monitor the patient for complications (Peate 2003, C).

Problem-solving table 5.5 Prevention and resolution (Procedure guideline 5.18)

Problem	Cause	Prevention	Action
Unable to insert the nozzle of the enema pack or rectal tube into the anal canal.	Tube not adequately lubricated. Patient in an incorrect position.	Ensure patient is relaxed and in the correct position.	Apply more lubricating jelly. Ask the patient to draw knees up further towards the chest. To ensure the patient is relaxed before inserting the nozzle or rectal tube.
	Patient unable to relax anal sphincter. Patient apprehensive and embarrassed about the situation.		Ask the patient to take deep breaths and 'bear down' as if defaecating.
Unable to advance the tube or nozzle into the anal canal.	Spasm of the canal walls.	Ask the patient to take slow deep breaths to help them relax.	Wait until spasm has passed before inserting the tube or nozzle more slowly, thus minimizing spasm. Ensure adequate privacy and give frequent explanations to the patient about the procedure.
Unable to advance the tube or nozzle into the rectum.	Blockage by faeces.		Withdraw tubing slightly and allow a little solution to flow and then insert the tube further.
	Blockage by tumour.		If resistance is still met, stop the procedure and inform a doctor.
Patient complains of cramping or the desire to evacuate the enema before the end of the procedure.	Distension and irritation of the intestinal wall produces strong peristalsis sufficient to empty the lower bowel.	Encourage the patient to retain the enema.	Stop instilling the enema fluid and wait with the patient until the discomfort has subsided.
Patient unable to open bowels after an evacuant enema.	Reduced neuromuscular response in the bowel wall.		Inform the doctor that the enema was unsuccessful and reassure the patient.

Suppositories**Definition**

A suppository is a solid or semi-solid, bullet-shaped pellet that is prepared by mixing a medication with a wax-like substance that melts once inserted into the rectum (Galbraith et al. 2007).

Evidence-based approaches**Rationale****Indications**

The use of suppositories is indicated under the following circumstances.

- To empty the bowel prior to certain types of surgery and investigations.
- To empty the bowel to relieve acute constipation or when other treatments for constipation have failed.

- To empty the bowel before endoscopic examination.
- To introduce medication into the system.
- To soothe and treat haemorrhoids or anal pruritus.

Contraindications

The use of suppositories is contraindicated when one or more of the following pertain.

- Chronic constipation, which would require repetitive use.
- Paralytic ileus.
- Colonic obstruction.
- Malignancy of the perianal region.
- Low platelet count.
- Following gastrointestinal or gynaecological operations, unless on the specific instructions of the doctor.

Methods of administration of suppositories

The use of suppositories dates back to about 460 BC. Hippocrates recommended the use of cylindrical suppositories of honey

smear with ox gall (Hurst et al. 1969). The torpedo-shaped suppositories commonly used today came into being in 1893, when it was recommended that they were inserted apex (pointed end) first (Moppett 2000).

This practice was questioned by Abd-el-Maeboud et al. (1991) who suggested that suppositories should be inserted blunt end first. The rationale for this is based on anorectal physiology; if a suppository is inserted apex first, the circular base distends the anus and the lower edge of the anal sphincter fails to close tightly. The normal squeezing motion (reverse vermicular contraction) of the anal sphincter therefore fails to drive the suppository into the rectum. These factors can lead to anal irritation and rejection of the suppository (Moppett 2000, Pegram et al. 2008). The research study by Abd-el-Maeboud et al. (1991) was very small but remains the only research evidence supporting this practice and consequently a common-sense approach is suggested (Bradshaw and Price 2006). A distinction can be made between suppositories administered for constipation, requiring a local effect, and those given to achieve a systemic effect.

In the management of constipation, a suppository placed against the bowel wall, rather than within faecal matter, enables body heat to soften the suppository. This requires an accurate insertion technique which may be better achieved by inserting the suppository apex first (Kyle 2009). However, Kyle (2009) goes on to suggest that patients may find it more acceptable

to self-administer suppositories blunt end first as the sucking action means there is no need to insert the finger into the anal canal. Suppositories for systemic use are best absorbed by the lower rectum. Here venous drainage avoids the portal circulation moving to the inferior vena cava quickly, resulting in a more rapid therapeutic effect (Kyle 2009). There is a need for further research in this area but until such work is carried out, expert opinion such as Kyle (2009) and common sense should guide practice.

Pre-procedural considerations

Pharmacological

There are several different types of suppository available. Retention suppositories are designed to deliver drug therapy, for example analgesia, antibiotic, non-steroidal anti-inflammatory drug (NSAID). Those designed to stimulate bowel evacuation include glycerine, bisacodyl and sodium bicarbonate. Lubricant suppositories, for example glycerine, should be inserted directly into the faeces and allowed to dissolve. They have a mild irritant action on the rectum and also act as faecal softeners (BNF 2014). However, stimulant types, such as bisacodyl, must come into contact with the mucous membrane of the rectum if they are to be effective as they release carbon dioxide, causing rectal distension and thus evacuation.

Procedure guideline 5.19 Suppository administration

Essential equipment

- Disposable incontinence pad
- Disposable apron and gloves
- Gauze squares or tissues
- Lubricating gel
- Suppository(ies) as required (check prescription before administering any suppository)
- Bedpan or commode if required

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. If you are administering a medicated suppository, it is best to do so after the patient has emptied their bowels.
- 2 Wash hands.
- 3 Draw curtains around the patient or close the door.
- 4 Ensure that a bedpan, commode or toilet is readily available.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To ensure that the active ingredients are not prevented from being absorbed by the rectal mucosa and that the suppository is not expelled before its active ingredients have been released (Moppett 2000, **E**).

To ensure the procedure is as clean as possible and for infection control reasons (Fraise and Bradley 2009, **E**).

To ensure privacy and dignity for the patient (NMC 2015, **C**).

In case of premature ejection of the suppositories or rapid bowel evacuation following their administration. **P**

Procedure

- 5 Assist the patient to lie on the left side, with the knees flexed, the upper knee higher than the lower one, with the buttocks near the edge of the bed.
- 6 Place a disposable incontinence pad beneath the patient's hips and buttocks.
- 7 Wash hands and put on apron and gloves.

This allows ease of passage of the suppository into the rectum by following the natural anatomy of the colon (Galbraith et al. 2007; Pegram et al. 2008). Flexing the knees will reduce discomfort as the suppository is passed through the anal sphincter (Moppett 2000, **E**).

To avoid unnecessary soiling of linen, leading to potential infection and embarrassment to the patient if the suppositories are ejected prematurely or there is rapid bowel evacuation following their administration. **E**

For infection prevention and control (Fraise and Bradley 2009, **E**).

8 Place some lubricating jelly on a gauze square and lubricate the blunt end of the suppository if it is being used to obtain systemic action. Separate the patient's buttocks and insert the suppository blunt end first, advancing it for about 2–4 cm. Repeat this procedure if a second suppository is to be inserted.	Lubricating reduces surface friction and thus eases insertion of the suppository and avoids anal mucosal trauma. The suppository is more readily retained if inserted blunt end first (Abd-el-Maeboud et al. 1991, R2b). The anal canal is approximately 2–4 cm long. Inserting the suppository beyond this ensures that it will be retained (Abd-el-Maeboud et al. 1991, R2b ; Pegram et al. 2008, E).
9 Once the suppository(ies) has been inserted, clean any excess lubricating jelly from the patient's perineal area using gauze squares.	To ensure the patient's comfort and avoid anal excoriation (Moppett 2000, E).
10 Ask the patient to retain the suppository(ies) for 20 minutes, or until they are no longer able to do so. If a medicated suppository is given, remind the patient that its aim is not to stimulate evacuation and to retain the suppository for at least 20 minutes or as long as possible.	This will allow the suppository to melt and release the active ingredients. Inform patient that there may be some discharge as the medication melts in the rectum (Henry 1999, E).
Post-procedure	
11 Remove and dispose of equipment, gloves and apron. Wash hands.	For infection prevention and control (Fraise and Bradley 2009, E).
12 Record that the suppository(ies) have been given, the effect on the patient and the result (amount, colour, consistency and content, using the Bristol Stool Chart, Figure 5.4), if appropriate, in the relevant documents.	To monitor the patient's bowel function (Gill 1999, C) and to maintain accurate records (NMC, 2010, C).
13 Observe patient for any adverse reactions.	To monitor for any complications (Peate 2003, E).

Digital rectal examination

Definition

A digital rectal examination (DRE) is an invasive procedure that can be carried out, as part of a nursing assessment, by a Registered Nurse who can demonstrate competence to an appropriate level in accordance with the NMC *Code of Conduct* (RCN 2012b, NMC 2015). The procedure involves the nurse inserting a lubricated gloved finger into the rectum.

Evidence-based approaches

Rationale

Indications

This examination can be performed in the following circumstances.

- To establish whether faecal matter is present in the rectum and, if so, to assess the amount and consistency.
- To ascertain anal tone and the ability to initiate a voluntary contraction and to what degree.
- To teach pelvic floor exercises.
- To assess anal pathology for the presence of foreign objects.
- Prior to administering rectal medication to establish the state of the rectum.
- To establish the effects of rectal medication.
- To administer suppositories or enema prior to endoscopy.
- To determine the need for digital removal of faeces (DRF) or digital rectal stimulation and evaluating bowel emptiness.
- To assess the need for rectal medication and to evaluate its efficacy in certain circumstances, for example in patients who have diminished anal/rectal sensation.
- For digital stimulation to trigger defaecation by stimulating the rectoanal reflex (Weisner and Bell 2004).
- To establish anal and rectal sensation (RCN 2012b).

Legal and professional issues

As DRE is an invasive and intimate procedure, it is important that consent is obtained from the patient prior to it being performed (Kyle 2011c, Steggall 2008). A DRE should form part of the bowel assessment, rather than being a stand-alone procedure (Kyle 2011c), and can be undertaken by Registered Nurses who demonstrate competency in this procedure, possessing the knowledge, skills and abilities required for lawful, safe and effective practice (RCN 2012b).

As nursing roles develop, nurse specialists and nurse practitioners are increasingly involved in areas of care that necessitate undertaking DRE as part of a physical assessment or procedure. Such instances may include:

- the assessment of prostate size, consistency, mobility and anatomical limits
- during procedures such as the placement of a rectal probe/sensor prior to urodynamic studies or the placement of catheters used in the treatment of constipation or anismus
- prior to using transanal irrigation
- the placement of an endoscope prior to colonoscopy or sigmoidoscopy (RCN 2012b).

Pre-procedural considerations

Specific patient preparation

Before carrying out a DRE, the perineal and perianal area should be checked for signs of rectal prolapse, haemorrhoids, anal skin tags, fissures or lesions, foreign bodies, scarring, infestations or a gaping anus. The condition of the skin should be noted, as should the type and amount of any discharge or leakage. If any of these abnormalities are seen, a DRE should not be carried out until advice is taken from a specialist nurse or medical practitioner (RCN 2012b, Steggall 2008).

Precautions

Special care should be taken in performing DRE in patients whose disease processes or treatments in particular affect

the anus or bowel mucosa. These conditions include (RCN 2012b):

- active inflammation of the bowel, for example ulcerative colitis
- recent radiotherapy to the pelvic area
- rectal/anal pain
- rectal surgery or trauma to the anal/rectal area in the last 6 weeks

- obvious rectal bleeding – consider possible causes for this
- spinal cord injury patients with an injury at or above the sixth thoracic vertebra, because of the risk of autonomic dys-reflexia
- patients with known allergies, for example latex
- patients with a known history of abuse
- tissue fragility related to age, radiation or malnourishment.

Procedure guideline 5.20 Digital rectal examination

Essential equipment

- Disposable incontinence pad
- Disposable apron and gloves (check if patient allergic to latex)
- Lubricating gel
- Gauze squares or tissues
- Bedpan or commode if required

Pre-procedure

Action

- 1 Explain and discuss procedure with the patient.
- 2 Ensure privacy.
- 3 Ensure that a bedpan, commode or toilet is readily available.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

To avoid unnecessary embarrassment to the patient and to promote dignity and privacy (NMC 2015, **C**).

DRE can stimulate the need for bowel movement (Weisner and Bell 2004, **E**).

Procedure

- 4 Assist the patient to lie in the left lateral position with knees flexed, the upper knee higher than the lower knee, with the buttocks towards the edge of the bed.
- 5 Place a disposable incontinence pad beneath the patient's hips and buttocks.
- 6 Wash hands with bactericidal soap and water or bactericidal alcohol handrub and put on disposable gloves.
- 7 Observe anal area prior to the insertion of the finger into the anus for evidence of skin soreness, excoriation, swelling, haemorrhoids, rectal prolapse and infestation.
- 8 Palpate the perianal area starting at 12 o'clock, clockwise to 6 o'clock and then from 12 anticlockwise to 6 o'clock.
- 9 Place some lubricating gel on a gauze square and gloved index finger. Inform the patient you are about to proceed.
- 10 Prior to insertion, encourage the patient to breathe out or talk and/or place gloved index finger on the anus for a few seconds prior to insertion.
On insertion of finger, assess anal sphincter control; resistance should be felt.
- 11 With finger inserted in the anus, sweep clockwise then anticlockwise, noting any irregularities.

This allows ease of digital examination into the rectum by following the natural anatomy of the colon (RCN 2012b, **C**). Flexing the knees reduces discomfort as the examining finger passes the anal sphincter (Kyle et al. 2005b, **C**).

To reduce potential infection caused by soiled linen. To avoid embarrassing the patient if faecal staining occurs during or after the procedure. **E**

For infection prevention and control (Fraise and Bradley 2009, **E**).

May indicate incontinence or pruritus. Swelling may be indicative of possible mass or abscess. Abnormalities such as bleeding, discharge or prolapse should be reported to medical staff before any examination is undertaken (RCN 2012b, **C**).

To assess for any irregularities, swelling, indurations, tenderness or abscess in the perianal area (RCN 2012b, **C**).

To minimize discomfort as lubrication reduces friction and to ease insertion of the finger into the anus/rectum. Lubrication also helps minimize anal mucosal trauma (Kyle et al. 2005b, **C**). Informing the patient assists with co-operation with the procedure (NMC 2015, **C**).

To prevent spasm of the anal sphincter on insertion (RCN 2012b, **C**). Gently placing a finger on the anus initiates the anal reflex, causing the anus to contract and then relax (RCN 2012b, **C**).

Digital insertion with resistance indicates good internal sphincter tone, poor resistance may indicate the opposite (RCN 2012b, **C**).

Palpating around 360° enables the nurse to establish if there is any swelling or tenderness within the rectum (RCN 2012b, **C**; Steggall 2008, **E**).

12 Digital examination may feel faecal matter within the rectum; note consistency of any faecal matter.	May establish loaded rectum and indicate constipation and the need for rectal medication (RCN 2012b, C).
13 Clean anal area after the procedure.	To prevent irritation and soreness occurring. Preserves patient dignity and personal hygiene.
Post-procedure	
14 Remove gloves and apron and dispose of equipment in appropriate clinical waste bin. Wash hands with bactericidal soap and water.	For infection prevention and control (Fraise and Bradley 2009, E).
15 Assist patient into a comfortable position and offer bedpan, commode or toilet facilities as appropriate.	To promote comfort. P
16 Document findings and report to appropriate members of the multidisciplinary team.	To ensure continuity of care and ensure appropriate corrective action may be initiated (RCN 2012b, C).

Digital removal of faeces

Definition

Digital removal of faeces (DRF) is an invasive procedure involving the removal of faeces from the rectum using a gloved finger. This should only be performed when necessary and after individual assessment (RCN 2012b).

Related theory

Managing bowel problems such as constipation and prolonged bowel evacuation in patients following spinal cord injury requires a multimodality approach. This includes dietary fibre, digital stimulation, enemas, suppositories, stool softeners and abdominal massage (Addison and White 2002). Digital stimulation is a method of initiating the defaecation reflex by dilating the anus, with either a finger or an anal dilator (Weisner and Bell 2004), but is only useful if the rectum is full.

Autonomic dysreflexia (AD) is unique to patients with spinal cord injury at the sixth thoracic vertebra or above. It is an abnormal response from the autonomic nervous system to a painful (noxious) stimulus perceived below the level of spinal cord injury (Harrison 2000, Powell and Rigby 2000, RCN 2012b). Distended bowel caused by constipation or impaction can lead to autonomic dysreflexia and therefore it is important that an effective programme of bowel management is established and followed (Harrison 2000). Acute AD may occur in response to digital intervention. It is therefore important that all healthcare professionals carrying out digital interventions on individuals with spinal cord injury are aware of the signs and symptoms of headache, flushing, sweating, nasal obstruction, blotchiness above the lesion and hypertension. The most significant symptom is the rapid onset of a severe headache; should this occur, the intervention must be stopped immediately (RCN 2012b).

Evidence-based approaches

Rationale

Advances in oral, rectal and surgical treatments have reduced the need for digital removal of faeces to be performed; however, for certain groups of patients, such as those with spinal injuries, spina bifida or multiple sclerosis, this procedure may be the only suitable bowel-emptying technique, forming a long-standing, integral part of their bowel routine (Kyle et al. 2005b, RCN 2012b).

Digital removal of faeces can be distressing, painful and dangerous. In particular, stimulation of the vagus nerve in the rectal wall can slow the patient's heart, in addition to the risk of bowel perforation and bleeding (Kyle et al. 2005b).

Indications

Indications for assisted evacuation of bowels (digital removal of faeces or digital stimulation) include:

- faecal impaction/loading
- incomplete defaecation
- inability to defaecate
- when other bowel-emptying techniques have failed or are unsuitable
- neurogenic bowel dysfunction
- patients with spinal cord injury (RCN 2012b).

Patients are at risk of rectal trauma if these procedures are not performed with care or knowledge. The nurse should be aware of any conditions that may contraindicate performance of these procedures (see 'Digital rectal examination, Precautions').

Legal and professional issues

Digital removal of faeces should be performed by Registered Nurses who demonstrate competency in this procedure, possessing the knowledge, skills and abilities required for lawful, safe and effective practice (RCN 2012b). In addition, they should ensure that their employer has defined policies and procedures for undertaking this role (RCN 2012b, Withell 2000). If appropriate, the patient and their personal carer may wish for the carer to maintain their established programme of bowel management (Harrison 2000).

Pre-procedural considerations

Specific patient preparations

If this procedure is used as an acute intervention, the patient's pulse rate should be recorded before and during the process. Patients with a spinal cord injury should also have their blood pressure measured before, during and after the procedure. A baseline blood pressure measurement should be available for comparison (RCN 2012b). Every time the procedure is performed, the consistency of the stool should be noted before continuing. If the stool is hard and dry, lubricant suppositories should be inserted and left for 30 minutes before commencing. If the stool is too soft to remove effectively, consider delaying the procedure for 24 hours to allow further water reabsorption to occur.

During the procedure the nurse should observe the patient for signs of:

- distress, pain or discomfort
- bleeding
- autonomic dysreflexia: hypertension, bradycardia, headache, flushing above the level of the spinal injury, sweating, pallor below the level of spinal injury, nasal congestion (Harrison 2000, RCN 2012b)
- collapse (RCN 2012b).

Procedure guideline 5.21 Digital removal of faeces

Essential equipment

- Disposable incontinence pad
- Receiver and/or yellow bag
- Specimen pot (if required)
- Bedpan or commode (if appropriate)
- Tissues or topical swabs
- Disposable apron and gloves (check if patient is allergic to latex)
- Lubricating gel

Pre-procedure

Action	Rationale
1 Explain and discuss procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Draw curtain around the patient or close the door to ensure privacy.	To avoid unnecessary embarrassment to the patient.
3 In spinal cord injury patients who are at risk of AD, a blood pressure reading should be taken prior to the procedure. A baseline blood pressure reading should be available for comparison. For such patients where this procedure is routine and tolerance is well established, this is not required.	In spinal cord injury, stimulus below the level of injury may result in symptoms of AD including headache and hypertension (Kyle et al. 2005b; RCN 2012b, C).

Procedure

4 Assist the patient to lie in the left lateral position with knees flexed, the upper knee higher than the lower knee, with the buttocks towards the edge of the bed.	This allows ease of digital insertion into the rectum, by following the natural anatomy of the colon (RCN 2012b). Flexing the knees reduces discomfort as the finger passes the anal sphincter (Kyle et al. 2005b, C).
5 Place a disposable incontinence pad beneath the patient's hips and buttocks.	To reduce potential infection caused by soiled linen. To avoid embarrassing the patient if faecal staining occurs during or after the procedure.
6 Wash hands with bactericidal soap and water or bactericidal alcohol handrub and put on disposable apron and gloves.	For infection prevention and control (Fraiese and Bradley 2009, E).
7 Place some lubricating gel on a gauze square and gloved index finger.	To minimize discomfort as lubrication reduces friction and to ease insertion of the finger into the anus/rectum. Lubrication also helps minimize anal mucosal trauma (Kyle et al. 2005b, C).
8 Inform the patient you are about to proceed.	Assists with patient co-operation with the procedure (NMC 2015, C).
9 In spinal cord injury patients, observe for signs of AD throughout the procedure (RCN 2012b, C).	In spinal cord injury, stimulus below the level of injury may result in symptoms of AD, including hypertension (Kyle et al. 2005b, C).
10 Observe anal area prior to the insertion of the finger into the anus for evidence of skin soreness, excoriation, swelling, haemorrhoids or rectal prolapse.	May indicate incontinence or pruritus. Swelling may be indicative of possible mass or abscess. Abnormalities such as bleeding, discharge or prolapse should be reported to medical staff before any examination is undertaken (RCN 2012b, C).
11 Proceed to insert finger into the anus/rectum. Proceed with caution in those patients with spinal cord injury.	The majority of spinal cord injury patients will not experience any pain (Kyle et al. 2005b, C).
12 If the stool is type 1 (see Figure 5.4), remove one lump at a time until no more faecal matter is felt.	To relieve patient discomfort (Kyle et al. 2005b, C).
13 If a solid faecal mass is felt, split it and remove small pieces until no more faecal matter is felt. Avoid using a hooked finger to remove faeces.	To relieve patient discomfort (Kyle et al. 2005b, C). Use of a hooked finger may cause damage to the rectal mucosa and anal sphincter (RCN 2012b).
14 If faecal mass is too hard to break up, or more than 4 cm across, stop the procedure and discuss with the multidisciplinary team.	To avoid unnecessary pain and damage to the anal sphincter. The patient may require the procedure to be carried out under anaesthetic (Kyle et al. 2005b, C).
15 As faeces is removed, it should be placed in an appropriate receiver.	To assist in appropriate disposal and reduce contamination or cross-infection risk.

16 Encourage patients who receive this procedure on a regular basis to have a period of rest or, if appropriate, to assist using the Valsalva manoeuvre.

Patient and nurse education is required to use this technique safely and so further guidance should be sought before introducing this manoeuvre as it may lead to complications such as haemorrhoids (Kyle et al. 2005b, **C**).

17 Wash and dry the patient's anal area and buttocks.

To ensure patient feels comfortable and clean. **P**

Post-procedure

18 Remove gloves and apron and dispose of equipment in appropriate clinical waste bin. Wash hands.

For prevention and control of infection (Fraise and Bradley 2009, **E**).

19 Assist patient into a comfortable position.

To promote comfort. **P**

20 In spinal cord injury patients, take a blood pressure reading.

In spinal cord injury, stimulus below the level of injury may result in symptoms of AD, including hypertension (Kyle et al. 2005b, **C**).

21 Document findings and report to appropriate members of the multidisciplinary team.

To ensure continuity of care and enable appropriate actions to be initiated (RCN 2012b, **C**).

Stoma care

Definition

Stoma is a word of Greek origin meaning mouth or opening (Taylor 2005).

Related theory

Every year approximately 11,000 new colostomies, 9000 new ileostomies and 2000 new urostomies are formed in the UK (Welser et al. 2009). The most common underlying conditions resulting in the need for stoma surgery are colorectal cancer, bladder cancer, ulcerative colitis and Crohn's disease. Other causes of stoma surgery include:

- pelvic cancer, for example gynaecological cancer
- trauma
- neurological damage
- congenital disorders
- diverticular disease
- familial polyposis coli
- intractable incontinence
- fistula
- radiation bowel disease
- bowel perforation (Burch 2011a, Taylor et al. 2012).

Types of stoma

Colostomy

A colostomy may be formed from any section of the large bowel. Its position along the colon will dictate the output and consistency of faeces. Therefore an understanding of the anatomy and physiology is essential to fully care for stoma patients.

The most common site for a colostomy is on the sigmoid colon. This will produce a semi-solid or formed stool and is generally positioned in the left iliac fossa and is flush to the skin (Burch 2011a). Stomas formed higher up along the colon will produce a slightly more liquid stool. A colostomy tends to act on average 2–3 times per day, but this can vary between individuals.

Colostomies can either be permanent (end) (Figure 5.23, Figure 5.24) or temporary (loop) (Figure 5.25, Figure 5.26). Permanent (end) colostomies are often formed following removal of rectal cancers, as in abdominoperineal resections of the rectum, whereas a temporary (loop) colostomy may be formed to divert the faecal output, to allow healing of a surgical join (anastomosis) or

Figure 5.23 End colostomy.

Figure 5.24 End colostomy.

Figure 5.25 Transverse (loop) colostomy (a) and ileostomy (b).

repair, or to relieve an obstruction or bowel injury (Taylor 2005). Permanent colostomies were the most commonly formed stoma but the number of temporary stomas is increasing, most of which are ileostomies rather than colostomies (IMS 2008).

As is evident from Figures 5.24 and 5.26, end and loop colostomies are very different in appearance. An end colostomy tends to be flush to the skin and sutured to the abdominal wall and consists of an end-section of bowel, whereas a loop colostomy is larger. During the perioperative period, it is supported by a stoma bridge or rod (see Figure 5.26). This is placed under the section of bowel and generally left in place for 3–10 days following surgery and then removed (Wright and Burch 2008).

Ileostomy

Ileostomies are formed when a section of ileum is brought out onto the abdominal wall. This is generally positioned at the end of the ileum on the right iliac fossa, but can be anywhere along the ileum. Consequently, the output tends to be

Figure 5.26 Loop colostomy with bridge *in situ*.

Figure 5.27 End ileostomy. *Source:* Reproduced with permission from Dansac Ltd.

looser, more liquid stool, as waste is being eliminated before the water is absorbed from the large bowel (colon). Due to the more acidic, abrasive nature of the stool at this stage, a spout is formed with this type of stoma. The ileum is everted to form a spout which allows the effluent to drain into an appliance, without coming into contact with the peristomal skin (Burch 2011b) (Figure 5.27). This prevents skin breakdown and allows for better management. The average output from an ileostomy is 200–600 mL per day.

Ileostomies can also be either permanent (end) (see Figure 5.27) or temporary (loop). Permanent ileostomies are often formed following total colectomies (removal of the entire colon). Loop ileostomies are increasingly common and are often formed to allow healing of a surgical join (anastomosis) or an ileoanal pouch (IMS 2008, Taylor 2005). These are sometimes held in place by a stoma bridge or rod. Refer to Procedure guideline 5.24: Stoma bridge or rod removal for more information on bridge/rod care and removal.

Urostomy/ileal conduit

An ileal conduit is the most common form of urostomy; the colon (colonic conduit) may also be used. Urostomy comes from the Greek words *uros* meaning urine and *stoma* meaning mouth or opening (Nazarko 2008). Approximately 1500 urostomies were formed in the UK in 2006 (Burch 2008).

A section of bowel is isolated, along with its mesentery vessels, and the remaining ends of the bowel are anastomosed to restore continuity. The isolated section is mobilized, the proximal end is closed and the ureters, once resected from the bladder, are implanted at this end. The distal end is brought out onto the surface of the abdominal wall and everted to form a spout (see Figure 5.27), as in an ileostomy (Fillingham and Fell 2004). Urine from a urostomy will contain mucus from the bowel used in its construction (Taylor 2005).

Evidence-based approaches

Stoma care has developed greatly over the years. Although an evidence base for this does exist, it mainly centres around clinical practice and experience.

Stoma care is very individual and requires full holistic patient assessment. The primary aim is to promote patient independence by providing care and advice on managing the stoma, therefore allowing the patient to continue with all the necessary activities of daily living.

Rationale

Indications

Stoma care is essential:

- to collect faeces or urine in an appropriate appliance
- to achieve and maintain patient comfort and security
- to support psychological adaptation and independence.

Legal and professional issues

As already discussed, stoma care is primarily based on experience and therefore the development of skills. It is a fundamental area of nursing practice that all Registered Nurses should have the competency to undertake. It has recently been recognized that many of the core nursing skills in stoma care are being carried out by healthcare assistants and carers. Therefore there is an increasing demand for education in this area. Stoma care often develops due to nurses who have an interest in this area and then further build on their skills. Due to the increasing demand for good effective stoma care, many courses and conferences now exist to improve patient care and enhance professional knowledge and skills.

Pre-procedural considerations

Equipment

Many of the appliances now available are very similar in style, colour and efficiency and often there is very little to choose between them when the time comes for the ostomate to decide what to wear.

The aim of good stoma care is to return patients to their place in society. One of the ways in which this can be facilitated is to provide them with a safe, reliable appliance. This means that there should be no fear of leakage or odour and the appliance should be comfortable, unobtrusive, easy to handle and disposable. The ostomate should be allowed a choice from the management systems available. It is also important to identify and manage problems with the stoma or peristomal skin at an early stage.

When choosing the appropriate management system for the new ostomate, factors which need to be considered include:

- type of stoma
- type of effluent
- patient's cognitive ability
- manual dexterity
- lifestyle
- condition of peristomal skin
- siting of stoma
- patient preference (Kirkwood 2006).

Appliances

Stoma appliances are made from an odour-proof plastic film. They adhere to the peristomal skin using an adhesive hydrocolloid base or flange (Williams 2011). Appliances may be opaque or clear and often have a soft backing to absorb perspiration. They usually have a built-in integral filter containing charcoal to neutralize any odour. The type of appliance used will depend on the type of stoma and effluent expected. Refer to Figure 5.28 to assist with appliance selection.

Choosing the right size

It is important that the flange of the appliance fits snugly around the stoma within 0.3 cm of the stoma edge (Kirkwood 2006). This narrow edge is left exposed so that the appliance does not rub on the stoma. Stoma appliances usually come with measuring guides to allow for choice of size. During the initial weeks following surgery, the oedematous stoma will gradually reduce in size and the appliance needs to be adapted accordingly.

Fear of malodour

Appliances usually have a built-in integral filter containing charcoal to neutralize any odour when flatus is released; therefore, smell is only noticeable when emptying or changing an appliance. There are also various deodorizers that come in the form of drops or powders that may be put into the pouch or sprays, which can be sprayed into the air just before changing or emptying the pouch (Burch and Sica 2005). The individual should be reassured that any problems with odour or leakage will be investigated and that in most circumstances the problem will be solved with alternative appliances or accessories.

Drainable pouches are used when the effluent is fluid or semi-formed, in the case of an ileostomy or transverse colostomy (Figure 5.29a). These pouches have specially designed filters, which are less likely to become blocked or leak faecal fluid. They need to be emptied regularly and the outlet rinsed carefully and then closed with a clip or 'roll-up' method. They may be left on for up to 3 days.

Urostomy pouches have a drainage tap for urine and should be emptied regularly (Figure 5.29b). They can be attached to a large bag and tubing for night drainage. These pouches can remain on for up to 3 days.

Closed pouches are mainly used when formed stool is expected, for example sigmoid colostomy (Figure 5.29c). They have a flatus filter and need to be changed once or twice a day.

One- or two-piece systems

All types of pouch (closed, drainable or with a tap) fall into one of two broad categories: one-piece or two-piece systems (Burch 2011b). Redmond et al. (2009) report that the majority of individuals with a stoma in the UK choose a one-piece system.

- *One-piece*: this comprises a pouch attached to an adhesive wafer that is removed completely when the pouch is changed. This is an easier system for an ostomate with dexterity problems, such as arthritis or peripheral neuropathy, to handle.
- *Two-piece*: this comprises a wafer onto which a pouch is clipped or stuck. It can be used with sore and sensitive skin because when the pouch is removed, the flange is left intact and so the skin is left undisturbed.

Plug system

Patients with colostomies may be able to stop the effluent by inserting a plug into the stoma lumen. This plug swells in the moist environment and behaves as a seal so that faeces can be passed at a more convenient time (Burch 2011a, Durnal et al. 2011).

Solutions for skin and stoma cleaning

Warm water is sufficient for skin and stoma cleaning. If patients choose to use a mild soap, it is important that all soap residue is removed as this may interfere with pouch adhesion. Detergents, disinfectants and antiseptics cause dryness and irritation and should not be used. The stoma is not a wound or a lesion and should be regarded as a resited urethra or anus.

See Table 5.6 for a summary of products used in managing problems associated with a stoma.

Deodorants

Aerosols

Use: To absorb or mask odour. *Method*: One or two puffs into the air before emptying or removing appliance. *Examples*: Limone, Naturcare, FreshAire.

Drops and powders

Use: For deodorizing bag contents. *Method*: Before fitting pouch or after emptying and cleaning drainable pouch, squeeze tube two or three times. *Examples*: Ostobon deodorant powder, Nodor S drops, Saltair No-roma.

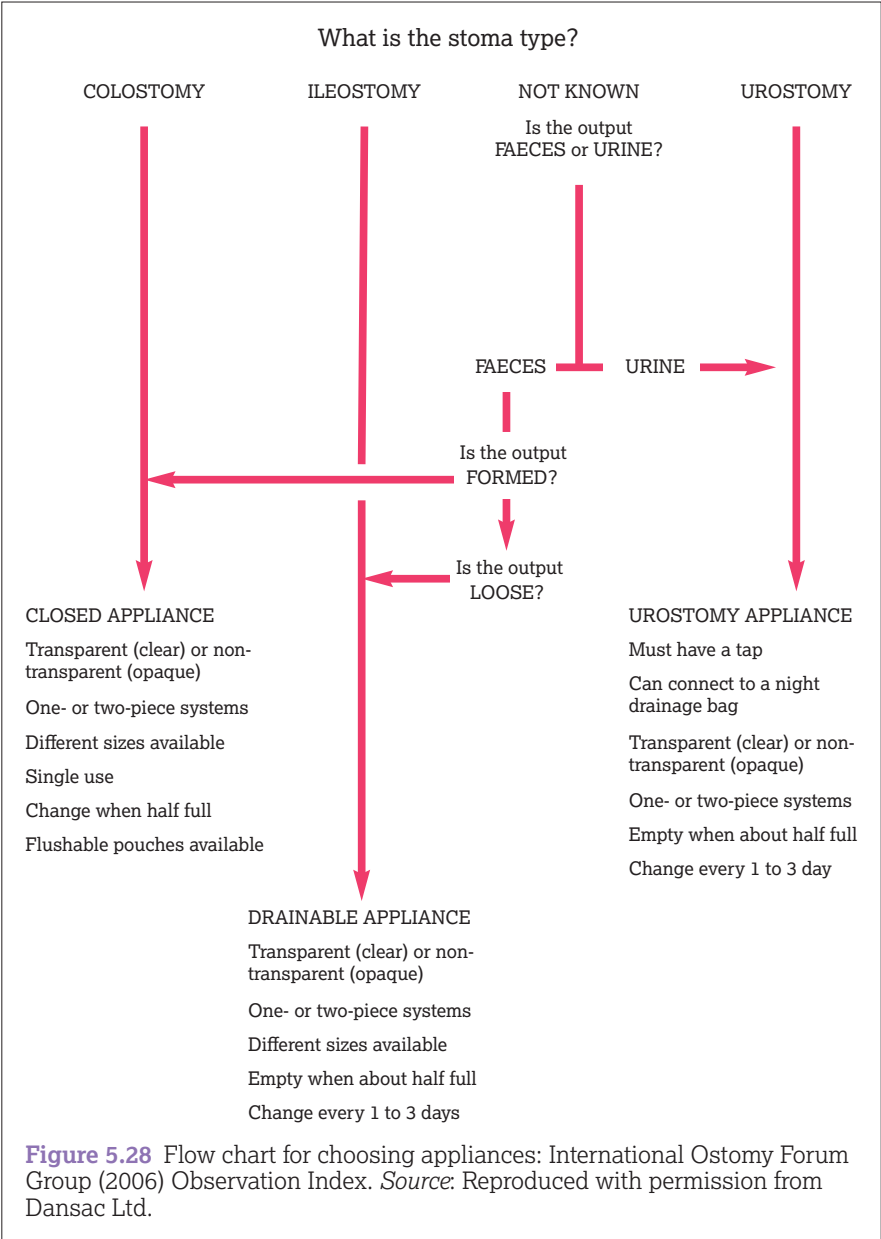

Figure 5.29 Stoma equipment. (a) Drainable bowel stoma pouch. (b) Urostomy pouch. (c) Closed bag.

Pre-operative assessment and care

Pre-operative care can be divided into two sections: physical and psychological.

Physical

Firstly, physical care consists of surgical preparation, which can be in the form of bowel preparation where patients are required to take laxatives to cleanse their bowel prior to surgery. This arguably improves surgical visibility and prevents contamination. This depends on the surgeon's preference and needs to be checked with the patient's surgical team on admission.

Many hospitals now carry out enhanced recovery programmes for colorectal patients. This involves intensive input pre-operatively, where selected patients are required to take nutritional drinks and develop skills in changing a stoma bag. This will improve recovery and management and consequently reduce hospital stay.

Finally, stoma siting is one of the most important elements of pre-operative care as the site of the stoma can have a huge impact on post-operative quality of life. Appropriate siting of a stoma minimizes future difficulties such as the stoma interfering

Table 5.6 A summary of products used for problems associated with stoma

Accessory	Product example	Use	Precautions
Creams	Chiron barrier cream (ABPI 1999)	Sensitive skin as a protective measure	Grease from creams can prevent adherence of the appliance
Protective films	Cavilon no sting barrier film, LBF	To prevent irritation and give protection	If contains alcohol, avoid on broken skin
Protective wafers	Stomahesive	To cover and protect skin	Allergies (rare)
Seals/washers	Cohesive seals Hollister barrier rings	Provide skin protection around the stoma. Useful to fill gaps and dips in skin	Allergies (rare)
Pastes	Stomahesive adapt paste	Useful to fill gaps and dips in skin and provide a smoother surface for applying the pouch	If contains alcohol, avoid on broken skin Should not be used as a solution to an ill-fitting pouch
Protective paste	Orabase paste	Protect raw, sore areas	
Powders	Ostoseal protective powder	Protect sore, wet areas and aid healing	Can sometimes affect adherence
Adhesive preparations	Saltair solution	To improve adherence of product	Should not be used as a solution to an ill-fitting pouch
Adhesive removers	Appeel Adhesive remover aerosols	Aids removal of pouch if patient experiencing pain when pouch removed	Some contain alcohol and should not be used on broken skin
Stoma baseplate securing tape	Hydroframe	To improve patient security. Useful for patients with parastomal hernias	Should not be used as a solution to an ill-fitting pouch
Thickening agents	Gel-X capsules, Ostosorb gel	To help solidify loose stoma output	If output is loose, cause should be investigated
Convex devices	Adapt ring convex inserts, soft seal	Useful for retracted stomas	Bruising and ulceration if used incorrectly
Aerosols	Limone, FreshAire	To mask and absorb odour	Avoid patient associating aerosol spray with stoma
Drops and powders	Nodor S Drops	Deodorizing bag contents	

with clothes or skin problems caused by leakage of the appliance (Cronin 2012). Stoma siting should be carried out by a nurse who has been deemed competent to do so.

Patient assessment is necessary, taking into account:

- physical restrictions and disabilities
- psychological status
- visual impairment
- manual dexterity

- lifestyle
- occupation
- hobbies/leisure/sporting activities
- ethnicity.

All these factors need to be carefully considered and discussed with the patient whilst siting the stoma. Patient involvement is important as it allows the patient control and enhances their ability to cope with a newly formed stoma.

Procedure guideline 5.22 Stoma siting

Essential equipment

- Stoma appliance
- Permanent marker pen
- Bed, trolley or couch to enable patient to lie flat

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient, ensuring they are aware that any mark is for guidance purposes only.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To familiarize the patient with the procedure.

(continued)

Procedure guideline 5.22 Stoma siting (continued)**Action**

- 2 Draw curtains around the patient or close the door to ensure privacy.
- 3 Wash hands thoroughly using bactericidal soap and water or bactericidal alcohol handrub.

Rationale

To avoid unnecessary embarrassment and to promote dignified care (NMC 2015, **C**).

To prevent spread of infection by contaminated hands (Fraise and Bradley 2009, **E**).

Procedure

- 4 Ensure the patient is in a supine (flat) position with one pillow under their head. Ask the patient to lift clothing to expose the abdomen.
- 5 Locate the rectus muscle. The muscle can be identified by asking the patient to raise their head. The muscle may also be palpated and easily felt when the patient coughs.
- 6 Identify a flat area of skin on the abdomen, as this facilitates safe adhesion of the appliance. Avoid siting on bony prominences, skinfolds, the waistline and belt areas.
- 7 Imagine a line running from the umbilicus to the iliac crest on the appropriate side. Place a piece of tape on the midpoint of this line or closest to it on a flat piece of skin. Mark the tape with an 'X'.
- 8 Allow the patient to sit up and move around as much as possible to reassess the positioning. Encourage the patient to carry out movements or activities that may be associated with their occupation or hobbies.
- 9 Secure an appliance to the temporary site and encourage the patient to spend some time wearing the appliance. Where possible, ensure the position allows the patient to view the stoma site and appliance sufficiently.
- 10 Once both the nurse and patient are satisfied with the site, use a permanent marker pen to indicate the site. Cover this mark with a film dressing.

In order to locate the rectus muscle and observe characteristics and contours of the abdomen.

Placing the stoma in the rectus muscle reduces the risk of peristomal herniation and prolapse (Rutledge et al. 2003, **E**).

Avoiding skin creases, especially in the region of the groin or umbilicus, will help to prevent urine or faecal matter tracking along the skin creases, causing leaks. This also helps the patient to visualize the stoma more easily. Restrictive clothing, like belts, over the site may lead to unnecessary pressure and leaks or trauma to the stoma. **E**

This initial marking is used to assess the suitability of the site with the patient sitting, walking, bending and moving (Rutledge et al. 2003, **E**).

This will help to determine the most appropriate site for the patient. **E**

Correct positioning will enable self-care of the stoma and post-operative rehabilitation (Rutledge et al. 2003, **E**).

To ensure the stoma site remains clearly marked until the time of surgery (Rutledge et al. 2003, **E**).

Post-procedure

- 11 Document actions and report to appropriate members of the multidisciplinary team.
- 12 Wash hands thoroughly using bactericidal soap and water or bactericidal alcohol handrub.

To ensure continuity of care and maintain accurate records (NMC 2010, **C**).

To prevent spread of infection by contaminated hands (Fraise and Bradley 2009, **E**).

Psychological

Psychological preparation of the individual facing stoma surgery should begin as soon as surgery is considered, preferably by utilizing the skills of a trained stoma care nurse. It is important that the information and discussions are tailored to the individual's needs, taking into account their level of anxiety and distress (Cronin 2012).

It is important that patients meet all members of the multidisciplinary team who are involved in their care and that they fully understand the need for the stoma surgery. This needs to be explained in order to obtain informed consent. It is beneficial if the patient is met in preassessment or at home prior to surgery to discuss the implications of stoma care and the patient's own role in rehabilitation. At this point it is also helpful to provide the patient with written information and access to self-help support groups.

Stoma counselling is ideally carried out by the specialist stoma care nurse involved in the patient's care but all nurses involved in the care of patients undergoing a stoma should be aware of the impact of having a stoma on:

- body image
- family relationships

- sexual relationships
- depression and anger
- fears and concerns.

It is often beneficial to provide patients with some patient information/literature to take home. This gives them an opportunity to digest the information and write down any questions that they have. There are many different aids available, such as information booklets, samples of various products, diagrams, DVDs and websites. These help to reinforce and clarify the verbal information given to the patient.

Specific patient preparation**Patient education**

Patients undergoing stoma formation have to make major physical and psychological adjustments following surgery. If surgery is elective, patient education should begin in the pre-operative period (Cronin 2012, O'Connor 2005). Adequate pre- and post-operative support is mandatory to improve quality of life for stoma patients (Bloeman et al. 2009). Individual holistic patient assessment is

key as it is important to identify appropriate teaching strategies for each patient. One of the most important ways in which a nurse can support the patient is to teach them stoma care, ensuring independence before discharge (Burch 2011a, Burch and Sica 2005). It is important that the patient is able to independently change their stoma bag, recognize problems and obtain support and supplies once discharged home. Providing patients with adequate informa-

tion and input helps to promote patient decision making by allowing them control (Henderson 2003).

All healthcare professionals are required to wear disposable gloves and apron when changing an appliance and this practice should be explained to patients so that they do not feel it is just because they have a stoma that these precautions are being taken (Cronin 2012).

Procedure guideline 5.23 Stoma bag change

This procedure may also be applied when teaching a patient how to care for their stoma.

Essential equipment

- Clean tray holding:
 - Tissues, wipes
 - New appliance
 - Measuring device/template
 - Scissors
 - Disposal bags for used appliances, tissues and wipes
- Relevant accessories, for example adhesive remover, protective film, seals/washers
- Bowl of warm water
- Soap (if desired)
- Jug for contents of appliance
- Gloves and apron

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Ensure that the patient is in a suitable and comfortable position where they will be able to watch the procedure, if well enough. A mirror may be used to aid visualization.	To allow good access to the stoma for cleaning and for secure application of the stoma bag. The patient will become familiar with the stoma and will also learn about the care of the stoma by observing the nurse. E
3 Use a small protective pad to protect the patient's clothing from drips if the effluent is fluid and apply gloves and apron.	Avoids the necessity for renewing clothing or bedclothes and demoralization of the patient as a result of soiling. E

Procedure

4 If the bag is of the drainable type, empty the contents into a jug before removing the bag.	For ease of handling the appliance and prevention of spillage. E
5 Remove the appliance slowly. Peel the adhesive off the skin with one hand while exerting gentle pressure on the skin with the other.	To reduce trauma to the skin (Burch 2011b, C).
6 Fold appliance in two to ensure no spillage and place in disposal bag.	To ensure safe disposal according to environmental policy (DEFRA 2005, C).
7 Remove excess faeces or mucus from the stoma with a damp tissue.	So that the stoma and surrounding skin are clearly visible. E
8 Examine the skin and stoma for soreness, ulceration or other unusual phenomena. If the skin is unblemished and the stoma is a healthy red colour, proceed.	For the identification of complications or the treatment of existing problems. E
9 Wash the skin and stoma gently until they are clean.	To promote cleanliness and prevent skin excoriation. E
10 Dry the skin and stoma gently but thoroughly.	The appliance will attach more securely to dry skin. E, C
11 Measure the stoma and cut appliance, leaving 3 mm clearance. Apply a clean appliance.	Appliance should provide skin protection. The aperture should be cut just a little larger than the stoma so that effluent cannot cause skin damage (Kirkwood 2006, C).

Post-procedure

12 Dispose of soiled tissues, used appliance, gloves and apron in a disposal bag and place it in an appropriate plastic bin (in the patient's home, the bag should be placed in a plastic bag, tied and disposed of in a rubbish bag).	To ensure safe disposal. E
13 Wash hands thoroughly using bactericidal soap and water or bactericidal alcohol handrub.	To prevent spread of infection by contaminated hands (Fraise and Bradley 2009, E).

Procedure guideline 5.24 Stoma bridge or rod removal

- Essential equipment
- Clean tray holding:
 - Tissues
 - New appliances
 - Disposal bags for used appliances and tissues
 - Relevant accessories, for example belt

- Bowl of warm water
 - Soap if desired
 - Jug for contents of appliance
 - Gloves and apron

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Ensure the patient is in a suitable and comfortable position.	To allow good access to the stoma for cleaning and for secure application of stoma bag. E
3 Apply gloves and apron.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
4 If the bag is of the drainable type, empty the contents into a jug before removing the bag.	For ease of handling the appliance and prevention of spillage. E

Procedure

5 Remove the appliance. Gently peel the adhesive off the skin with one hand while exerting gentle pressure on the skin with the other.	To reduce trauma to the skin (Burch 2011a, 2011b, C).
6 Remove excess faeces or mucus from the stoma with a damp tissue.	So that the stoma and surrounding skin are clearly visible. E
7 Slide the bridge gently to one side to ensure the mobile wing of the bridge is away from the stoma. Turn this wing so that it becomes flush with the bridge. Gently slide the bridge through the stoma loop (see Action figure 7).	To prepare bridge for removal. E
8 Fold the bridge in half so that it appears in a 'C' shape. Gently slide the bridge through the stoma loop (see Action figure 7).	
9 Examine the skin and stoma for soreness, ulceration or other unusual phenomena. If the skin is unblemished and the stoma is a healthy red colour, proceed.	For the prevention of complications or the treatment of existing problems. E
10 Wash the skin and stoma gently until they are clean.	To promote cleanliness and prevent skin excoriation. E
11 Dry the skin and stoma gently but thoroughly.	The appliance will attach more securely to dry skin. E
12 If the skin is red and/or broken, apply barrier cream. If the stoma is not a healthy red colour, inform medical and/or stoma care nurse.	To promote skin healing. E
13 Apply a clean appliance.	To contain effluent from the stoma. E
14 Dispose of soiled tissues, the bridge, the used appliance, gloves and apron.	To prevent environmental contamination. E
15 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).

Action figure 7 Removal of stoma bridge/rod.

Post-procedural considerations

Initial and ongoing care

Post-operative stoma care

In theatre, an appropriately sized transparent drainable appliance should be applied, which should be left on for approximately 2 days. For the first 48 hours post-operatively, the stoma should be observed for signs of ischaemia or necrosis, and stoma colour (a pink and healthy appearance indicates a good blood supply), size and output should be noted, as should the presence of any devices, such as ureteric stents or bridge with a loop stoma (Kirkwood 2006).

Table 5.7 recommends the most appropriate bag type to use on each type of stoma and the expected output. The drainable appliance should always be emptied frequently, gas should be allowed to escape and the appliance should not be allowed to get more than half full with effluent. If the appliance becomes too full, leaks may occur and the weight from the effluent or the pressure from gas may cause the appliance to fall off. A leak-proof, odour-resistant well-fitted appliance does much to promote patient confidence at this time (Kirkwood 2006). The first time a bowel stoma acts, the type, appearance, quantity and consistency of the matter passed should be recorded; this includes any flatus that may be passed (Kirkwood 2006).

Immediately post-operatively, patients would not be expected to perform their own stoma care but, if appropriate, teaching that would have begun pre-operatively should be recommenced within the first 24–48 hours following surgery. During appliance changes, observations should be made of the following.

- *Stoma*: colour, size and general appearance: oedematous, flush with abdomen, retracted.
- *Peristomal skin*: presence of any erythema, broken areas, rashes.
- *Stoma/skin margin (mucocutaneous margin)*: sutures intact, tension on sutures, separation of stoma edge from skin (mucocutaneous separation).

Any abnormalities should be reported to the stoma care nurse and medical staff (Burch 2004, Kirkwood 2006). Viewing the stoma may be difficult for the patient, who may be very aware of other people's reaction to it. The patient's reaction to their stoma should be observed and recorded.

Colostomy function

In the first few days, a sigmoid colostomy will produce haemoserous fluid and wind. By day 5 there should be some faecal fluid and then by day 7–14, semi-formed stool. A closed appliance may then be used. Rarely a stoma may be formed in the transverse colon, usually as a result of an emergency procedure (Cronin

2012), and in such cases only a small amount of water will be reabsorbed from the faecal matter, so the stool is less formed. Therefore a drainable pouch will be required.

Patients with a sigmoid colostomy (ostomates) should generally be advised to have a balanced and mixed diet. To avoid constipation, ostomates are advised to take adequate oral fluids and fibre in the form of '5-a-day' fruit and vegetables (Burch 2011c). If either constipation or loose stool is a problem, then dietary intake should be reviewed. Ostomates may find that their colostomy is usually active at particular times of the day, but ultimately the only means of gaining control with a sigmoid colostomy is by using a plug system or by regular irrigation. Stoma care nurses will need to assess patients for their suitability for either using a plug system or irrigation.

Ileostomy function

For the first few days the stoma will produce haemoserous fluid and wind. By days 5–10 there will be brown faecal matter. The fluid output after surgery can be as much as 1500 mL/24 hours but this will gradually reduce to 500–850 mL/24 hours as the bowel settles down (Black 2000). It is important that fluid balance recordings are made and serum electrolytes are measured as patients are at risk of sodium and/or magnesium depletion (Burch 2004). Sometimes the output from a stoma remains high (>1000 mL/24 hours), which may be due to the amount of small bowel removed at surgery or an underlying bowel condition; these patients require careful management. Patients who continue to have a high output from their stoma may need to be managed by specialist teams which include gastroenterologists, dietitians and stoma care nurses in order to provide ongoing support (Slater 2012).

The effluent from an ileostomy takes on a porridge-like consistency when a normal intake of food is established (Burch 2011c). A drainable appliance is therefore used. The effluent contains enzymes, which will excoriate the skin (Burch 2011b), so if the pouch leaks, it must be changed promptly to prevent skin breakdown. The effluent cannot be controlled but may vary throughout the day. Patients with ileostomies often find that the output is thicker first thing in the morning and after meals, or the output is looser with reduced dietary intake (Burch 2011c). Sometimes medication which reduces peristaltic action, for example codeine or loperamide, may be used to control excessive watery output. If using loperamide, this should be taken half an hour to an hour before food in order to achieve an optimal effect.

Urostomy/ileal conduit function

Urine will dribble from the stoma every 20–30 seconds and it starts draining immediately. Normal output is 1500 mL/24 hours, but may be less after periods of reduced fluid intake, for example

Table 5.7 Decision tool to use when selecting appropriate bag/pouch

Type of stoma	Expected post-operative output	Recommended bag to be used	Expected stoma output on discharge	Recommended bag to be used on discharge
Colostomy	Haemoserous fluid Flatus Liquid/loose stool	Clear drainable bag	Soft formed stool Bowel action 1–3 times a day	Closed opaque bag
Ileostomy	Haemoserous fluid Liquid/loose stool Flatus	Clear drainable bag	Loose stool Approximately >600 mL per day	Opaque drainable bag
Urostomy	Urine Mucus	Clear drainable bag with tap	Urine 0.5 mL/kg/h	Opaque drainable bag with tap

at night. Urinary stents (fine-bore catheters) may be in place from the ureters past the anastomosis and out of the stoma. They are placed to maintain patency and protect the suturing until primary healing is completed (Black 2000). Stents are left *in situ* for 7–10 days.

Body image

198 Stoma formation creates many issues for the patient and many struggle with body image. Studies suggest that this is often overlooked (Opus 2010). The circumstances in which the stoma is formed will influence psychological recovery (Black 2000). Communication is key and it is important to allow the patient and family to discuss their concerns and anxieties. Therefore stoma care nurses play a vital role in supporting the patient and family. It is important to promote patient independence and acceptance.

Diet

All patients should be encouraged to eat a wide variety of foods and drink 1.5–2 litres of fluids each day. Our digestive system reacts in an individual way to different foods and so it is important that patients try a wide range of foods on several occasions and that none should be specifically avoided (Burch 2011c). Patients can then make decisions about different foods based on their own experience of their own reaction. Explanations should be given of how the gut functions, how it has been changed since surgery and the effects certain foodstuffs may cause.

Colostomy and ileostomy formation means the loss of the anal sphincter so passage of wind cannot be controlled. High-fibre foods such as beans and pulses produce wind as they are broken down in the gut; hence individuals who eat large quantities of these foodstuffs may be troubled by wind. There are several non-food causes of wind, such as chewing gum, eating irregularly and drinking fizzy drinks, which should be considered before blaming a particular food. Eating yoghurt or drinking buttermilk may help reduce wind for these patients. Green vegetables, pulses and spicy food are examples of foods that may cause colostomy and ileostomy output to increase or become watery. Boiled rice, smooth peanut butter, apple sauce and bananas are some of the foods that may help thicken stoma output (Black 2000, Burch 2011c).

Some foods, for example tomato skin and pips, may be seen unaltered in the output from an ileostomy. Celery, dried fruit, nuts and potato skins are some of the foods which can temporarily block ileostomies (Black 2000, Burch 2011c). The blockage is usually related to the amount eaten and the offending food can be tried at another time in small quantities, ensuring it is chewed well and not eaten in a hurry.

There are no dietary restrictions with a urostomy. It must be stressed, however, that an adequate fluid intake must be maintained to minimize the risk of urinary tract infection due to a shortened urinary tract. The recommended fluid intake for all individuals is 1.5–2.0 litres per day (Burch 2011c). Fluid intake should be increased in hot weather or at times when there is an increase in sweating, for example with exercise or fever. Patients should be made aware of certain foods that may cause a change to the usual character of the urine. For example, beetroot, radishes, spinach and some food dye may discolour urine; some drugs may also have this effect, for example metronidazole, nitrofurantoin. Similarly, following consumption of asparagus or fish, urine may develop a strong odour.

Fear of malodour

This is a common fear for patients with bowel stomas, often based on hearsay or experience with other ostomates in hospital or the community. Appliances are odour free when fitted correctly. Flatus may be released via charcoal filters and deodorizers are available. The individual must be reassured,

however, that any problems that occur post-operatively will be investigated, with a good possibility of their being solved by such means as the use of alternative appliances (Black 2000, Burch 2004).

Sex and the ostomate

The possibility of sexual impairment for both men and women after stoma surgery depends on the nature of the operation and the ensuing damage to the nerves and tissues involved. The psychological impact of the surgery and its effect on the individual's body image must also be taken into consideration. Surgery that results in physical sexual disability will have psychological repercussions, while some sexual difficulties may be of psychological origin (Black 2004). Impairment may be permanent or temporary. In the latter case, resolution of the difficulty may take anything up to 2 years. Pre- and post-operative counselling should be offered for both patient and partner.

All patients may experience loss of libido and sexual desire. Ejaculatory disturbances occur following cystectomy so men facing this surgery should be offered sperm banking prior to surgery. Erectile dysfunction is a common complication of pelvic surgery and there are a number of treatment options available. These include oral medications (sildenafil, tadalafil, vardenafil), sublingual apomorphine, intraurethral and intracavernosal alprostadil, vacuum devices and penile implants (Ashford 1998, Kirby et al. 1999, Newey 1998).

Female patients may experience dyspareunia; this may be due to narrowing or shortening of the vagina, a reduction in the volume of vaginal secretions or changes in genital sensations (Black 2004). The use of a lubricant, adopting different positions during lovemaking or encouraging greater relaxation by extending foreplay may help resolve painful intercourse (Black 2004).

Planning for discharge

Discharge planning for the patient with a stoma should commence once the patient is admitted. It is important to set a provisional discharge date and set realistic goals with the patient. Prior to discharge, ideally the patient should have returned to their prior level of independence, be eating a normal diet and should be competent in stoma care. Family or close friends are likely to require support and information so that they are in a position to help the ostomate and this should be provided as much as possible before discharge. If family or close friends are involved during all stages of stoma surgery, and patients are well informed, they are better able to adapt to life with a stoma (Cronin 2012).

Acceptance of the stoma is a gradual process and, on discharge from hospital, patients may only be beginning to adapt to life with a stoma. Indeed, in a survey of patients following stoma formation ($n=100$), 56% felt that support was needed for the first 6 months, indicating the ongoing need for professional advice and support for a substantial amount of time after stoma surgery (Taylor et al. 2012).

Continuity of care for these patients is crucial. Effective communication and collaboration between healthcare professionals are key to psychological adaptation and successful rehabilitation (Borwell 2009).

Follow-up support

The patient should be discharged home with:

- 2 weeks of stoma supplies
- contact details of community stoma care nurse
- prescription details of products being used
- information on delivery company, if relevant.

The patient should be discharged with an adequate supply of stoma products until a prescription is obtained from the

		Tick Box	Date, Signature & Print Name
1.	Planned date of discharge: _____	Yes <input type="checkbox"/> No <input type="checkbox"/>	
2.	Is the patient independent with stoma care	Yes <input type="checkbox"/> No <input type="checkbox"/>	
3.	Community stoma care nurse informed	Yes <input type="checkbox"/> No <input type="checkbox"/>	
4.	Community nurses informed if necessary	Yes <input type="checkbox"/> No <input type="checkbox"/> N/A <input type="checkbox"/>	
5.	Date of first home visit by community stoma care nurse	Date:

9.	Patient given two weeks supply of stoma products	Yes <input type="checkbox"/> No <input type="checkbox"/>	

Figure 5.30 An example of a stoma discharge checklist.

general practitioner. Written reminders should also be provided on how to care for the stoma, how to obtain supplies of appliances, and any other information that may be required. The patient should have details of non-medical stoma clinics, details about the relevant agencies and information about voluntary associations. Arrangements should also be made for a home visit from the stoma care nurse and/or the community nurse (Cronin 2005). Figure 5.30 provides an example of a discharge checklist.

Obtaining supplies

All NHS patients with a permanent stoma are entitled to free prescriptions for their stoma care products, and should complete the relevant forms for exemption from payment. Appliances can then be obtained from the local chemist, free home delivery services or directly from the appropriate manufacturers.

Complications

As a healthcare professional providing support and care to stoma patients, it is important to be able to distinguish normal from abnormal. The observational index (Figure 5.31) provides a reference guide to use when observing, recording and

reporting. If any of the complications are noted, it is important to ensure that the medical team and/or stoma care nurse is informed. Advice on how to manage these problems should be obtained from your specialist stoma care nurse. Early recognition of problems and complications can prevent more serious complications later.

Chapter 6

Moving and positioning

Procedure guidelines

- 6.1** Positioning the patient: supine 213
- 6.2** Positioning the patient: sitting in bed 214
- 6.3** Positioning the patient: side-lying 215
- 6.4** Positioning the patient: lying down to sitting up 216
- 6.5** Positioning the patient: in a chair/wheelchair 218
- 6.6** Moving from sitting to standing: assisting the patient 219
- 6.7** Assisting the patient to walk 220
- 6.8** Positioning the unconscious patient or patient with an airway in supine 222
- 6.9** Positioning the unconscious patient or patient with an airway in side-lying 224
- 6.10** Positioning the patient to maximize V/Q matching with unilateral lung disease in a self-ventilating patient 226
- 6.11** Positioning the patient to maximize V/Q matching for widespread pathology in a self-ventilating patient 227
- 6.12** Positioning to maximize the drainage of secretions 230
- 6.13** Positioning the neurological patient with tonal problems 233
- 6.14** Log rolling for suspected/confirmed cervical spinal instability 237
- 6.15** Positioning for suspected/confirmed cervical spinal instability: pelvic twist to right 240
- 6.16** Log rolling for suspected/confirmed thoracolumbar spinal instability 242
- 6.17** Early mobilization of the patient in bed 243
- 6.18** Positioning the pre-operative and post-operative amputation patient 247

Overview

The aim of this chapter is to provide guidance on various aspects of moving and positioning patients, acknowledging the need to be clinically effective and, where possible, evidence based. It relates to moving and positioning of adults and does not specifically cover positioning of children or neonates.

The main objectives of the chapter are to:

208

- 1 outline the general considerations regarding moving and positioning
- 2 provide guidance on the principles of moving and positioning whether the patient is in bed, sitting or preparing to mobilize
- 3 consider optimal moving and positioning including modifications for patients with different clinical needs.

The principles of moving and positioning will relate to the effect on the patient, but the practitioner needs to ensure that they consider their own position regarding the safety aspects of manual handling. For recommendations and further information on safe manual handling, refer to government (HSE 1992, 2012) and local trust policies, the manual handling advisor or the physiotherapist (PT).

In this chapter the general principles of moving and positioning will be discussed first followed by considerations of positioning for patients with specific clinical needs, which will require modification or additional considerations of the general principles. The first specific clinical area covered will be moving and positioning of unconscious patients and patients with an artificial airway. Following this, there will be a section looking at additional considerations and modifications for patients with different respiratory requirements. The next section of the chapter will relate to the specific moving and positioning needs of patients with a neurological problem, including the management of patients with spinal cord compression. The final clinical area to be considered will relate to moving and positioning considerations and modifications for upper and lower limb amputees.

Moving and positioning: general principles

Definition

The verb 'to position' is defined as 'a way in which someone or something is placed or arranged' (Pearsall 2010). In medical terms, 'position' relates to body position or posture. Moving and positioning lie within the broader context of manual handling, which incorporates 'transporting or supporting a load (including lifting, putting down, pushing, pulling, carrying or moving) by hand or bodily force' (HSE 1992).

Anatomy and physiology

The human body is a complex structure relying on the musculoskeletal system to provide support and also to assist in movement. The musculoskeletal system is an integrated system consisting of bones, muscles and joints.

Whilst bones provide the structural framework for protecting vital organs and providing stability, skeletal muscles maintain body alignment and help movement (Tortora and Derrickson 2011). In order for skeletal muscles to provide these functions, they often cross at least one joint and attach to the articulating bones that help form the joint so that when a muscle contracts, movement of a joint can occur in one direction. Muscles tend to work in synergy with each other (rather than in isolation) not just to create but also to control the movement. The ability of a muscle to either contract or to extend assists their function (Figure 6.1). However, muscles will waste if not used and can also become shortened if not stretched regularly.

Joints are supported not just by the muscles but also by ligaments which are strong connective tissue structures attached

either side of the joint, for example the knee joint (Figure 6.2). Ligaments can also become shortened if they are maintained in one position repeatedly or over a long period of time, which can then lead to problems maintaining full joint movement.

Evidence-based approaches

Rationale

Moving and positioning are important aspects of patient care because together they can affect the patient physically, physiologically and psychologically. They have a major impact on the patient's recuperation and well-being and can address impairments in order to maximize function.

Optimum positioning is a good starting point to maximize the benefit of other interventions such as bed exercises, breathing exercises, assisting rest and mobility in order to facilitate recovery and enhance function. However, although it is important, it must not be seen in isolation and is just one aspect of patient management within the context of preventative, rehabilitative, supportive and palliative rehabilitation models (Dietz 1981) where the overall goal is to assist independence.

It is important to frequently evaluate the effect that moving and positioning have on the individual with different pathologies to ensure that the intervention is helping to achieve the desired result or goal. This relates to considering whether the moving and positioning procedure is being clinically effective and, where possible, is evidence based.

There are several points to consider with regard to the clinical effectiveness of moving and positioning.

- Is the timing right for moving the patient? For example, is the pain relief adequate?
- Is it being carried out in the correct way? This relates to manual handling with regard to preventing trauma to both the patient and the practitioner. It is well known that nurses have a high incidence of work-related musculoskeletal injuries (Nelson et al. 2008) so that approved patient handling techniques are essential for safe practice.
- Is the required position taking into account all the pertinent needs of the patient? This emphasizes the need to consider the patient in a holistic manner and take into account any comorbidities as well as the primary focus that is being addressed.
- Is it achieving the desired or preventing a detrimental result?

Indications

Assistance in moving and positioning is indicated for patients who have difficulty moving or require periods of rest when normal function is impaired.

Contraindications

There are no general contraindications for moving and positioning. The severity of an illness may leave no choice except bedrest, but the rest alone is rarely beneficial.

Patients who are clinically unstable may also need medical attention prior to any moving or change in position.

Principles of care

The principles of positioning are based on patterns of posture which maximize function with the minimal amount of effort (Gardiner 1973). The control of body posture includes the alignment of body segments to each other and to the supporting surface (Edwards and Carter 2002). These basic principles of positioning can be applied regardless of a patient's pathology. The aim is to reduce impairment, facilitate function and alleviate symptomatic discomfort and to assist future rehabilitation where appropriate.

The main principles underpinning all interventions regarding patient positioning and mobilization focus on the short- and long-term goals of rehabilitation and management for each specific patient. It is imperative that a thorough assessment is carried out prior to any intervention in order to plan appropriate goals

of treatment. It may be necessary to compromise on one principle, depending on the overall goal. For example, for the palliative patient, it may be that the primary aim of any intervention is to facilitate comfort at the cost of reducing function. Regular reassessment is necessary to allow for modification of plans to reflect changes in status.

Effects of bedrest/decreased mobility

Patients with acute medical conditions and decreased mobility are at risk of developing secondary complications of bedrest such as pulmonary embolus (PE) (Riedel 2001), deep vein thrombosis (DVT) or respiratory infection (Convertino et al. 1997). Historically patients complaining of pain, dyspnoea, neurological dysfunction and fatigue were advised to rest. However, inactivity can cause a variety of problems including:

- deconditioning of many of the body's systems (particularly cardiorespiratory and musculoskeletal)
- deterioration of symptoms
- fear of movement
- loss of independence
- social isolation (Creditor 1993, Hanks 2010).

Therefore, patients should be encouraged or assisted to mobilize or change position, at frequent intervals. The use of rehabilitation programmes in the patient with critical illness has the potential to decrease time on the critical care unit, shorten overall hospital

stay and prevent readmission (Thomas 2009). Early referral to therapy services is advantageous.

If bedrest is unavoidable then the following factors should be taken into account:

- patient comfort and adequate support
- avoidance of the complications of prolonged bedrest
- the optimum frequency of position change.

210 Active movements, as advised by the physiotherapist, should be practised where possible in order to:

- maintain full joint range
- maintain full muscle length and extensibility
- assist venous return
- maintain sensation of normal movement (Adam and Forrest 1999).

Active ankle movements (Figure 6.3) are to be encouraged to assist the circulation, as failure to exercise the calf muscle for prolonged periods may result in limited or poor blood circulation in the lower leg and increases the risk of DVT (O'Donovan et al. 2006).

Risk assessment

There is an absolute requirement to assess the risks arising from moving and handling patients that cannot reasonably be avoided (CSP 2014). Once the risk of not moving the patient is deemed to be greater than moving the patient (see previous rationale), consider the following (TILE).

- T** *Task/operation*: achieving the desired position or movement.
- I** *Individual*: this refers to the handler/s. In patient handling, this relates to the skills, competencies and physical capabilities of the handlers. It is also important to consider

health status, gender, pregnancy, age and disability. It is also important to consider the competency and abilities of all staff involved with the task.

- L** *Load*: in the case of patient handling, the load is the patient. The aim of rehabilitation is where possible to encourage patients to move for themselves or contribute towards this goal. This may mean that additional equipment is needed. For assistance with regard to this, liaise with the physiotherapist and/or occupational therapist.
- E** *Environment*: before positioning or moving the patient, think about the space, placement of equipment and removal of any hazards.

Other factors, for example any line attached to the patient, must also be considered when undertaking a risk assessment. The key points to consider are summarized in Box 6.1.

Effective use of therapeutic handling in the context of the use of a comprehensive competency-based training tool can benefit patient outcome, enabling balance and motor training in early rehabilitation with minimal risk to staff (Mehan et al. 2008). Where there is any doubt about patients with complex needs, seek advice from the PT or the occupational therapist (OT) for assessment. Once a risk assessment has been carried out, this needs to be recorded prior to proceeding with any manual handling intervention (CSP 2014).

Consent must be obtained before any intervention is started. Consent is the voluntary and continuing permission of the patient to receive a particular treatment based on an adequate knowledge of the purpose, nature and likely risks of the treatment, including the likelihood of its success and any alternatives to it. Permission given under any unfair or undue pressure is not consent (NMC 2013). This principle reflects the right of patients to determine what happens to their own bodies, and is a fundamental part of good practice (DH 2009).

Legal and professional issues

For recommendations and further information on safe manual handling, refer to professional guidance (CSP 2014), government

Box 6.1 Risk assessment

- 1 Assess the patient clinically.
- 2 Consider realistic clinical goals and functional outcomes in discussion with the patient and ascertain the level at which the patient will be able to participate in the task.
- 3 Consider whether the proposed intervention involves hazardous manual handling and reduce the hazard by:
 - a adapting the technique
 - b introducing equipment. Studies advocate the use of assistive devices to promote safer patient handling for patients with complex needs following assessment (Nelson et al. 2006, Rockefeller 2008), with a positive impact on patient outcomes with no detrimental effect on staff handling following assessment (Nelson et al. 2008)
 - c seeking advice/assistance from appropriately skilled colleagues.
- 4 Risk assessment should be an ongoing process and be constantly updated.
- 5 After the procedure, document the risk assessment in the communication section of the patient's care plan, being sure to include the date, the number of staff involved and the equipment needed to perform the task. Also document any changes in the patient's condition, such as skin redness. It is important to also document the intended duration of time for which the patient should be maintained in this new position.

and local trust policy (HSE 1992) and the manual handling advisor or PT. This is particularly relevant when handling complex, high-risk situations.

Pre-procedural considerations

Before positioning or moving the patient consider the following factors.

Assessment

Pressure/skin care

All clinical staff should be aware of the risk factors for developing pressure sores. These include age, malnutrition, immobility, loss of sensation, vascular disease and acute illness. The risk of skin damage when the patient is positioned or moved will be increased by factors including incontinence, profuse perspiration and obesity (Hickey and Powers 2009). Direct pressure to the skin and friction during movement of patients are two of the most common causes of injury to the skin that can lead to pressure ulcers. Sometimes a scoring system such as Norton or Waterlow is used to identify patients at risk. These are helpful but should only be used as an aide mémoire for staff and not replace clinical judgement (RCN 2001). Any patient with a pressure sore or who is thought to be at risk of developing one should be positioned with the use of pressure-relieving equipment such as specialist mattresses and cushions. Additional use of pillows/towels may be required depending on individual assessment.

Wounds

Consider the location of wounds and injuries when selecting a comfortable position. Ideally positions should avoid pressure on or stretching of any wounds and consideration should be given to the timing of dressing changes, which ideally should be done prior to positioning to avoid disturbing the patient twice.

Sensation

Take extra care in positioning patients with decreased sensation as numbness and paraesthesia (abnormal skin sensation) may result in skin damage as the patient is unaware of pressure or chafing. These patients may not be able to adjust their position or alert nursing staff so it is very important to check the patient's skin regularly for areas of redness or breakdown.

Oedema/swelling

Where possible, swollen limbs should not be left dependent but be supported on pillows/footstool as elevation will help to maximize venous return and minimize further swelling. Oedema may result in pain, fragile skin or loss of joint movement.

Pain

Ensure the patient has optimal pain relief before moving. Patients who are pain free at rest may need additional analgesic cover before movement. It is important to allow adequate time for any pain medication to take effect.

Weakness

Consider the patient's ability to maintain the position. Additional support may be required in the form of pillows or towels to maintain the desired posture.

Limitations of joint and soft tissue range (contractures)

Soft tissue changes and contractures occur through disuse in normal muscle (Jones and Moffatt 2002). As a result, restrictions in joint range may mean that positions need to be modified or become inappropriate.

If there is the potential for any joint or soft tissue restrictions then liaise with the PT or OT regarding any specific exercises or positions necessary for the patient to avoid developing

contractures. This may affect position choice or may involve incorporating appropriate splinting to maintain muscle length.

Communication and involvement with the multidisciplinary team (MDT) will assist rehabilitation interventions as treatment could be incorporated during positional changes. This potentially allows for more physical assistance in moving the patient without involving other staff, allows collaborative working such as changing sheets, repositioning and assessment of pressure areas, and will minimize unnecessary disturbance of the patient (Hough 2001).

Fracture or suspected fracture

Patients with unstable fractures or suspected fractures should not be moved and the area should be well supported. A change of position could result in pain, fracture displacement and associated complications. Patients with osteoporosis or metastatic bony disease with unexplained bony pain should be treated as having a suspected fracture. Osteoporosis refers to a reduction in the quantity and quality of bone due to loss of both bone mineral and protein content. Risk factors for osteoporosis increase with age and include being female, Caucasian and postmenopausal, having a low body mass index (BMI), a positive family history of osteoporosis, a sedentary lifestyle and smoking. Before an osteoporotic lesion becomes apparent radiologically, at least 50% of bone mass must be lost so that pain may precede radiological changes (McGarvey 1990).

Altered tone

Tone can be altered by positioning with either positive or negative consequences. Further information on moving and handling patients with either neurological impairment or who are unconscious is outlined later in this chapter.

Spinal stability

It is important to establish spinal stability before positioning or moving the patient. The specifics of moving and positioning a patient with spinal cord compression are discussed later in this chapter.

Medical devices associated with treatment

Care should be taken to avoid pulling on lines or causing occlusion if the patient has a catheter, intravenous infusion, venous access device or drain. Pulling on devices may cause pain and/or injury to the patient and be detrimental to care. Prior to any moving or positioning procedure, ensure that any electrical pumps have been disconnected and sets are untangled and flowing freely. Once the moving or positioning procedure has been completed, ensure all devices are reconnected.

Medical status/cardiovascular instability

The defining parameter for mobilization is that the patient's oxygen transport system is capable of increasing the oxygen supply to meet metabolic demand (Pryor and Prasad 2008). Patients who are medically unstable may become more unstable during movement. Therefore, patients who are acutely unwell should be monitored carefully during and after any change of position or when mobilizing.

Fatigue

Fatigue can be a distressing symptom, so advice and help should be given to the patient about how to pace their everyday activities. Barsevick et al. (2002) describe energy conservation as 'the deliberate planned management of one's personal energy resources in order to prevent their depletion'. Therefore, prioritizing activities may help to avoid engaging in tasks that are unnecessary or of little value (Cooper 2006).

Cognitive state

It is important to explain to the patient the reasons for moving and positioning appropriate to their level of understanding.

Always explain what will happen step by step and give clear instructions to the patient to enable them to participate in the movement.

It is known that impaired cognition (the mental process involved in gaining knowledge and comprehension) and depression are intrinsic risk factors for falls in older people (DH 2001).

Privacy and dignity

212

In order to maintain privacy and dignity during positioning, ensure the environment is as private as possible by shutting the door and/or the curtains prior to moving the patient (CSP 2014). It may be appropriate to ask visitors to wait outside. The process of uncovering the patient may make them feel vulnerable and/or distressed, so keep them covered as much as is practically possible during the procedure. Make sure catheter bags and drains are hung as discreetly as possible under the patient's bed/chair.

Patient explanation/instruction

Explain to the patient the reasons for changing their position and where possible gain their verbal consent. If patients are fully informed of the planned change in position they may be able to participate with the manoeuvre and reduce the need for assistance.

Documentation/liaison with MDT

It is important to check to see if there are any instructions or indications regarding positioning or moving the patient in their documentation. If unsure then check with the MDT as this may provide guidance on what positions are more appropriate and any special precautions that need to be considered prior to moving and positioning.

Recent initiatives have looked at specific areas to improve patient care following the publication of *High Impact Actions for Nursing and Midwifery* in 2009 (RCM et al. 2009). One area identified in this report is falls prevention with the aim of demonstrating a reduction in the number of falls in older people within NHS care.

Risk assessment: prevention of falls

The National Patient Safety Agency reported 152,000 falls in England and Wales in acute hospitals in 2009, 26,000 in mental health trusts and 28,000 in community hospitals. The number of falls is set to rise in line with increasing numbers of older and frail people with more complex health needs (RCM et al. 2009).

Definition

A fall is a sudden, unintentional change in position causing an individual to land at a lower level, on an object, the floor or the ground other than as a consequence of sudden onset of paralysis, epileptic seizure or overwhelming external force.

Falls are the most common cause of serious injury in older people, and of hospital attendance and are the most common precipitating event for care home admission (NICE 2013). Falls may result in a loss of confidence or independence which, in turn, may lead to a need for increased or extended support from statutory health and social care agencies (Ward et al. 2010). Preventing falls in the older person has been well described in national guidance and all prevention programmes should include particular reference to the care of the older person (Age UK 2013, Becker et al. 2003, Oliver et al. 2007, Ward et al. 2010).

The causes of falls are complex and elderly hospital patients are particularly likely to be vulnerable to falling due to medical conditions including delirium, cardiac, neurological or musculoskeletal conditions, side-effects from medication or problems with their balance, strength or mobility. Problems such as reduced or poor memory can create a greater risk of falls when someone is out of their normal environment and on a hospital ward, as they are less able to see and avoid any hazards.

Continence problems can mean patients are vulnerable to falling whilst making urgent journeys to the toilet. However, patient safety has to be balanced with independence, rehabilitation, privacy, and dignity – a patient who is not allowed to walk alone will very quickly become a patient who is unable to walk alone. Addressing inpatient falls and fall-related injuries is therefore a challenge for all healthcare organizations (NPSA 2010, Patient Safety First 2009).

The prevention of falls is complex and, as with many other types of risk assessment and prevention, a systematic multi-professional approach is recommended. Individual needs and the different environmental factors associated with different settings – for example, home, care home or hospital – will need to be assessed regularly.

Many interventions have been demonstrated to reduce the incidence of falls, including exercise programmes, identification bracelets, alarm systems and risk assessments (Ward et al. 2010). Part of the Chief Nursing Officer for England's programme of 'High Impact Actions for Care' includes 'Staying Safe – Preventing Falls' (Ward et al. 2010), the aim of which is to demonstrate a year-on-year reduction in the number of falls sustained by older people in NHS-provided care. However, patient safety must always be carefully balanced with patient independence and their right to make informed choices (RCM et al. 2009). The following checklist has been developed for healthcare professionals to use on the wards regularly throughout the day to reduce the risk factors for falling.

- Hydration: making sure patients have something to drink.
- Checking toilet needs.
- Ensuring patients have the right footwear.
- Decluttering the area.
- Making sure patients can reach what they need, such as the call bell.
- Making sure bedrails are correctly fitted.
- Ensuring patients have an appropriate walking aid, if applicable.

It is the responsibility of all staff to undertake regular inspections of their work areas to determine when factors are causing a falls risk and take appropriate action. All staff should be trained in how to reduce/prevent falls within their areas. Every patient should be provided with a clear orientation to the ward and ward layout and their individual needs considered. Clear signage to key areas such as bathrooms and toilets is important, especially to elderly patients who may become easily disorientated outside their familiar environment.

It is the responsibility of all staff to report any environmental hazards within their working areas and to ensure that spillages are removed and appropriate signage is used to warn people of hazards.

Risk factors

It is important to consider the risk of falls when undertaking a manual handling risk assessment on patient admission. The patient's risk of falls should be reconsidered either at weekly intervals or if the patient experiences a fall.

Falls generally occur due to a complex interaction of diverse risk factors and situations. Over 400 risk factors associated with falling have been reported (NHS Centre for Reviews and Dissemination 1996), but these can be broadly divided into intrinsic (person-related), extrinsic (environment-related) and behavioural (activity-related) risk factors (Connell and Wolf 1997, Stalenhoef et al. 2002).

Intrinsic risk factors

- Previous fall/fracture/stumbles and trips
- Impaired balance and gait/restricted mobility
- Medical history of Parkinson's disease, stroke, arthritis, cardiac abnormalities

- Fear of falling
- Medication including polypharmacy, psychotropic medication
- Dizziness
- Postural hypotension
- Syncope
- Reduced muscle strength
- Foot problems
- Incontinence
- Cognitive impairment
- Impaired vision
- Low mood
- Pain

Extrinsic risk factors

- Stairs and steps
- Clutter and tripping hazards, for example rugs, flexes
- Floor coverings
- Poor lighting, glare, shadows
- Lack of appropriate adaptations such as grab rails, stair rails
- Low furniture
- No access to telephone or alarm call system
- Poor heating
- Thresholds and doors
- Difficult access to property, bins, garden, uneven ground
- Inappropriate walking aids
- Pets

Behavioural risk factors

- Limited physical activity/exercise
- Poor nutrition/fluid intake
- Alcohol intake
- Carrying, reaching, bending, risk-taking behaviour such as climbing on chairs, use of ladders; footwear

In order to reduce the risk, it is important to investigate every fall that does occur and understand the circumstances surrounding it. A useful way of analysing falls is to categorize them and to map areas on the ward or areas in the hospital where more than one patient has fallen. Common themes can then be identified and strategies can be implemented to reduce the risk.

Positioning the patient: in bed

Evidence-based approaches

Rationale

Falls from the bed are common and this must be considered when positioning a patient in bed.

Equipment

Sliding sheets are used to assist patients to roll or change position in bed. Due to the slippery surface of the slide sheet fabric, friction is reduced and it is easier to move or relocate the patient with very minimal effort or discomfort.

Procedure guideline 6.1 Positioning the patient: supine

Essential equipment

- Pillows/towels
- Sliding sheets/manual handling equipment if indicated following risk assessment in accordance with local manual handling policy
- Bed extension for tall patients

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands thoroughly or use an alcohol-based handrub.
- 3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, **E**).
- To minimize the risk of injury to the practitioner (Smith 2011, **C**).

Procedure

4 Either:

Place one pillow squarely under the patient's head. For patients with an airway or who have had recent head and neck surgery, take care not to occlude or displace tubes or increase pressure to vulnerable areas.

Or:

Use two pillows in a 'butterfly' position so that two layers of pillow support the head with one layer of pillow under each shoulder.

Or:

Use a folded towel under the patient's head if this provides natural spinal alignment.

To support the head in a neutral position and to compensate for the natural lordosis (anatomical concavity) of the cervical spine. **E**

To ensure the airway is patent. **E**

To increase patient support and comfort. **E**

This may be necessary for the patient with pain, breathlessness (see 'Moving and positioning of the patient with respiratory compromise') or an existing kyphosis (anatomical convexity of the spine). **E**

To prevent excessive neck flexion. **E**

(continued)

Procedure guideline 6.1 Positioning the patient: supine (*continued*)

Action	Rationale
5 Ensure the patient lies centrally in the bed.	To ensure spinal and limb alignment. E To reduce the risk of falls by ensuring the patient is not too close to the edge of the bed. E
6 Place pillows and/or towels under individual limbs to provide maximum support for the patient with painful, weak or oedematous limbs.	To ensure patient comfort. E, P
7 Ensure the patient's feet are fully supported by the mattress. For taller patients use a bed extension if required.	To ensure patient comfort. E
8 Place a pillow at the end of the hospital bed to support the ankles at 90° of flexion if the patient has weakness or is immobile around the ankle.	To ensure patient comfort. E To prevent loss of ankle movement. E

Positioning the patient: sitting in bed**Evidence-based approaches****Rationale****Indications**

Patients should be encouraged to sit up in bed periodically if their medical condition prevents them from sitting out in the chair. If the patient is unable to participate fully in the procedure, manual handling equipment should be used to help achieve the desired position. Attention should also be given to sitting posture. Poor posture is one of the most common causes of low back pain which may

frequently be brought on by sitting for a long time in a poor position (McKenzie 2006) as it causes increased pressure in the disc (Claus et al. 2008).

Contraindications

Post lumbar puncture, patients should lie flat to prevent dural headache in accordance with local policy.

Spinal instability

Refer to 'Moving and positioning of the patient with actual or suspected spinal cord compression or spinal cord injury' (Procedure 6.14: Log rolling for suspected/confirmed cervical spinal instability).

Procedure guideline 6.2 Positioning the patient: sitting in bed

See Figure 6.4.

Essential equipment

- Pillows
- Manual handling equipment may be required, for example sliding sheets or a hoist, depending on local policy

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).

Procedure

4 Ask the patient to sit up in the centre of the bed. The angle at which the patient sits may be influenced by pain, fatigue, abdominal distension or level of confusion/agitation.	To reduce the risk of falls by ensuring the patient is not too close to the edge of the bed. To encourage haemodynamic (physical factors that govern blood flow) stability. E To enable effective breathing patterns, maximizing basal expansion (Pryor and Prasad 2008, R4).
5 Ask the patient to position their hips in line with the hinge of the automatic mattress elevator or backrest of the bed.	To assist in functional activities such as eating and drinking. E To ensure good postural alignment, that is, flexing at the hip when sitting up in bed. E To prevent strain on the spine. E

Figure 6.4 Sitting up in bed.

6 Place a pillow under the patient's knees or use the electrical control of the bed to slightly bend the patient's knees. Extra care should be taken if the patient has a femoral line or is on haemofiltration (a renal replacement therapy usually used to treat acute renal failure).

To reduce strain on the lumbar spine. **E**

To maintain the position. **E**

7 Place a pillow under individual or both upper limbs for patients with a chest drain, upper limb weakness, trunk weakness, surgery involving shoulder/upper limb/breast/thorax, fungating wounds involving axilla, breast and shoulder, upper limb/truncal lymphoedema or fractures involving ribs or upper limbs.

To provide upper limb support. **E**

To maintain trunk alignment. **E**

To encourage basal expansion (Pryor and Prasad 2008, **E**).

Positioning the patient: side-lying

Evidence-based approaches

Rationale

Indications

This can be a useful position for patients with:

- compromised venous return, for example; pelvic/abdominal mass, pregnancy
- global motor weakness
- risk of developing pressure sores
- unilateral pelvic or lower limb pain

- altered tone (see 'Moving and positioning the patient with neurological impairment')
- fatigue
- chest infection, for gravity-assisted drainage of secretions
- lung pathology (see 'Moving and positioning the patient with respiratory compromise')
- abdominal distension, for example ascites (intraperitoneal accumulation of a watery fluid), bulky disease, to optimize lung volume (see 'Moving and positioning the patient with respiratory compromise').

Contraindications

Suspected or actual spinal fracture or instability.

Procedure guideline 6.3 Positioning the patient: side-lying

See Figure 6.5.

Essential equipment

- Pillows
- Manual handling equipment may be required following risk assessment, for example sliding sheets or a hoist, depending on local policy

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands thoroughly or use an alcohol-based handrub.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, **E**).

(continued)

Figure 6.5 Side-lying.

Procedure guideline 6.3 Positioning the patient: side-lying (*continued*)

Action

- 3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.

Rationale

To minimize the risk of injury to the practitioner (Smith 2011, **C**).

Procedure

- 4 Place one or two pillows in a 'butterfly' position under the patient's head, ensuring the airway remains patent. Extra care should be taken for those patients with a tracheostomy, central lines or recent head and neck surgery.

To support the head in mid-position. **E**

To support shoulder contours. **E**

- 5 Ask/assist the patient to semi-flex the lowermost leg at the hip and the knee. Extra care should be taken with the degree of flexion for those patients who have hip or knee pain or loss of movement, fracture involving the femur or pelvis, leg oedema, femoral lines or other venous access devices. Ensure the patient is lying centrally in the bed.

To support the patient in a stable position and prevent rolling. **E**

To reduce the risk of falls by ensuring the patient is not too close to the edge of the bed. **E**

- 6 *Either:*

To prevent lumbar spine rotation. **E**

Ask/assist the patient to semi-flex the uppermost leg at the hip and knee. Use a pillow for support under the leg placed on the bed.

To support the pelvic girdle. **E**

Or:

Place a pillow between the patient's knees.

To aid pressure care. **E**

- 7 Place the underneath arm in front with scapula protracted, i.e. pushed forward position (this would not be appropriate for patients with shoulder pathology). Extra care should be taken with patients with low tone in the affected arm, swollen arms or who have access lines in that arm.

To promote patient comfort. **E**

To promote shoulder alignment. **E**

To provide additional support and comfort. **E**

Procedure guideline 6.4 Positioning the patient: lying down to sitting up

See Figures 6.6, 6.7 and 6.8.

Essential equipment

- Manual handling equipment may be required dependent on risk assessment, for example sliding sheets or a hoist, depending on local policy

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

- | | |
|--|---|
| 2 Wash hands thoroughly or use an alcohol-based handrub. | To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E). |
| 3 Ensure that the bed is at the optimum height for patients or handlers. If two handlers are required try to match handlers' heights as far as possible. | To minimize the risk of injury to the practitioner (Smith 2011, C). |
- Procedure**
- | | |
|--|---|
| 4 Ask the patient to bend both knees and turn their head towards the direction they are moving (see Figure 6.6). Abdominal wounds should be supported by the patient's hands. Extra care should be taken with patients who have joint pathology, oedema, ascites or positional vertigo (dizziness or giddiness). | To assist the patient to roll using their bodyweight. E |
| 5 Ask patient to reach towards the side of the bed with the uppermost arm and roll on to their side. | |
| 6 Ask the patient to bend their knees and lower their feet over the edge of the bed. | |
| 7 Ask the patient to push through the underneath elbow and the upper arm on the bed to push up into sitting (see Figure 6.7). As the patient sits up, monitor changes in pain or dizziness which could indicate postural hypotension or vertigo. Be aware that the patient with neurological symptoms or weakness may not have safe sitting balance and may be at risk of falling. | To help to lever the patient into a sitting position using the weight of their legs. E |
| 8 Achieve upright sitting position with appropriate alignment of body parts (see Figure 6.8). | To ensure safe sitting position achieved. E |

Figure 6.6 Lying to sitting (Action 4).

Figure 6.8 Lying to sitting (Action 8).

Figure 6.7 Lying to sitting (Action 7).

Positioning the patient: in a chair/wheelchair

Pre-procedural considerations

Equipment

Pressure cushion

This is a piece of equipment designed to evenly redistribute the weight of a patient to provide pressure relief for those who are vulnerable to skin breakdown. It is an effective aid to increasing patients' sitting tolerance. There are various types available and they are usually provided by the OT specific to the needs of the patient.

Procedure guideline 6.5 Positioning the patient: in a chair/wheelchair

Essential equipment

- Upright chair with arms that provide support from the elbow to wrist – if using a wheelchair, make certain that the chair has been measured where possible by an OT to ensure correct fit and position of the foot rests
- Manual handling equipment may be required following risk assessment, for example a hoist, depending on local policy
- Pillows/rolled-up towel
- Footstool if the patient has lower limb oedema (swelling)
- Pressure cushion

Procedure

Action	Rationale
1 Place a pressure cushion in the chair and ask the patient to sit well back in the chair. They should have a maximum 90° angle at their hips and knee joints. The patient may not be able to achieve this position if they have pain, abdominal distension or hip/back pain. It may be necessary to refer the patient to the OT for chair raises, a specialized cushion or appropriate seating if a comfortable or safe position cannot be achieved.	Patients with reduced mobility are at greater risk of pressure skin damage. To provide a stable base of support for balance and reduce the risk of falls. E To ensure good body alignment. E To achieve a safe sitting position. E
2 Place a pillow or rolled-up towel in the small of the patient's back as is comfortable for the patient.	To allow the patient's back to be supported in a good position. E
3 Ensure the patient's feet are resting on the floor or supported surface. Use pillows or a rolled-up towel to provide support under the feet if necessary. Make sure the patient's feet are supported on the foot rests if using a wheelchair.	To provide postural alignment and support the lumbar spine. E
4 If the patient has lower leg oedema, use a foot stool, ensuring the whole leg and foot are supported and avoiding hyperextension (defined as an excessive extension of a limb or joint) at the knees.	To improve venous drainage. E
5 Discourage the patient from crossing their legs.	To reduce risk of developing a DVT (O'Donovan et al. 2006, R4).

Moving the patient from sitting to standing

Pre-procedural considerations

If the patient stands from the side of a hospital bed, it is helpful to raise the bed slightly. This reduces the work of standing for the

patient, ensuring that the hips are level or higher than the knees with the feet in contact with the floor.
A physiotherapy referral may be appropriate.

Figure 6.9 Sitting to standing (Action 1).

Figure 6.10 Sitting to standing (Action 4).

Procedure guideline 6.6 Moving from sitting to standing: assisting the patient

See Figures 6.9 and 6.10.

Essential equipment

- Walking aid if required (if previously issued by physiotherapist)
- Suitable non-slip, well-fitting, supportive and flat footwear (if not available then bare feet are preferable to socks or stockings which may slip) (Figure 6.11)

Procedure

Action	Rationale
1 Ask the patient to lean forward and 'shuffle' (by transferring their weight from side to side) and bring their bottom closer to the front of the chair or edge of the bed (see Figure 6.9).	To bring the patient's weight over their feet. E
2 Ask the patient to move their feet back so they are slightly tucked under the chair with their feet hip width apart.	To provide a stable base prior to moving. E
3 Instruct the patient to lean forward from their trunk.	To help initiate movement. E
4 Instruct the patient to push through their hands on the arms of the chair or surface on which they are sitting as they stand (see Figure 6.10). Encourage a forward and upward motion whilst extending their hips and knees.	To facilitate a normal pattern of movement. E
5 Once standing, ask the patient to stand still for a moment to ensure balance is achieved before attempting to walk.	To minimize energy expenditure. E
	To ensure safe static standing and reduce the risk of falling. E

Walking

'Walking requires alternating support on one leg and then the other' (Gillis 1989).

Patients may use a variety of different walking aids to help them mobilize. All aids are designed to improve balance and therefore reduce the risk of falls.

It is assumed that patients will take equal amounts of body-weight through both legs, defined as being fully weight bearing

(FWB). If a patient has to be non-weight bearing (NWB) or partially weight bearing (PWB) this will be due to bone or joint pathology, e.g. fracture, joint instability, inflammation or infection. Restrictions in weight bearing should always be clearly documented and communicated by the medical staff. Weight bearing will also be affected by pain, weakness, sensory changes and confidence. If the patient has difficulty mobilizing, appears unsafe or is at risk of falling for any reason, refer for physiotherapy assessment.

(a)

(b)

Figure 6.11 Examples of a supportive shoe.

Procedure guideline 6.7 Assisting the patient to walk*Essential equipment*

- Walking aid if required (if previously issued by physiotherapist)
- Suitable non-slip, well-fitting, supportive and flat footwear (if not available then bare feet are preferable to socks or stockings which may slip) (see Figure 6.11)

Procedure

220

Action

- 1 Stand next to and slightly behind the patient. If patient requires support, place your arm nearest the patient lightly around their pelvis. Your other hand should hold the patient's hand closest to you. Observe changes in pain as the patient walks.
- 2 Give verbal supervision/cueing as required to achieve safe walking.

Rationale

- To give appropriate support. **E**
- To assess patient safety and reduce the risk of falls. **E**
- To increase patient confidence. **E,P**
- To provide encouragement. **E**
- To ensure patient safety. **E**

A physiotherapist will assess and issue the patient with an appropriate walking aid. All patients should be given verbal and written instructions on their use. If they are unsure please refer to the patient information sheets for instructions.

Problem-solving table 6.1 Prevention and resolution (Procedure guidelines 6.1, 6.2, 6.3, 6.4, 6.5, 6.6 and 6.7)

Problem	Cause	Prevention	Action
Increase in pain/nausea.	Change in posture and position of joints and soft tissues. Patients who are symptom-controlled at rest may suffer incidental pain when moving.	Pre-procedural symptom control. Ongoing assessment of symptoms and adjustment of medication.	Assist the patient to move slowly and offer support and reassurance where needed.
Change in medical status.	Change in position may cause a drop in blood pressure or trigger cardiovascular instability.	Monitor carefully.	Always have two people present if the patient is at risk of cardiovascular instability. Be prepared to return to original position.
Bowel/bladder elimination.	Change in position may stimulate bladder and bowels.	Put pads and pants on the patient before moving, where appropriate.	It may be necessary to stop and clean the patient before continuing to move or position.
Increase in loss of fluid, e.g. wound.	Change in position may cause breakdown of primary healing or increase in muscular activity which may increase fluid loss.	Give support to wounds during movement where possible.	Stop and alert medical team for assessment.
Loss of consciousness, fainting.	Change in position may cause decrease in blood pressure.	Allow adequate time for the patient to adjust to a more upright position. Sit patient up in bed and then sit over the edge of the bed and allow time for positional adjustment in blood pressure before attempting to stand.	Call for help and follow emergency procedure. Refer to local procedure for managing a falling patient.
Fall.	Multifactorial.	Risk assessment and planning.	Call for help and follow emergency procedure. Refer to local procedure for managing a falling patient.
Poor adherence to/tolerance of sitting position.	Discomfort, reduced tolerance, cognitive issues.	Use pillows/towels to ensure patient is well supported and comfortable. A timed goal often helps with patient compliance. Start with a short time, for example 30 minutes, and build up the time slowly. Always tell the patient how long they are aiming to sit out for and make sure the call bell is within reach.	Combine sitting out with a meal time as this can help the patient to eat more easily and also help to distract the patient from the length of time they have to sit out.
Inability to maintain the position.	Patients who are weak and/or fatigued may be at risk of slipping or falling.	Careful positioning of towels and pillows may be needed to maintain a central safe posture in the chair.	Observe the patient regularly.

Moving and positioning the unconscious patient

Definition

Consciousness is a state of awareness of self, environment and one's response to that environment. To be fully conscious means that the individual appropriately responds to the external stimuli. An altered level of consciousness represents a decrease in this full state of awareness and response to environmental stimuli (Boss 1998).

Anatomy and physiology

Physiological changes in the unconscious patient

Unconsciousness is a physiological state in which the patient is unresponsive to sensory stimuli and lacks awareness of self and the environment (Hickey 2009). There are many central nervous system conditions that can result in the patient being in an unconscious state. The depth and duration of unconsciousness span a broad spectrum of presentations from fainting, with a momentary loss of consciousness, to prolonged coma lasting several weeks, months or even years. The physiological changes that occur in unconscious patients will depend on the cause of unconsciousness, the length of immobility while unconscious, outcome and quality of care. Also drugs, for example some muscle relaxants such as those used in intensive care, can contribute to muscle weakness, raised intraocular and intracranial pressure, electrolyte imbalances and airway tone (Booij 1996). Unconsciousness can lead to problematic changes for patients which have implications for nursing interventions, including moving and positioning.

Evidence-based approaches

Principles of care

The general principles of care already mentioned earlier in the chapter are relevant to this section. However, there are some other general principles that also should be considered for these patients.

Sedation

In the critically ill patient, sedation is an essential part of the management. In addition to managing the primary neurological problem, the nurse must also incorporate a rehabilitation framework to maintain intact function, prevent complications and disabilities, and restore lost function to the maximum possible.

Communication

There is evidence that unconscious patients are aware of what is happening to them and can hear conversations around them (Jacobson and Winslow 2000, Lawrence 1995). It is therefore important to tell them what is going to happen; that they are going to be moved, and explain the procedure just as it would be explained to a conscious patient.

Immobility

The human body is designed for physical activity and movement. Therefore any lack of exercise, regardless of reason, can result in multisystem deconditioning, anatomical and physiological changes. Guidance from a physiotherapist for passive exercises early in the period of unconsciousness may help in the prevention of further complications. There is, however, no evidence to justify the inclusion of regular passive movements within the standard management of a patient's care. Intervention should be specific to the patient's presentation (Harrison 2000, Pryor and Prasad 2008).

The risk of deep vein thrombosis and pulmonary embolism is increased in the unconscious patient. This is due to several

factors including blood pooling in the legs, hypercoagulability and prolonged pressure from immobility in bed (Hickey and Powers 2009).

Effects of immobility of muscle

- *Decreased muscle strength*: the degree of loss varies with the particular muscle groups and the degree of immobility. The antigravitational muscles of the legs lose strength twice as quickly as the arm muscles and recovery takes longer.
- *Muscle atrophy*: this means loss of muscle mass. When the muscle is relaxed, it atrophies about twice as rapidly as in a stretched position. Increased muscle tone prevents complete atrophy so patients with upper motor neurone disease lose less muscle mass than those with lower motor neurone disease (Hickey and Powers 2009). For more information see 'Moving and positioning the neurological patient with tonal problems'.

Respiratory function

Due to the immobility of the unconscious patient, there is an increased threat of developing respiratory complications such as atelectasis, pneumonia, aspiration and airway obstruction. Respiratory assessment should be carried out prior to moving and changing position in order to provide a baseline that can be referred to following the procedure. The assessment should include checking patency of the airway, monitoring the rate, pattern and work of breathing, use of a pulse oximeter (an instrument for measuring the proportion of oxygenated haemoglobin in the blood) and measuring blood gases to assess adequacy of gaseous exchange.

Patients may require mechanical ventilation for the following reasons.

- Inability to ventilate adequately, for example post-anaesthesia or inspiratory muscle fatigue or weakness.
- Inability to protect own airway or presenting with upper airway obstruction.
- Ability to breathe adequately but may be inadvisable depending on diagnosis, for example with an acute head injury.

Mechanical ventilation may be required for days, weeks or even months (MacIntyre and Branson 2009). It is worth remembering that mechanically ventilated patients often cannot express any sort of preference for certain body positions. If the patient is intubated with an endotracheal tube, they are at increased risk of developing nosocomial infections (Hickey and Powers 2009) so it is important that lung volumes and respiratory mechanics should be continuously monitored (Hickey and Powers 2009). For more information see 'Moving and positioning the patient with respiratory compromise'.

Cardiovascular function

Immobility can cause changes in cardiovascular function, for example increased cardiac workload, decreased cardiac output and decreased blood pressure. In addition, the positioning of the unconscious patient will cause central fluid shift, from the legs to the thorax and head, so the head of the unconscious patient with raised intracranial pressure may need to be elevated to at least 30° (Hickey and Powers 2009).

Changes in cardiovascular function may be secondary to neurological changes so the patient's neurological function should be monitored. Hypovolaemia, which is a blood disorder consisting of a decrease in the volume of circulating blood, sepsis or cardiogenic shock, which occurs when there is failure of the pump action of the heart resulting in reduced cardiac output, are other factors that should be considered. This is because they will cause cardiovascular instability and should be treated accordingly (Geraghty 2005).

Moving and positioning the patient with an artificial airway

Definition

Some patients, whether unconscious or not, may not be able to maintain a ‘safe’ airway and therefore may require an artificial airway to support the respiratory system. Patients may have a particular airway depending upon their individual need and presentation. The different airways include:

- nasal
- endotracheal
- tracheostomy.

For more detailed information regarding these and other specific care issues and including anatomy and physiology, see Chapter 9: Respiratory care.

Evidence-based approaches

Principles of care

Maintaining a patent artificial airway

When moving patients with an artificial airway, it is important to maintain neutral head and neck alignment within the movement plane. It is sensible to have one member of staff in sole charge of looking after the patient’s artificial airway to avoid risks of trauma, dislodgement and occlusion and, if ventilated, prolonged disconnection from oxygen source. Changing position will also alter the neck musculature so it is important to ensure the tracheostomy tapes are tied securely before and after moving the patient.

With newly formed tracheostomies there is an increased risk of dislodgement 7–10 days following the procedure as the surrounding fascia and muscle need to repair to form the tract (Hough 2001). During this time it is important to have the following equipment by the patient’s bedside:

- tracheal dilators
- two spare tracheostomy tubes, one a size smaller
- tracheostomy tapes
- spare inner cannula

- inner tube cleaners, oxygen supply and tracheostomy mask
- humidification
- suction equipment
- Ambu-bag.

These are essential in case the patient’s airway is compromised (for guidance on how to use this equipment see Chapter 9: Respiratory care).

Emergency situations

The three most significant life-threatening emergency situations with a tracheostomy tube are blockage, displacement and haemorrhage. These are discussed in more depth in Chapter 9: Respiratory care. If any of these occur whilst moving your patient, stop and call for assistance immediately.

Staff should not be moving a patient with a tracheostomy, particularly a new tracheostomy, unless they are experienced in managing these emergency situations or working alongside someone who is.

Legal and professional issues

Consent

If an individual is unconscious, an understanding of the Mental Capacity Act 2005 is essential.

Pre-procedural considerations

It is important to ensure regular positional changes, as with any patient unable to move themselves (Harrison 2000), to help maintain pressure areas and reduce complications of prolonged bedrest. Ideally, the patient should be moved 2 hourly and positions alternated between side-lying and supine.

It is important to consider fitting antiembolic stockings on the patient if appropriate and in line with local trust policy. These help reduce the risk of venous thromboembolism (Geraghty 2005). See Chapter 13: Perioperative care.

Equipment

Artificial airway

If the patient has a tracheostomy, ensure the appropriate equipment is at the bedside (see Chapter 9: Respiratory care) and the tracheostomy tapes are tightly secured.

Procedure guideline 6.8 Positioning the unconscious patient or patient with an airway in supine

See Figures 6.12, 6.13, 6.14.

Essential equipment

- Manual handling equipment may be required following risk assessment, for example sliding sheets or a hoist, depending on local policy
- Pillows
- Towels
- Splints
- Bed extension for tall patients
- At least three members of staff to move patient; refer to local trust policy
- If patient has artificial airway, one extra staff member to be in charge of airway
- Appropriate emergency airway equipment at bedside in line with local trust policy

Pre-procedure

Action	Rationale
1 Explain the procedure to the patient. If the patient is alert and has an airway, ensure they understand the procedure and give their valid consent.	To inform the patient of the procedure, even if unconscious (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).

3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).
4 It is important to document the patient's vital signs prior to moving.	This will provide a baseline for any changes that may occur during the moving or positioning procedure.
Procedure	
5 Head: maintain proper alignment of head and neck; support with pillow or towel roll.	Helps to maintain a patent airway. P
6 Elevate the head of the bed by 30°.	Helps reduce the risk of nosocomial pneumonia (Drakulovic et al. 1999, R1b ; Methany and Frantz 2013). This facilitates the drainage of secretions from the oropharynx, minimizes the risk of aspiration, assists the maintenance of adequate cerebral perfusion pressure and promotes an effective breathing pattern (Hickey and Powers 2009, E).
7 Body: position in alignment with spine (utilize towels and pillows).	This helps to maintain correct alignment of the body and minimize complications such as contractures. It will also help to maintain musculoskeletal function (Geraghty 2005, E).
8 Limbs:	
<i>Upper:</i>	
Support arms and wrists on pillows and towels (see Figure 6.12) or splints (see Figure 6.13); flex the arms at the elbow.	To prevent shoulder drag and wrist drop (Geraghty 2005, E).
<i>Lower:</i>	
Place a pillow between the knees, use pillows or splints to flex the ankles parallel to the feet, align the hips with the head (see Figure 6.14).	To prevent skin breakdown and foot drop (Geraghty 2005, E). To prevent internal rotation of the upper leg (Hickey and Powers 2009, E).
Post-procedure	
9 Monitor colour, temperature and pulses of the limbs.	To enhance pulmonary function, prevent atelectasis and hypostatic pneumonia (Geraghty 2005, E) and to help preserve musculoskeletal function and prevent deep vein thrombosis (Hickey and Powers 2009, E).

Figure 6.12 Hand resting on towel.

Figure 6.13 Hand resting in splint.

Figure 6.14 Foot resting in splint.

Procedure guideline 6.9 Positioning the unconscious patient or patient with an airway in side-lying*Essential equipment*

- Manual handling equipment may be required following risk assessment, for example sliding sheets or a hoist, depending on local policy
- Pillows
- Towels
- Splints
- Bed extension for tall patients
- Minimum of three members of staff to move patient
- If patient has artificial airway, one extra staff member to be in charge of airway, and appropriate emergency equipment at bedside in line with local trust policy

Pre-procedure

Action	Rationale
1 Explain the procedure to the patient. If the patient is alert and has an airway, ensure they understand the procedure and are aware of what is going on.	To inform the patient of the procedure, even if unconscious (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
3 Ensure that the bed is at the optimal height for patients or handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).

Procedure

4 Place one or two pillows in 'butterfly' position under the patient's head, ensuring the airway remains patent. Extra care should be taken for those patients with a tracheostomy, central lines or recent head and neck surgery.	To support the head in mid-position. E To support shoulder contours. E
5 Ask/assist the patient to semi-flex the lowermost leg at the hip and the knee. Extra care should be taken with the degree of flexion for those patients who have hip or knee pain or loss of movement, fracture involving the femur or pelvis, leg oedema, femoral lines or other venous access devices.	To support the patient in a stable position and prevent rolling. E
6 <i>Either:</i> Ask/assist the patient to semi-flex the uppermost leg at the hip and knee. Use a pillow to support under the leg placed on the bed. <i>Or:</i> Place a pillow between the patient's knees.	To prevent lumbar spine rotation. E To support the pelvic girdle. E To aid pressure care. E
7 Place the underneath arm in front with scapula protracted (this may not be appropriate for patients with shoulder pathology). Extra care should be taken with patients with low tone in the affected arm, swollen arms or who have access lines in that arm.	To promote patient comfort. E To promote shoulder alignment. E To provide additional support and comfort. E

Problem-solving table 6.2 Prevention and resolution (Procedure guidelines 6.8 and 6.9)

Problem	Cause	Prevention	Action
Change in medical status.	With any change in position, transient changes in vital signs also occur.	It is essential, due to the patient's inability to communicate, that any changes in respiratory and cardiovascular status are closely monitored with any positional change or intervention (Harden 2008, Hough 2001).	If oxygen saturation (SaO ₂) drops and does not return to its usual value within 5 minutes, or heart rate (HR) increases or decreases by over 10 bpm and does not settle, the patient should be returned gently to the previous position (Hough 2001).
Joint muscle trauma.	Joints and muscles of the unconscious patient are relatively unprotected and prone to trauma (Pryor and Prasad 2008).	Ensure upon changing position that all limbs are in appropriate positions and not overstretched.	Once repositioned, ensure limbs are well supported.

Problem	Cause	Prevention	Action
Risk of excess pressures on body parts.	Body parts, such as ears, positioned without due care and attention.	Also if patient is in side-lying, ensure the ear is not twisted under the head (Hough 2001).	Move patient's head to change position of ear to a more comfortable position.
Artificial airway patency blocked.	Change of position of neck or of airway.	Ensure endotracheal/tracheostomy tube is secure. This may involve checking the cuff pressure and the endotracheal/tracheostomy ties (see Chapter 9: Respiratory care) as movement will alter the soft tissue distribution which will impact on these. Monitor vital signs closely to ensure return to normal values within 5 minutes of position change (Hough 2001).	Call for assistance immediately. Refer to Chapter 9: Respiratory care for more specific guidance on emergency management of the airway.

Post-procedural considerations

The general principles of care mentioned earlier in the chapter are relevant to this section. However, there are also some other general principles that need to be considered for these patients. It is important to ensure regular positional changes as with any patient unable to move themselves (Harrison 2000) to help maintain pressure areas and reduce complications of prolonged bedrest. Ideally, the patient should be moved 2 hourly and positions alternated between side-lying and supine.

Documentation

Alterations in level of consciousness, in cardiovascular and respiratory systems will also need to be recorded.

Moving and positioning the patient with respiratory compromise

Definition

The causes of respiratory compromise may be multifactorial and should be established before undertaking positioning interventions. Compromise may be due to medical intervention (e.g. side-effects of medication), metabolic, surgical or primary respiratory pathologies. The guidelines regarding principles of moving and positioning are applicable to these patients but particular observation is required regarding their response to the intervention.

Anatomy and physiology

Both skeletal and muscular structures that make up the thoracic cage and surround the lungs play a vital role in respiration (see Chapter 9: Respiratory care). Compromise of one or more of these (e.g. abdominal muscle dysfunction due to abdominal surgery, ascites or deconditioning) may lead to an alteration in normal respiratory function and the ability to generate an effective cough (Hodges and Gandevia 2000).

Evidence-based approaches

Principles of care

The main aim of positioning management of the patient with respiratory symptoms is to:

- maximize ventilation/perfusion (V/Q) matching
- minimize the work of breathing (WOB)
- maximize the drainage of secretions.

In many instances, positioning, as outlined above, may enhance medical management by the use of the effects of gravity upon the cardiovascular and respiratory systems. This may reduce the need for more invasive intervention (Jones and Moffatt 2002) such

as mechanical ventilation. Therefore, the most advantageous positioning should be integrated into the overall 24-hour plan, and positions that may have an adverse effect should be avoided (Bott et al. 2009).

The general principles of care mentioned earlier in the chapter are all relevant to this aspect of care.

Positioning to maximize ventilation/perfusion matching

Definition

For optimal gaseous exchange to take place, it is necessary that the air and the blood are in the same area of lung at the same time. Matching of these is expressed as a ratio of alveolar ventilation to perfusion (V/Q). A degree of mismatch can occur either due to adequate ventilation to an underperfused area (dead space) or inadequate ventilation to a well-perfused area (shunt) (West 2012).

Anatomy and physiology

The function of the lungs is to exchange oxygen and carbon dioxide between the blood and atmosphere. Oxygen from the atmosphere comes into close contact with blood via the alveolar capillary membrane. Here it diffuses across into the blood and is carried around the body. The amount of oxygen that reaches the blood depends on the rate and depth of the breath, the compliance of the chest and any airway obstruction (Lumb and Nunn 2010).

In a self-ventilating individual in the upright position, ventilation will be preferential in the dependent regions as:

- the apex of the lung is more inflated and therefore has less potential to expand
- the bases of the lung are compressed by the weight of the lungs and the blood vessels and therefore have more potential to inflate.

Perfusion to the alveoli is approximately equal to that of the systemic circulation but as the pressure is far less, the distribution is gravity dependent. The variability in the distribution of perfusion throughout the lung is far greater than that of ventilation (West 2012).

Evidence-based approaches

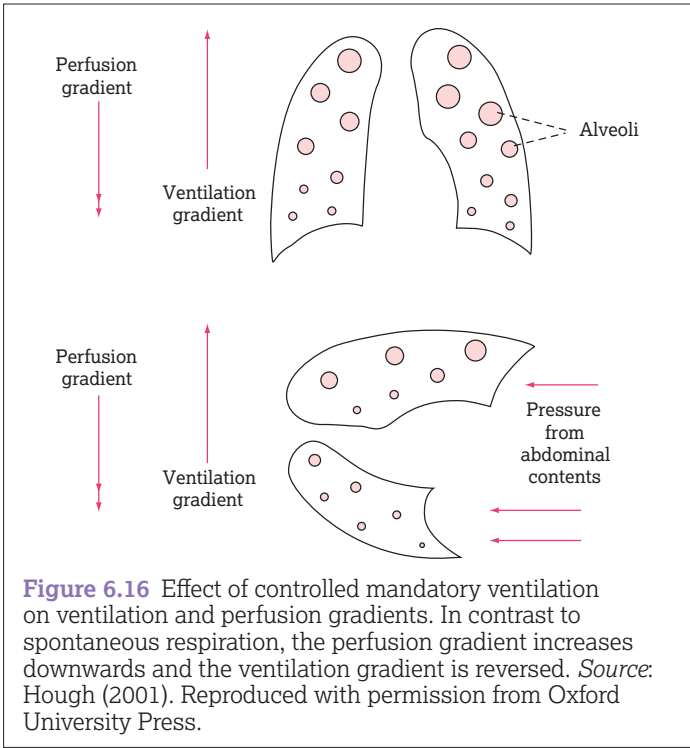

Principles of care

In a self-ventilating upright position, V/Q is not exactly matched even in a healthy lung but is regarded as optimal in the bases (Figure 6.15) as there is the greatest perfusion and ventilation. Similarly in a side-lying position, the effect of gravity alters the distribution of perfusion and ventilation so that the dependent area of lung, that is, the bottom of the lung, has the best V/Q ratio (West 2012).

In a patient receiving mechanical ventilation, especially in a mandatory mode (where the ventilator rather than the patient initiates

and terminates the breath), the distribution of ventilation and perfusion will alter (Figure 6.16). As ventilation is driven by a positive pressure, rather than the negative pressure when self-ventilating, air will take the path of least resistance. Ventilation will therefore be optimal in the apex of the lungs in the upright position or the non-dependent/uppermost lung in side-lying. This can, however, be altered further in the presence of lung pathology. Perfusion will remain preferentially delivered to the bases (in the upright position) or the dependent/lowermost lung (in side-lying) and have a higher gradient (variability from apex to bases) than in self-ventilating patients as the positive pressure displaces blood from areas of highest ventilation. These two situations mean that the V/Q ratio of those receiving mechanical ventilation can have a higher degree of mismatch. Strategies such as positive end-expiratory pressure (PEEP) and a higher oxygen delivery will help to overcome this (West 2012).

Pre-procedural considerations

The general principles of care mentioned earlier in the chapter are all relevant to this section. However, there are also some other general principles that need to be considered for these patients.

Pharmacological support

Oxygen requirements

Repositioning can cause a temporary fall in oxygen saturation or a raised respiratory rate. If the fall is greater than 4% or recovery time is protracted, supplemental oxygen delivery may be required for several minutes before, during and after moving.

Procedure guideline 6.10 Positioning the patient to maximize V/Q matching with unilateral lung disease in a self-ventilating patient	
Essential equipment <ul style="list-style-type: none">• Pillows/towels• Sliding sheets/manual handling equipment if indicated following risk assessment in accordance to local manual handling policy• Bed extension for tall patients	
Pre-procedure	
Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraiese and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).
Procedure	
4 Position in side-lying on the unaffected side. Refer to the general principles of moving and positioning the patient in side-lying (see Procedure guideline 6.3: Positioning the patient: side-lying).	Ventilation and perfusion are both preferentially distributed to the dependent areas of lung.

Procedure guideline 6.11 Positioning the patient to maximize V/Q matching for widespread pathology in a self-ventilating patient

Essential equipment

- Pillows/towels
- Sliding sheets/manual handling equipment if indicated following risk assessment in accordance with local manual handling policy
- Bed extension for tall patients

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands thoroughly or use an alcohol-based handrub.
- 3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, **E**).
- To minimize the risk of injury to the practitioner (Smith 2011, **C**).

Procedure

- 4 Position the patient in high sitting as discussed in the general principles of moving and positioning of the patient in sitting in bed or chair (see Procedure guideline 6.2: Positioning the patient: sitting in bed and Procedure guideline 6.5: Positioning the patient: in a chair/wheelchair).

The effects of shunting mean perfusion will best match ventilation in high supported sitting (Dean 1985, **R4, E**).

Problem-solving table 6.3 Prevention and resolution (Procedure guidelines 6.10 and 6.11)

Problem	Cause	Prevention	Action
Reduced oxygen saturations. This will be evident by looking at the saturation level on the oximeter (measures the proportion of haemoglobin in the blood) if present, or by observing the patient's colour and work exerted by breathing.	Movement causes an increase in oxygen demand from the tissues. If this is not matched by adequate delivery then saturation levels will be lower.	Preoxygenate prior to movement if patient is requiring high levels of oxygen or is ventilated.	Increase the concentration of oxygen delivered until satisfactory saturations are achieved. Aim to reduce this as much as possible but consider that a higher level of oxygen may be required in the altered position. If this is still not tolerated, return the patient to previous position.
Raised or tense shoulders/increased effort in breathing.	Use of accessory muscles to assist with respiration.	Use pillows/towels to support upper limbs in positions where they are not able to actively fix and thereby alter their function.	Reassurance to patient. Increase oxygen concentration until respiratory rate returns to normal. If position remains poorly tolerated, return to the previous position.

Positioning to minimize the work of breathing

Anatomy and physiology

At rest, inspiration is an active process whereas expiration is passive. The main muscle involved in inspiration is the diaphragm (Figure 6.17). The diaphragm contracts, thereby increasing the volume of the thoracic cavity. Additionally, the external intercostals work by pulling the sternum and ribcage upwards and outwards, likened to a pump and bucket handle (Figure 6.18). When increased ventilation is required (e.g. with exercise or in disease), the accessory muscles (scalenes and sternocleidomastoid) assist with this process (Lumb and Nunn 2010).

If this situation is prolonged, as in respiratory disease, the diaphragm activity reduces and the accessory muscles have to do a higher proportion of the work. This can be observed in a patient who adopts a posture of raised shoulders.

Although expiration should be passive in normal conditions, the internal intercostals and muscles of the abdominal wall (transversus abdominis, rectus abdominis and the internal and external obliques) are utilized in times of active expiration to push the diaphragm upwards, reducing the volume of the thoracic cavity and forcefully expelling air. This can be observed clinically when the abdominal wall visibly contracts and pulls in the lower part of the ribcage during expiration (Lumb and Nunn 2010).

Evidence-based approaches

Principles of care

Many people suffering with long-term breathlessness adopt positions that will best facilitate their inspiratory muscles (Bott et al. 2009). The aim of any position is to restore a normal rate and depth of breathing in order to achieve efficient but adequate ventilation (Box 6.2 [citing Figure 6.19]).

Figure 6.17 The diaphragm as seen from the front. Note the openings in the vertebral portion for the inferior vena cava, oesophagus and aorta.

Box 6.2 Positioning to minimize the work of breathing

There are certain resting positions that can help reduce the work of breathing, as shown in Figure 6.19.

- 1 High side-lying (see Figure 6.19a)
- 2 Forward lean sitting (see Figure 6.19b)
- 3 Relaxed sitting (see Figure 6.19c)
- 4 Forward lean standing (see Figure 6.19d)
- 5 Relaxed standing (see Figure 6.19e)

These positions serve to:

- support the body, reducing the overall use of postural muscle and oxygen requirements
- improve lung volumes
- optimize the functional positions of the respiratory (thoracic and abdominal) muscles (Dean 1985).

Pre-procedural considerations

The general procedural considerations mentioned earlier in the chapter are all relevant to this section. However, there are also some other general principles that need to be considered for these patients.

Pharmacological support

Administering nebulizers

If prescribed, administering nebulizers approximately 15 minutes prior to moving will help to dilate the airways, making breathing more efficient and ensuring better oxygen delivery to the blood.

Oxygen requirements

Repositioning can cause a temporary fall in oxygen saturation or a raised respiratory rate. If the fall is greater than 4% or recovery time is protracted, supplemental oxygen delivery may be required for several minutes before, during and after moving.

Non-pharmacological support

Pacing

It may be necessary to allow the patient time to rest during the process of getting into a new position to limit the exertion and therefore increased respiratory demand.

Environment

A breathless patient may be anxious about carrying out a task that could exacerbate their breathlessness. By reducing additional stressors such as noise and a cluttered environment, this can be minimized.

Positioning to maximize the drainage of secretions

Anatomy and physiology

The trachea branches into two bronchi, one to each lung (Figure 6.20). Each main bronchus then divides into lobar and then segmental bronchi (upper, middle and lower on the right, upper and lower on the left), each one branching into two or more segmental bronchi with a smaller and smaller diameter, until they reach the bronchioles and finally the alveoli (Tortora and Derrickson 2011).

The walls of the airways are lined with epithelium which contains cilia. The cilia constantly beat in a co-ordinated movement, propelling the mucus layer towards the pharynx. The mucus layer traps any dust particles/foreign objects which can then be transported along the 'mucociliary escalator', an important part of the lungs' defence mechanism. An increased volume of mucus is produced in response to airway irritation and in some disease states (Lumb and Nunn 2010).

Figure 6.18 Movement of chest wall on inspiration. (a) The upper ribs move upwards and forwards, increasing the anteroposterior dimension of the thoracic cavity. As a result, the sternum also rises forwards. (b) The lower ribs move like bucket handles, increasing the lateral dimension of the thorax. *Source:* Aggarwal and Hunter (2007). Reproduced with permission from BMJ Publishing Group Ltd.

Figure 6.19 Positions to support breathing.

Figure 6.20 The bronchial tree. *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

A reduced ability to effectively remove this mucus can lead to an increased bacterial load and therefore may compromise respiratory functioning by causing airway obstruction. Consequently leading to segmental atelectasis or lobar collapse, long term this can lead to chronic inflammation and airway destruction (Lumb and Nunn 2010).

Pre-procedural considerations

The general principles of care mentioned earlier in the chapter and the pre-procedural considerations to minimize the work of breathing are all relevant to this section. However, there are also some other pre-procedural considerations that need to be taken into account for these patients.

Procedure guideline 6.12 Positioning to maximize the drainage of secretions

Essential equipment

- Pillows/towels
- Sliding sheets/manual handling equipment if indicated following risk assessment in accordance with local manual handling policy
- Bed extension for tall patients

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands thoroughly or use an alcohol-based handrub.
- 3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, **E**).
- To minimize the risk of injury to the practitioner (Smith 2011, **C**).

Procedure

- 4 Auscultate the chest.
- 5 Position patient with segment to be drained uppermost.
- 6 Leave to drain for 10 minutes if tolerated.
- 7 Physiotherapy techniques such as breathing/manual techniques may be carried out whilst in position.

- To determine most affected area and therefore area to be treated. **E**
- Use gravity to facilitate drainage of secretions. Bronchopulmonary segment needs to be perpendicular to gravity. **E**
- Suggested optimal duration (Fink 2002, **R**).
- To further assist the removal of secretions. **E**

Problem-solving table 6.4 Prevention and resolution (Procedure guideline 6.12)

Problem	Cause	Prevention	Action
Reduced oxygen saturations. This will be evident by looking at the saturation level on the oximeter, if present, or by observing the patient's colour and work exerted by breathing.	Movement causes an increase in oxygen demand from the tissues. If this is not matched by adequate delivery then saturation levels will be lower. Positions to drain secretions may not comply with positions to match V/Q.	Preoxygenate prior to movement if patient is requiring high levels of oxygen or is ventilated.	Increase the concentration of oxygen delivered until satisfactory saturations are achieved. Aim to reduce this as much as possible but consider that a higher level of oxygen may be required in the altered position. If this is still not tolerated, return the patient to previous position.
Large volume of secretions/increased audible secretions/coughing.	Drainage of distal secretions into more proximal airway.	Clear airway prior to movement. Regular airway clearance following movement.	Clear airway of any secretions either by coughing or suctioning.

Non-pharmacological support

Humidification

Drainage of secretions will be optimized if the patient and therefore the mucus layer and cilia are well hydrated. This can be ensured by adequate humidification (see Chapter 9: Respiratory care).

The problem-solving, post-procedural considerations and complications in general principles of moving and positioning patients and respiratory compromise also apply to these patients. Refer to relevant sections in this chapter.

Moving and positioning the patient with neurological impairment

The general principles of positioning discussed earlier can be applied for this group of patients. However, the complexity of these patients highlights the difficulty of a uniform approach to overall management. Therefore, this section will look at some of the variations in presentation of this patient group and suggest some principles to be considered when positioning these patients.

This will cover recommendations for assisting patients presenting with physical neurological symptoms affecting their central nervous system (CNS) and peripheral nervous system (PNS) as a consequence of their disease or treatment itself. These may include:

- hemiparesis (weakness or paralysis affecting one half of the body, also known as hemiplegia) or monoparesis (weakness or paralysis affecting one limb)
- hemi-aesthesia (sensory loss affecting one half of the body, also known as paraesthesia)
- peripheral motor/sensory neuropathies (dysfunction or pathology affecting one or more peripheral nerves resulting in altered movement or sensation)
- spinal cord compression/injury.

Definition

Neurological insult through disease or illness can cause damage to patients' central, peripheral and autonomic nervous systems, affecting the relay of messages along nerve pathways and preventing normal motor and sensory function. Sequelae associated with neurological deficit include altered muscle tone, abnormal movement patterns, sensory, cognitive (the mental processes involved in gaining knowledge and comprehension, including thinking, knowing, remembering, judging, problem solving, imagination, perception and planning), perceptual (interpretation of sensation into meaning) and speech and language problems.

Anatomy and physiology

The nervous system is a complex organ which allows us to automatically and volitionally adjust to internal and external environments. This maintains equilibrium of body systems and enables effective, efficient motor and cognitive function. It can be considered in three main areas: central nervous system, peripheral nervous system and autonomic nervous system (ANS). The CNS consists of two parts: the brain and spinal cord. The brain consists of four lobes (frontal, temporal, parietal and occipital), the midbrain, pons, medulla oblongata and cerebellum. Each has individual and joint roles, and interconnects with the others via a complex system of pathways producing automatic and volitional movement and cognitive function. These connect with every part of the body via the PNS, consisting of cranial and spinal nerves which carry motor (efferent) and sensory (afferent) fibres (see Chapter 11: Observations). The ANS, made up of sympathetic and parasympathetic components, regulates structures not under conscious control, for example arterial blood pressure, gastrointestinal motility and secretion, urinary bladder emptying, sweating, body temperature, and is activated mainly by centres in the brainstem, spinal cord and hypothalamus. Illness, disease and/or side-effects of treatment can affect any or all of these systems which will have implications for clinical practice and patient management.

Related theory

Disease or damage to the central or peripheral nervous system can lead to temporary or permanent complex physical, cognitive, psychological and psychosocial problems (BNOS/DH 2011, Carr et al. 2008, Formica et al. 2011, Lindsay et al. 2011, NICE 2006). These may include:

- weakness – unilateral, bilateral or global
- altered muscle tone
- sensory changes
- balance problems
- perceptual problems
- visual problems
- cognitive problems
- dysphagia (an impairment of swallowing that may involve any structures from the lips to the gastric cardia)
- dysphasia (an acquired communication disorder that impairs a person's ability to process language in verbal or written forms. It does not affect intelligence but does affect how someone can

Box 6.3 The physical benefits of movement

- Sensorimotor appreciation.
- Posture and balance control.
- Maintenance of joint and soft tissue range of movement.
- Maximization of functional independence.
- Minimization of tonal changes such as spasticity (Hawkins et al. 1999).
- Cardiorespiratory fitness (Convertino et al. 1997).

use language either temporarily or permanently. It does not include speech impairments caused by damage to the muscles involved with speech – that is dysarthria)

- dysarthria (a speech disorder resulting from motor weakness, inco-ordination or stiffness of muscles used for speaking)
- autonomic dysfunction
- behavioural changes.

If a person with a neurological presentation is unable to move, they are deprived of the physical benefits of movement (Box 6.3) and are at risk of developing secondary complications including joint contractures.

Effective management of patients with neurological impairment requires holistic assessment including consideration of altered tone, abnormal patterns of movement, joint protection and prevention of soft tissue changes and contractures.

Altered tone and abnormal patterns of movement

Tone is defined clinically as 'the resistance that is encountered when the joint of a relaxed patient is moved passively' (Britton and Ng 1998). Alterations in tone will affect functional recovery in patients with neurological problems and require careful management. This can be through positioning, splinting if required and oral and focal pharmacological intervention (Barnes 2008).

Increased tone and spasticity are disorders of spinal proprioceptive reflexes. Spasticity is defined as:

'a motor disorder characterised by a velocity dependent increase in tonic stretch reflexes (muscle tone) with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of the upper motor neurone syndrome.' (Barnes 2008, p.1)

Normal movement is dependent on a neuromuscular system that can receive, integrate and respond appropriately to multiple intrinsic and extrinsic stimuli. Key components include:

- normal postural tone
- reciprocal innervation of muscles
- sensory-motor feedback and feedforward mechanism (Duff et al. 2012)
- balance reactions (Edwards 2002b)
- biomechanical properties of muscle (Edwards 1998).

Where any of these components are altered through CNS or PNS disease, abnormal movement patterns will exist which will affect the patient's functional ability. Positioning and active movement are key in managing the influence of altered tone and abnormal patterns of movement in the recovery of motor control in patients with neurological problems.

Joint protection

Positioning is suggested as a strategy to prevent pain and to prevent loss of range of movement for patients with low tone (hypotonia), particularly around the shoulder (Ada et al. 2005, Dean et al. 2000, Kaplan 1995). This aims to prevent the patient's functional deterioration (Gloag 1985). Dean et al. (2000) identified that these complications often prevent a patient's full participation

in rehabilitation, contributing to poor upper limb functional outcome. Several factors were described for this.

- Glenohumeral subluxation due to lack of muscular activity around the shoulder.
- Trauma to the shoulder complex through unsuitable exercise.
- Trauma through inappropriate handling of the patient by staff during transfers.

232 Dean et al. (2000) acknowledged that consistency in education is essential to address these common problems. Ada et al. (2005) recommended that patients with little upper limb function in the early stages after a stroke undergo a programme of positioning of the affected shoulder. Their study showed statistical significance in maintaining shoulder range when compared with patients who received standard upper limb care of arm support and exercise only. Such specific joint positioning requires assessment by the physiotherapist for each individual patient.

Soft tissue changes and contractures

Joint range and subsequent function are at risk with increased tone (hypertonia). Restriction in the range of movement is not always simply due to increased tone of the relevant muscles. The surrounding soft tissues, tendons, ligaments and the joints themselves can develop changes leading to an increased likelihood of them being maintained in a shortened position (Barnes 2008). Adaptation of the mechanical properties of muscle also contributes to increased tone in patients with hypertonia (O'Dwyer et al. 1996). It is possible, but not proven, that maintaining a joint through a full range of movement may prevent the longer-term development of soft tissue contractures (Barnes 2008).

Professionals agree that positioning is a key element in the rehabilitation and management of patients with neurological deficit (Davies 2000, Edwards and Carter 2002, Raine et al. 2009, Stokes and Stack 2012). An optimal position is not always possible due to variables such as the patient's medical condition and presence of contractures (Edwards 1998). There appears to be an overall lack of consensus in clinicians' actual practice regarding the key components of the positions necessary to limit the onset of spasticity (Chatterton et al. 2001, Jackson 1998, Mee and Bee 2007). However, prevention of complications is an important aim (Bobath 1990, Davies 2000, Edwards and Carter 2002, Mee and Bee 2007, Raine et al. 2009). Stokes and Stack (2012) describe positioning in bed and Pope (2002) details positioning in sitting with principles of optimum alignment to prevent secondary complications such as pain, and to optimize function such as socialization. Edwards (1998) recommends a variety of postures especially for patients with hypertonia.

Evidence-based approaches

Principles of care

The general principles of care mentioned earlier in the chapter are all relevant to this section. However, there are some additional principles that need to be considered for these patients. For those with acute and long-standing neurological issues, principles of moving and positioning can be applied at any time along their treatment trajectory from undertaking rehabilitation, experiencing deteriorating function or those requiring palliative management. Posture and postural control will be affected in these patients. 'Posture' describes the biomechanical alignment and orientation of the body to the environment (Duff et al. 2011), whilst 'postural control' provides orientation and balance (Lundy-Ekman 2007). Positional influences in the patient with neurological impairment may affect spinal, pelvic and shoulder girdle alignment with risk of soft tissue shortening due to the following potential problems.

- Flattened lumbar spine.
- Extended thoracic spine.
- Pelvis tilted backwards.
- Retracted hip.

- Elevated shoulder, retracted scapula.
- Feet tend toward plantarflexion (Duff et al. 2011).

Therefore, additional considerations should be applied for the neurological patient with severe tonal management issues. These should always be discussed with the physiotherapist.

Pre-procedural considerations

The general principles of moving and positioning patients can be applied when assisting those with complex neurological impairment. Patients with neurological impairment may be able to participate in usual transfer techniques but risk assessment will consider several additional factors. This section will identify considerations for staff in their decision making. Where there is any doubt when moving patients with complex needs, guidance should be sought from a physiotherapist/occupational therapist.

Risk management

Patients with neurological deficits may vary in their presentation on a daily basis. The additional considerations for positioning and moving patients with neurological impairment are listed in Box 6.4.

Equipment

Splints and orthoses

In advanced spasticity, it is often the soft tissue changes that contribute most to subsequent disability, such as limb deformity leading to poor function and problems with regard to hygiene, positioning, transferring and feeding and making the individual prone to pressure sores (O'Dwyer et al. 1996). Therapeutic splinting may maintain and assist function (Edwards 1998, Raine et al. 2009, Shumway-Cook and Woollacott 2012).

An orthosis or splint is an external device designed to apply, distribute or remove forces to or from the body in a controlled manner in order to control body motion and prevent alteration in the shape of body tissues (see Figure 6.13 and Figure 6.14). The aim is to compensate for weak or absent muscle function or to resist unopposed action of spastic muscle (Charlton 2009). They may help gain alignment for proximal and truncal activity (Raine et al. 2009) and enable more balanced and efficient walking (Hesse 2003). As

Box 6.4 Considerations for moving patients with neurological impairment

- Variations in tone, for example flaccidity or spasm.
- Cognitive problems including attention deficit.
- Behavioural problems.
- Communication problems.
- Variable client ability, for example 'on/off' periods for patients with Parkinson's disease and patients with changing presentations, for example multiple sclerosis, degenerative conditions.
- Sensory and proprioceptive problems, including reduced midline awareness.
- Pain/altered sensitivity.
- Decreased balance and co-ordination.
- Visual disturbance.
- Varying ability over 24 hours, for example, fatigue at the end of the day, at night.
- Effects of medication.
- Varying capability of the patient according to the experience and/or skill mix of handler(s).
- Post-surgery, presence of tracheotomy, chest and other drains.
- Traumatic and non-traumatic spinal injury – risk of spinal instability.
- Importance of maintaining privacy and dignity.

Source: CSP (2014). Reproduced with permission from The Chartered Society of Physiotherapy (www.csp.org.uk).

with all therapeutic interventions, they should only be used after detailed assessment and based on sound clinical reasoning.

If a splint or an orthosis is required, then this will normally be provided and fitted by a physiotherapist and/or occupational therapist. They will also give instructions on how to use it.

Seating

Appropriate seating is also advocated as an adjunct to management for effective postural support (Kirkwood and Bardsley 2001, Pope 2002, Raine et al. 2009). Occupational therapists and physiotherapists will consider this for management of patients with complex needs and provide appropriate seating if required.

Environment and positioning

Problems of perception (interpretation of sensation into meaningful forms) are considered to be one of the main factors limiting functional motor recovery following stroke (Verheyden and Ashburn 2012). These can affect patients with disease or illness affecting their CNS. Here, the patient fails to respond appropriately to stimuli presented on their hemiplegic side, the contralateral side to the brain lesion (Verheyden and Ashburn 2012). Environmental factors such as correct positioning are essential for ensuring optimal level of function for each individual (Edwards 2002a, Pope 2002). Clinical management strategies include:

- addressing the patient from the affected side
- deliberate placement of items of interest to the patient on that side (with appropriate assistance to access those items, e.g. drinks)
- advice to carers to position themselves on the patient's affected side whilst talking to them in order to orientate them to their affected side
- positioning the patient on their affected side, enabling function with their sound side.

Limited evidence exists to suggest the benefit of these approaches (Verheyden and Ashburn 2012). However, it is recognized as a useful treatment adjunct for these patients, through promotion of sensory awareness/appreciation, including perception and body image and enabling function (Edwards and Carter 2002, Grieve and Gnanasekaran 2008, Raine et al. 2009, Stokes and Stack 2012).

Rehabilitation opportunity

Patients with neurological illness or disease present with an assortment of clinical symptoms. Positioning can assist in their holistic management and allow future opportunity for rehabilitation where their illness or disease allows. For example, the Department of Health (DH 2013) identifies the importance of early rehabilitation for patients with cancer.

Procedure guideline 6.13 Positioning the neurological patient with tonal problems

Essential equipment

- Pillows or towels (as guidance or basic positioning)

Optional equipment

- Hand/foot resting splint if required
- Resting splint if required

Medicinal products

- Analgesia as required
- Antispasmodics as required

Pre-procedure

Action	Rationale
1 Explain the procedure to the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraiese and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).

Procedure

4 Follow basic advice for positioning the patient in supine, side-lying and sitting in bed as described in the above procedure guidelines for positioning patients.	To promote alignment of body segments and support against gravity for patients with high or low tone resulting in asymmetrical posture (Edwards and Carter 2002, E ; Stokes and Stack 2012, R4). To ensure patient comfort. E
5 Consider and apply possible modifications as specified below for the supine (Action figure 5). • Place pillow under hemiplegic hip for alignment. • Place additional pillows or wedge under knees and/or head.	To control pelvic and spinal alignment. E To optimize patient comfort. E To maintain joint and soft tissue range (ACPIN 1998, C , E ; Barnes 2001, R4 ; Edwards 1998, E).
6 Place pillow to support feet in neutral/plantargrade position. • Apply foot resting splint, ankle foot orthosis (AFO) (Action figure 6 and see Figure 6.14) if recommended to weak foot and ankle. NB: Ensure the splint is fitted correctly. • Place pillow under weak arm. • Apply resting splint for hand/forearm if required.	To maintain soft tissue and joint range (Duff et al. 2011, E ; Edwards 1998, E).

(continued)

Procedure guideline 6.13 Positioning the neurological patient with tonal problems *(continued)*

Action	Rationale
<p>7 Consider and apply possible modifications as specified below for side-lying (Action figure 5b).</p> <ul style="list-style-type: none">• Place pillow under head and in front of trunk.• Place pillow in front of trunk.• Place patient's affected arm on pillow. Apply resting splint for hand/forearm if required.	<p>To support the patient's affected shoulder and upper limb due to a risk of trauma, pain, muscle and soft tissue shortening (Ada et al. 2005, R2b; Dean et al. 2000, R2b).</p> <p>To reduce the influence of asymmetrical posturing of head and trunk in patients with high or low tone. Action Figure 5 Positioning the patient with neurological weakness. (a) Supine: affected arm supported on pillow. (b) Side-lying: affected arm supported on pillow.

Action Figure 6 (a) Ankle foot orthosis (AFO). (b) Ankle foot orthosis *in situ*.

Problem-solving table 6.5 Prevention and resolution (Procedure guideline 6.13)

Problem	Cause	Prevention	Action
Unable to position patient's legs in bed due to increased tone – legs remain 'stiff'.	Abnormal tone (high or low) affecting limbs secondary to CNS involvement (cortical/spinal).	Assess for other noxious stimuli which may increase tone in patients with CNS disease. Ensure pain control. Ensure bowel management. Ensure effective catheter drainage. Assess for infection.	Use leg flexion position in bed control. And/or: Position small folded pillow/rolled towel under patient's knees. Avoid contact of patient's feet against end of bed – this can stimulate increased tone in legs. Liaise with physiotherapist.
Unable to achieve comfortable position for patient with CNS involvement. Patient's limbs may demonstrate persistent increased tone despite positioning.	Possible causes: • inadequate pain control • inadequate antiepilepsy medication • other noxious stimuli.	Assess for other noxious stimuli which may increase tone in patients with CNS disease. Ensure pain control. Ensure bowel management. Assess for infection.	Reassess patient. Ensure adequate analgesia. Ensure adequate antiepilepsy medication. Consider a medical review.
Patient's arm remains flexed/unable to position in bed.	Abnormal tone (high or low) affecting limbs due to CNS involvement.		Position small flat pillow under patient's affected arm to provide support Or: Position small flat pillow across patient's abdomen to support both upper limbs. Use of resting splint if indicated for patient management – liaise with physiotherapist and/or occupational therapist.
Patient is unaware of affected side.	Sensory/motor inattention.		Ensure patient's environment is made available to them. Ensure affected limbs are supported by pillows/folded/rolled towel as required (refer to positioning for patients with neurological deficits).

Post-procedural considerations

Ongoing care

Where the patient requires use of a splint to maintain joint range and position, skin integrity must be closely monitored (see Chapter 15: Wound management), including skin/pressure care, and any adverse effects treated accordingly following assessment. The instructions for the use of the splint (usually provided by the PT or OT) should specify the recommended length of time that the splint should be applied and the periods of rest from wear. If skin integrity is compromised due to pressure from the splint, it should be reviewed by the dispensing professional before continuing with its use.

Moving and positioning of the patient with actual or suspected spinal cord compression or spinal cord injury

Definition

Spinal cord compression or injury is when the function of the spinal cord becomes compromised.

Anatomy and physiology

The spinal cord is about 45 cm in length and extends from the base of the brain, surrounded by the vertebrae, to the pelvis.

Nerves situated within the spinal cord, called upper motor neurones (UMNs), carry the messages between the brain and spinal nerves along the spinal tract. Spinal nerves are classified as lower motor neurones (LMNs). Spinal nerves branch out from the spinal cord at each vertebral level to communicate with specific areas of the body.

Following damage to the spinal cord through traumatic vertebral displacement or tumour/oedema growth, 'spinal shock' may occur, which is a temporary suppression of spinal cord activity caused by oedema at and below the level of the lesion in spinal cord injury. Within the confines of the vertebral canal, the oedematous cord is compressed against the surrounding bone. A complex series of physiological and biochemical reactions occur due to resulting oedema and vascular damage. Circulation of blood and oxygen is disrupted; ischaemic tissue necrosis follows with an immediate cessation of conductivity within the spinal cord neurones. This can persist for 2–6 weeks (Harrison 2000).

Related theory

Spinal cord compression or injury encompasses the following.

- **Traumatic spinal cord injury (SCI).** This is damage or trauma to the spinal cord that results in loss of or impaired function causing reduced mobility or feeling. The spinal cord does not have to be severed in order for a loss of functioning to occur. Common causes include trauma (for example, car accident, gunshot, falls, sports injuries) or disease (for example, transverse

myelitis, polio, spina bifida, Friedreich's ataxia). It is estimated that 500–700 people sustain traumatic SCI in the UK each year (Harrison 2000).

- *Primary/benign spinal cord compression (PSCC).*
- *Degenerative conditions.* These include osteoporosis, which is a reduction in the quantity and quality of bone, and spondylosis, a degenerative osteoarthritis of the joints between the centre of the spinal vertebrae and/or neural foramina (Mann et al. 2000).
- *Haematoma* (Kalina et al. 1995).
- *Primary tumours.* These include intradural extramedullary tumours (neurofibromas, meningiomas: Lohani and Sharma 2004), intramedullary tumours (ependymomas) and low-grade astrocytomas (Britton and Ng 1998).
- *Metastatic spinal cord compression (MSCC).* This is an oncological emergency, defined as compression of the dural sac and its contents (spinal cord and cauda equina) by an extradural mass (Loblaw et al. 2003). Causes include:
 - direct soft tissue extension from vertebral bony metastases
 - tumour growth through intravertebral foramina (e.g. from retroperitoneal tumours or paravertebral lymphadenopathy)
 - compression due to bony collapse
 - intramedullary metastases (rare).

The true incidence of MSCC is unknown due to current restrictions in detection rate and coding systems in the UK (NICE 2008). Postmortem evidence indicates it is present in 5–10% of patients with advanced cancer.

Classification

Spinal cord compression (SCC) is classified as either stable or unstable.

- *Stable:* this is where spinal alignment is intact with no further risk of progression of neurological symptoms as the spine is still able to maintain and distribute weight appropriately.
- *Unstable:* this is where spinal fractures/lesions pose a risk of spinal cord injury and potentially irreversible neurological symptoms due to (potential) abnormal movement at the fracture site. Additionally, it can be further classified as complete or incomplete.
- *Complete spinal cord injury:* when the cord 'loses all descending neuronal control below the level of the lesion' (Lundy-Ekman 2007, p.230).
- *Incomplete spinal cord injury:* when 'the function of some ascending and/or descending fibres is preserved within the spinal cord' (Lundy-Ekman 2007, p.230).

Clinical presentation

Clinical presentation of SCC is dependent on the location of the compression, the duration of its presence and consequently the level of neural function that is spared. The patient presents with loss of all voluntary movement and sensation below the level of the injury/lesion. There is also progressive loss of sympathetic and parasympathetic activity throughout the area (Harrison 2000).

In SCC, early diagnosis is crucial in order to at best prevent and otherwise minimize irreversible neurological damage. Common symptoms include:

- back pain and/or radicular pain – nerve root symptoms resulting in pain or loss of sensation within a dermatome
- limb weakness
- difficulty walking
- sensory loss
- cauda equina signs (saddle anaesthesia, bladder or bowel dysfunction)
- sexual dysfunction (NICE 2008).

Stable spine

The general principles of care mentioned earlier in the chapter are all relevant to this group of patients. However, patients need to be

assessed for adequate pain control prior to moving and positioning, and care should be taken to avoid excessive rotation of the spine when turning.

Unstable spine

For patients with an unstable spine or severe mechanical pain suggestive of spinal instability, specific instructions for moving must be followed until bony and neurological stability is radiologically confirmed (Harrison 2000, NICE 2008). This is to ensure spinal alignment and reduce the risk of further spinal damage and potential loss of function (Harrison 2000, NICE 2008).

'Careful handling, positioning and turning can prevent secondary cord damage during transfer and movements for patients with spinal cord injury' (Harrison 2000). Procedure guideline 6.1: Positioning the patient: supine, Procedure guideline 6.3: Positioning the patient: side-lying and Procedure guideline 6.13: Positioning the neurological patient with tonal problems, are relevant to moving patients with metastatic spinal cord compression. However, this patient group will require additional considerations to enable safe practice without compromising their clinical condition. These may include:

- lateral surface transfer, for example bed to trolley using a PAT lateral transfer board. Manual support of the patient's head and neck should be given for any flat surface transfer (Harrison 2000). This ensures appropriate spinal alignment and patient comfort
- log rolling for personal/pressure care for patients with unstable SCC.

Evidence-based approaches

Rationale

When moving and turning the patient with confirmed/suspected spinal instability who is being nursed flat, log rolling must be used. This is a technique to maintain neutral spinal alignment. It is an essential method to enable the patient to use a slipper pan and also to maintain pressure areas through regular turning every 2–3 hours (NICE 2008). Patients should only be moved with adequate numbers of staff who have been fully trained in moving patients with spinal cord compression/injury. Differing methods are recommended dependent on the level of the lesion/injury (Harrison 2000).

- Cervical and thoracic lesions (T4 and above):
 - pelvic twist for pressure care
 - log roll with five people required.
- Thoracolumbar lesions:
 - log roll with four people required (Harrison 2000).

Contraindications

The pelvic twist is contraindicated in the presence of thoracolumbar or pelvic injury/damage and pre-existing spinal deformity or rigidity, for example ankylosing spondylitis (Harrison 2000).

Principles of care

The general principles of care mentioned earlier in the chapter are all relevant to individuals with SCC. However, there are some other factors that need to be considered for these patients. Early and accurate diagnosis and, if appropriate, treatment are necessary to optimize neurological functioning. Timely referral to rehabilitation services is imperative for assessment, appropriate intervention and thorough discharge planning to enable smooth transition back into the community (NICE 2008). Active rehabilitation may be postponed until the medical team has confirmed that the patient's spine is stable. However, there is a significant role for members of the rehabilitation team in the management of these patients in terms of:

- assessment of motor recovery
- minimizing further complications such as chest infections which may arise as a result of prolonged bedrest

- effective, co-ordinated discharge planning. The positioning and moving needs of these patients are often complex and so discharge planning may be lengthy and multifaceted, requiring ongoing support and rehabilitation in the community to optimize functional independence (Miller and Cooper 2010).

For patients with complex symptoms, e.g. spinal instability, weakness, sensory impairment, refer to the physiotherapist.

Pre-procedural considerations

Patients may be able to assist with moving, positioning and transfers depending on:

- spinal stability
- pain
- level of lesion
- muscle power
- sensory impairment
- exercise tolerance
- patient confidence.

Pain management: pharmacological and non-pharmacological

As already discussed, spinal and radicular pain can be an indicator of SCC in the first instance but, in relation to moving and handling, it can also be suggestive of changes in neurology once gradual sitting and mobilization commence (NICE 2008). Implementation of a pain assessment chart can enable continuity of care, allowing accurate assessment and evaluation of all pharmacological (i.e. non-steroidal anti-inflammatory drugs, opiates, bisphosphonates and epidural) and non-pharmacological interventions (i.e. relaxation and therapeutic management).

Equipment

Spinal brace/cervical collar

Where there is confirmed or risk of spinal instability due to vertebral injury or collapse, patients will require external spinal support. This may be in the form of a spinal brace or collar. A properly fitted hard collar (Figure 6.21) must be used when there is suspicion of spinal instability (Harrison 2000, NICE 2008). This is available from surgical appliances/orthotics or some physiotherapy departments. Manufacturer's product details and care instructions are provided upon issue. Staff should be guided by medical advice and local policy.

Figure 6.21 Hard collar *in situ*.

Moving and handling aids

Patients may be able to assist with transfers using transfer boards, standing aids, mobility aids, frames, crutches and sticks. If they are unable to assist, there is a variety of moving and handling aids, for example lateral patient transfer boards, hoists and standing hoists, which maintain the safety of both the patient and the carer (HSE 1992). For lesions affecting the cervical and thoracolumbar spine or where injuries make turning difficult, an electric turning bed can be used (Harrison 2000).

Assessment and recording tools

The focus of an initial neurological assessment is to establish the level of cord injury and act as a baseline against which future improvements or declines may be compared (Harrison 2000). Standard assessments, including pain, motor and sensory charts, should be used as a baseline and updated with any change in a patient's presentation. Assessments will depend on local policy and may include:

- American Spinal Injury Association (ASIA) Spinal Cord Injury Classification (ASIA 2002)
- ASIA Spinal Cord Injury Impairment Scale (ASIA 2002)
- Spinal Cord Independence Measure (SCIM III) (Catz and Itzkovich 2007, Catz et al. 2007, Itzkovich et al. 2007)
- pain assessment chart, for example visual analogue scale (Tiplady et al. 1998)
- manual handling risk assessment
- pressure ulcer assessment, refer to Chapter 15: Wound management.

Procedure guideline 6.14 Log rolling for suspected/confirmed cervical spinal instability

See Figure 6.22.

Essential equipment

- Pillows – minimum of four
- Collar or spinal brace
- A minimum of five people is needed to move a person with cervical spinal instability

Optional equipment

- Slipper pan
- Clean sheets
- Hygiene equipment
- Continence pads
- Pressure care

(continued)

Procedure guideline 6.14 Log rolling for suspected/confirmed cervical spinal instability (*continued*)**Pre-procedure****Action****Rationale**

- | | |
|--|--|
| 1 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Wash hands thoroughly or use an alcohol-based handrub. | To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E). |
| 3 Ensure that the bed is at the optimum height for handlers. If two or more handlers are required try to match handlers' heights as far as possible. | To minimize the risk of injury to the practitioner (Smith 2011, C). |
| 4 Ensure there are sufficient personnel available to assist with the procedure (minimum five for patients with cervical spinal instability). | Four staff to maintain spinal alignment and one to perform personal/pressure care check during the procedure (Harrison 2000, C). |

Procedure

- | | |
|--|--|
| 5 Assess patient's motor and sensory function. | To provide a baseline to compare against after the procedure (Harrison 2000, C). |
| 6 Lead practitioner stabilizes the patient's neck, supporting the patient's head. | To co-ordinate and lead log roll. E
To take responsibility for providing instructions and ensuring all other practitioners are ready before commencing the manoeuvre (Harrison 2000, C). |
| 7 Ideally, the lead practitioner's hands should offer support for the entire cervical curve from the base of the skull to C7. | To immobilize patient's head. E
To ensure spinal alignment is monitored throughout the procedure (Harrison 2000, C). |
| 8 The second practitioner stands at the thorax and positions their hands over the patient's lower back and shoulder. | To ensure the lower spine remains aligned (Harrison 2000, C). |
| 9 The third practitioner stands at the hip area and places one hand on the patient's lower back and the other under the patient's upper thigh. | To prevent movement at thoracolumbar site (Harrison 2000, C). |
| 10 The fourth practitioner stands at the patient's lower leg and places one hand under knee and the other under ankle. | To ensure the lower spine remains aligned (Harrison 2000, C). |
| 11 Ensure there is a fifth person standing on the opposite side of bed. | To position the equipment or take care of hygiene needs. E
To assess upper back and occiput. This needs to be carried out once a day to check pressure areas (Harrison 2000, C). |
| 12 The lead practitioner holding the head provides clear instructions to the team; for example, 'We will roll on three: One, two, three'. | To ensure co-ordinated approach to the move. E |
| 13 Each practitioner remains in place whilst the necessary action is performed. | |
| 14 The person holding the head then provides clear instructions to return to supine. | To complete the move. E |
| 15 In order to leave the patient in a lateral position: | |
| (a) All practitioners must stay in place until the practitioner holding the patient's head confirms neutral spine alignment. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |
| (b) Position patient between 30° and 50° lateral tilt. | To ensure pressure care. E
To prevent excessive pressure being exerted on lower trochanter (Harrison 2000, C). |
| (c) The fifth person places a pillow lengthwise behind the patient from shoulder to hip. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |
| (d) The fifth person places a pillow under the patient's upper thigh lengthwise from hip to foot. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |
| (e) The fifth person places pillow between foot and end of bed. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |

Post-procedure

- | | |
|---|--|
| 16 Reassess and record neurological symptoms. | To ensure clinical status maintained (Harrison 2000, C). |
|---|--|

Procedure guideline 6.15 Positioning for suspected/confirmed cervical spinal instability: pelvic twist to right

See Figure 6.23. This procedure is for cervical and upper thoracic injuries only. It is contraindicated in the presence of thoracolumbar or pelvic trauma.

Essential equipment

- Collar or spinal brace
- Foam wedge or pillows

Optional equipment

- Equipment required for the purpose of the log roll, for example slipper pan, clean sheets, hygiene equipment, pads or pressure care

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).
4 Ensure there are three people available to assist with the procedure.	

Procedure

5 The lead practitioner stands at the head. Place hands firmly on patient's shoulders.	To take responsibility for providing instructions and ensuring all other practitioners are ready before commencing the manoeuvre. E To prevent movement of unstable cervical spine. E
6 A second practitioner positions themselves on the left side of the bed to which the patient will be turned.	
7 The third practitioner assists the second practitioner to lift the patient's leg to allow them to place their left hand under the leg to the right hip and their right hand under the patient's lumbar region.	To prevent an angle of more than 30°. E
8 The patient's left hip is then upwardly rotated by the second practitioner.	The second practitioner's hands provide a barrier against friction during the turn. E
9 Both the lead and second practitioners maintain their position whilst the third practitioner places a folded pillow beneath the patient's left buttock above the sacrum. Place additional pillow under upper buttock if required.	To prevent undue pressure risk to sacral/buttock region (Harrison 2000, C).
10 Place two pillows below the patient's left leg.	To support the left leg. E
11 Position a pillow at the foot end of the bed.	Minimize the risk of foot drop (Harrison 2000, C).

Post-procedure

- In the event of a worsening of pain or neurological symptoms, reassessment by medical team.

Figure 6.23 Pelvic twist for patient with unstable cervical spine. *Note:* in practice five people are needed for this manoeuvre. *Source:* Adapted from SIA (2000). Reproduced with permission from the Spinal Injuries Association (www.spinal.co.uk/).

Procedure guideline 6.16 Log rolling for suspected/confirmed thoracolumbar spinal instability*Essential equipment*

- Pillows
- Collar or spinal brace

Optional equipment

- Slipper pan
- Clean sheets
- Hygiene equipment
- Pads
- Pressure care

*Pre-procedure***Action****Rationale**

- | | |
|--|---|
| 1 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Wash hands thoroughly or use an alcohol-based handrub. | To reduce the risk of contamination and cross-infection (Fraiese and Bradley 2009, E). |
| 3 Ensure that the bed is at the optimum height for patients or handlers. If two handlers are required try to match handlers' heights as far as possible. | To minimize the risk of injury to the practitioner (Smith 2011, C). |
| 4 Ensure there are sufficient personnel available to assist with the procedure (minimum four for patients with thoracolumbar spinal instability). | Three staff to maintain spinal alignment and one to perform personal/pressure care check during the procedure (Harrison 2000, C). |
| 5 Assess patient's motor power and sensation as per local documentation agreement. | For assessment before and after log roll (Harrison 2000, C). |

Procedure

- | | |
|---|--|
| 6 The lead practitioner stands at the patient's thorax and positions hands over the patient's lower back and shoulder. | To co-ordinate and lead log-roll. E
To take responsibility for providing instructions and ensuring all other practitioners are ready before commencing the manoeuvre (Harrison 2000, C). To ensure the lower spine remains aligned (Harrison 2000, C). |
| 7 The second practitioner stands at the hip area. Place one hand on the patient's lower back and the other under the patient's upper thigh. | To prevent movement at thoracolumbar site (Harrison 2000, C). |
| 8 The third practitioner stands at the patient's lower leg. Place hands under knee and ankle. | To ensure the lower spine remains aligned (Harrison 2000, C). |
| 9 Ensure there is a fourth person standing on the opposite side of bed. | To position the equipment or take care of hygiene needs. E
To assess upper back and occiput. E
To be carried out once a day to check pressure areas (Harrison, 2000 C). |
| 10 The lead practitioner provides clear instructions to the team, for example 'We will roll on three: One, two, three'. | To ensure co-ordinated approach to the move. E |
| 11 Each practitioner remains in place whilst the necessary action is performed. | |
| 12 The person holding the head then provides clear instructions to return to supine. | To complete the move. E |
| 13 In order to leave the patient in a lateral position: | |
| (a) All practitioners must stay in place until the practitioner holding the patient's head confirms neutral spine alignment. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |
| (b) Position patient between 30° and 50° lateral tilt. | To ensure pressure care. E
To prevent excessive pressure being exerted on lower trochanter (Harrison 2000 C). |
| (c) The fourth person places pillow lengthwise behind patient from shoulder to hip. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |
| (d) The fourth person places pillow under patient's upper thigh lengthwise from hip to foot. | To ensure the lower spine remains aligned (Harrison 2000, C).
To ensure patient comfort. E |

- (e) The fourth person places pillow between foot and end of bed.

To ensure the lower spine remains aligned (Harrison 2000, **C**).
To ensure patient comfort. **E**

Post-procedure

- 14 Reassess and record neurological symptoms. In the event of a worsening of pain or neurological symptoms, reassessment by medical team.

To ensure clinical status maintained (Harrison 2000, **C**).

Procedure guideline 6.17 Early mobilization of the patient in bed

Essential equipment

- Collar/spinal brace for patients with unstable spine

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for patients or handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner (Smith 2011, C).
4 Ensure there are sufficient personnel available to assist with the procedure (minimum of four for patients with thoracolumbar spinal instability).	Three staff to maintain spinal alignment and one to perform personal/pressure care check during the procedure (Harrison 2000, C).

Procedure

5 Assess stabilization of neurological symptoms.	To assess and evaluate clinical symptoms (NICE 2008, C).
6 Confirm mobilization status with medical staff.	
7 Ensure collar/brace is <i>in situ</i> for patients with unstable spine.	To ensure safety and stability (Harrison 2000, C ; NICE 2008, C).
8 Assist the patient to move from supine to sitting at 60° in bed over 3–4 hours by gradually lifting the bed head.	
9 Perform regular close monitoring of blood pressure and neurological symptoms.	To assess and evaluate clinical symptoms (NICE 2008, C).
10 On confirmation of stable symptoms, assist patient to sit over edge of bed unsupported (see Procedure guideline 6.4: Positioning the patient: lying down to sitting up).	To ensure safe handling (CSP 2014, C ; HSE 1992, C).
11 Closely monitor any changes in symptoms.	To assess and evaluate clinical symptoms (NICE 2008, C).
12 On confirmation of stable symptoms, proceed to standard principles of mobilization (see Procedure guideline 6.6: Moving from sitting to standing: assisting the patient) and follow risk assessment consideration. Refer to the general principles for moving patients with neurological impairment.	To ensure safe handling (CSP 2014, C ; HSE 1992, C).

Post-procedural considerations

Ongoing care

Reassessment by the medical team will be necessary in the event of an increase in pain or neurological symptoms.

Documentation

Any changes in (neurological) presentation and/or function must be documented both prior to and following any procedure.

Problem-solving table 6.6 Prevention and resolution (Procedure guidelines 6.14, 6.15, 6.16 and 6.17)

Problem	Cause	Prevention	Action
1 Autonomic dysreflexia (mass reflex): <ul style="list-style-type: none"> Severe hypertension (abrupt rise in blood pressure) – systolic blood pressure can easily exceed 200 mmHg. 	Overstretching of bladder or rectum (urinary obstruction being the most common cause). Ingrown toenail or other painful stimuli. Fracture (#) below level of lesion. Pressure sore/burn/scald/sunburn. UTI/bladder spasm. Renal or bladder calculi. Visceral pain or trauma.	Closely monitor urinary drainage. Ensure effective bowel management regime.	THIS IS A MEDICAL EMERGENCY: Identify or eliminate the most common (most lethal) cause of autonomic dysreflexia, which is non-drainage of urine.
<ul style="list-style-type: none"> Bradycardia. Pounding headache. Flushed or blotchy appearance of skin above the level of lesion. Profuse sweating above the level of lesion. Pallor below the level of lesion. Nasal congestion. Non-drainage of urine. 	Pregnancy/delivery. DVT/PE. Severe anxiety/emotional distress (Lundy-Ekman 2007, Harrison 2000).		If this is not the cause, then proceed to investigate alternative causes according to the list given. Reassure the patient throughout because anxiety increases the problem. Remove the noxious stimulus, for example recatheterize immediately in the event of a blocked catheter. Do not attempt a bladder washout because there is no guarantee that the fluid will be returned. If possible, sit the patient up, or tilt the bed head up, to induce some element of postural hypotension. If symptoms remain unresolved after removal of noxious stimulus, or if the noxious stimulus cannot be identified, administer a proprietary chemical vasodilator, such as sublingual glyceryl trinitrate (GTN) or captopril 25 mg, sublingually. (<i>Note:</i> Nifedipine capsules, which were previously recommended for use in treating or preventing autonomic dysreflexia, are being withdrawn as they have been implicated in episodes of severe hypotension.) Record blood pressure and give further reassurance. Monitor patient's condition. Refer to local spinal injuries unit (SIU) for a specialist opinion/referral (Harrison 2000).
2 Orthostatic hypotension	Loss of sympathetic vasoconstriction. Loss of muscle-pumping action for blood return.	Antiembolic stockings. Careful assessment and monitoring during early mobilization/upright positional changes.	Medical review.
3 Pain Increased pain on movement to the extent that it is perceived by the patient as severe or does not reverse with rest.	Potential extension of spinal cord compression.	Ensure patients with unstable spine are moved appropriately.	Nurse patient flat. Reassess spinal stability prior to further movement (NICE 2008).

Problem	Cause	Prevention	Action
4 Respiratory function Reduced respiratory function in patient with cervical level SCC.	Ineffective use of main respiratory muscles for effective ventilation for tetraplegic patients with lesions at C3 and above. Most patients with tetraplegia (paresis/paralysis of arms, trunk, lower limbs and pelvic organs) at C4 and below are able to make sufficient respiratory effort to avoid the need for mechanical ventilation. They will, however, require oxygen therapy (Harrison 2000).	Ensure effective GI clearance/management – constipation and impaction of the bowel are a common complication of SCI management. This may place undue pressure on the diaphragm and lessen breathing space for effective respiratory function (Harrison 2000). Closely monitor respiratory function during any procedure.	Ensure appropriate head/neck support as required – collar/cervicothoracic brace for unstable cervical spinal involvement during any moving and positioning but if patients respiratory function decreases contact medical team urgently.
5 Cardiac syncope, i.e. fainting with unconsciousness of any cardiac cause	A cervical collar applied too tightly may cause cardiac syncope (Harrison 2000).	Ensure appropriate fit of cervical collar.	Check cervical collar is not too tight. Liaise with orthotist/PT.
6 Cardiac syncope: 2° hypoxia following initial injury. 2° turning to left side.	Sustained hypoxia increases vagal activity with a high risk of cardiac syncope (Harrison 2000). Turning the patient on to their left side for prolonged periods can increase vagal stimulation and may induce cardiac syncope. This problem is not usual during routine turning or twisting to the left side for pressure relief.	Avoid turning the patient on to their left side for prolonged periods (e.g. during a back wash or sheet change). Turning the patient onto their right side does not have the same effect.	Administer high concentrations of oxygen and atropine (Harrison 2000). Measure dynamic trend of the patient's observations (Harrison 2000).

Complications

There are a number of potential long-term complications that may occur during or after moving and positioning SCC/SCI patients. These are due to initial injury, the subsequent effects of changes in bowel and bladder functions and paralysis, that is, complete loss of motor function, associated with their disease or injury through autonomic and peripheral nervous system dysfunction, and those associated with bedrest.

- 1 Spinal shock:** following initial injury/lesion development, spinal shock can occur due to the loss of vasomotor tone throughout the paralysed areas of the body.

This is most pronounced in cases of tetraplegia. Patients present with hypotension, bradycardia and poikilothermia, that is, having a body temperature that varies with the temperature of its surroundings. This is due to a temporary/permanent loss of reflexes and muscle tone/control potentially leading to a compromised cardiac output. The patient must be closely monitored throughout and following any procedure or transfer, as recommended by medical staff.

- 2 Autonomic dysfunction:** following injury/lesion development, secondary effects occur due to autonomic dysfunction, a potential complication for all patients with complete spinal cord lesions above the level of T6 (see Problem-solving table 6.6).

- a Autonomic dysreflexia:** a mass reflex due to excessive activity of the sympathetic nervous system elicited by noxious stimuli below the level of the lesion.

This is a medical emergency; unresolved, it can cause fatal cerebral haemorrhage. Patients present with severe hypertension (abrupt rise in blood pressure), systolic blood pressure that can easily exceed 200 mmHg, bradycardia, 'pounding' headache, flushed or blotchy appearance of skin above the level of lesion, profuse sweating above the level of lesion, pallor below the level of lesion, nasal congestion, non-drainage of urine.

- b Orthostatic hypotension:** extreme fall in blood pressure on assuming an upright position (systolic >20 mmHg, diastolic >10 mmHg). More common in tetraplegia than quadriplegia (Krassioukov et al. 2009, Lundy-Ekman 2007).

- c Poor thermoregulation:** compensatory sweating above the level of lesion and loss of ability to shiver below the level of lesion.

Patients should avoid exposure to excessive heat/cold temperatures; peripheral vasodilation means that the patient's core temperature can soon equal the environmental temperature through circulatory conduction – poikilothermia. Ensure that the patient's body temperature is maintained at an appropriate level during all procedures, treatments, investigations and transfers. Active warming should be undertaken cautiously for fear of causing skin damage (Harrison 2000).

- 3 Pressure care:** risk to skin integrity and the development of pressure sores due to a lack of movement, poor circulation and altered sensation.

- 4 *Circulation*: risk of DVT due to the loss of vasomotor tone throughout the paralysed areas of the body. Application of thigh-length thromboembolic deterrent (TED) stockings can replace some of the lost muscle resistance, as well as reducing the risk of DVT (Harrison 2000).

246 Moving and positioning the patient with an amputation

Definition

Amputation refers to the loss of a part or whole of a limb normally as a result of trauma or vascular disease but can also be a result of malignancy or congenital deficiency (Figure 6.24). The majority of amputations are as a result of vascular disease affecting the older population who are likely to have co-morbidities.

Related theory

The level of the amputation and the surgical technique can affect both the cosmetic appearance as well as the potential functional ability for the individual.

‘There are certain levels of amputation that provide a residual limb suitable for a prosthetic fitting, function and cosmesis. Cosmetic appearance will depend to some extent on the level of the amputation and what prosthetic options this leaves. It is essential that one of these levels is selected rather than the boundary of the dead or diseased tissue with the viable tissue.’ (Engstrom and van de Ven 1999, p.6)

Evidence-based approaches

Rationale

Indications

Any patient who has had an upper or lower limb amputation in order to:

- prevent problems arising as a consequence of reduced mobility
- maintain range of movement and muscle strength in order to rehabilitate the patient early post-operatively and to regain maximum function as soon as possible
- help decrease phantom (sensation in the part of the extremity that has been amputated) and residual limb pain.

Contraindications

Leaving the limb on the amputated side unsupported as this can:

- exacerbate pain
- hinder wound healing
- increase stump oedema.

Principles of care

The main goals of moving and positioning with regard to amputee management are to:

- maximize function by preventing contractures (particularly if the patient's goal is prosthetic rehabilitation)
- help to control stump oedema in order to assist wound healing
- assist the regaining of functional independence as soon as possible.

There are also two important points to consider when assisting an amputee patient.

- First, any level of amputation, either of an upper or lower limb, will alter the patient's centre of gravity, potentially resulting in decreased balance. This in turn will increase the risk of falls for these patients.
- Second, body symmetry and posture will be altered which can also affect balance and may lead to poor postural habits that will hinder recovery and function.

Where possible, the process of positioning starts at the pre-operative stage for amputation as a result of vascular problems or malignancy. In this situation the affected limb is often painful and the patient is frequently less able to mobilize. As a result, the patient may adopt positions of comfort that can lead to contractures. These positions are often maintained post amputation due to comfort and habit but are also due to changes in muscle balance (Engstrom and van de Ven 1999). For example, above-knee amputees may adopt a flexed and abducted position of their stump due to an alteration in muscle balance and pain but this can lead to contracture over time if not corrected.

Contractures can profoundly affect the potential for prosthetic rehabilitation and overall function so early correct positioning is paramount in this cohort of patients (Munin et al. 2001).

Pre-operatively, patients should also be encouraged to keep as mobile as possible within pain limits to reduce the effects of deconditioning.

Pain, including phantom limb pain, can be a major problem with these patients in the early post-operative stages.

In order to ensure that everyone works together towards a common goal, the British Association of Chartered Physiotherapists in Amputee Rehabilitation (BACPAR 2006) recommends a comprehensive assessment by key professionals to establish rehabilitation goals. This assessment should be carried out as soon as possible following the decision to amputate and will need to undergo regular review. Nurses play a vital role at all stages providing technical and physical care, including wound care and assisting in personal hygiene (Kelly and Dowling 2008) which will all impact on the patient's rehabilitation.

The general principles of care mentioned earlier in the chapter are all relevant to these patients. However, particular attention should be given to any possible balance issues for both upper limb and lower limb amputations as previously mentioned. Following lower limb amputation, patients should be mobilized with caution, particularly if a prosthetic assessment is planned. This is because standing for long periods or hopping can:

- negatively influence stump oedema and wound healing
- overtire a patient, particularly elderly patients or those who are physically deconditioned prior to the amputation
- encourage the patient to adopt poor gait patterns due to excessive weight bearing on the remaining limb, leading to difficulty with prosthetic rehabilitation.

Figure 6.25 Two designs of stump board. (a) An adjustable stump board: the angle can be varied for comfort. (b) A fixed stump board: this slides underneath the wheelchair cushion. *Source:* Engstrom and Van de Ven (1999). Reproduced with permission from Elsevier.

Pre-procedural considerations

Equipment

Stump board

This will be required when sitting out in a wheelchair to ensure that the limb is fully supported and help prevent knee flexion contractures for below-knee (transtibial) amputees (Figure 6.25).

Wheelchair and seating cushion

Where possible, occupational therapists will assess and provide a wheelchair and a suitable cushion for lower limb amputees. If a patient has a bilateral lower limb amputation, they will need a specially adapted wheelchair with the wheels set back in order to provide sufficient stability.

Procedure guideline 6.18 Positioning the pre-operative and post-operative amputation patient

Essential equipment

- Stump board (for below-knee amputees sitting out in wheelchair)
- Pillows
- Hoists and appropriate amputee and rehabilitation slings or sliding sheets may be required if the patient presents as a manual handling risk

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

(continued)

Procedure guideline 6.18 Positioning the pre-operative and post-operative amputation patient (*continued*)

Action	Rationale
2 Wash hands thoroughly or use an alcohol-based handrub.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
3 Ensure that the bed is at the optimum height for the patient and handlers. If two handlers are required try to match handlers' heights as far as possible.	To minimize the risk of injury to the practitioner and patient (Smith 2011, C).
Procedure	
Upper limb amputee	
4 Ensure patient is maintaining full range of motion of all remaining joints of the upper limb by encouraging active movements of the limb.	To prevent contractures in case of possible prosthetic rehabilitation and functional use. E
Below-knee amputee	
5 Maintain knee extension.	
<ul style="list-style-type: none"> In bed: do not place a towel or pillow under the knee unless it is supporting the whole of the stump; that is, do not encourage the knee to be maintained in a flexed position. In chair: use a stump board on the wheelchair if one has been issued. If the patient is sitting out in the chair then support the amputation with a footstool and pillows. 	<ul style="list-style-type: none"> To prevent knee flexion contracture. E To assist stump oedema management. E To promote healing. E To support knee joint. E To prevent excessive knee flexion. E To aid stump oedema management (White 1992, R4, E). To protect the residual limb. E
Above-knee amputee	
6 Maintain hip in a neutral position.	To maintain hip extension. E
<ul style="list-style-type: none"> In bed: ensure the patient is periodically lying supine. Or: Consider prone-lying or side-lying with the hip in neutral position. In sitting: ensure that the patient does not place a towel or pillow under stump. 	<ul style="list-style-type: none"> To prevent hip flexion contracture. E To avoid shortening of hip flexors and abductors. E To prevent excessive hip flexion. E

Problem-solving table 6.7 Prevention and resolution (Procedure guideline 6.18)

Problem	Cause	Prevention	Action
Painful stump following transfer or change of position.	Fear of movement. Pressure on distal end of stump over wound. Stump dependent, leading to increased oedema and reduced blood flow. Unsupported stump.	Reassure patient. Ensure that stump is well supported following change in position. Ensure adequate analgesia prior to movement and support stump wherever possible during the procedure.	Explain procedure to patient prior to moving position. Ensure that there is no pressure over the wound site following the procedure.
Wound breakdown.	Unsupported stump during movement. Infection. Vascular insufficiency.	Ensure that stump is well supported during and following change in position.	Ensure that there is no pressure over the wound site following the procedure. Seek medical review.

Post-procedural considerations**Mobilization following amputation**

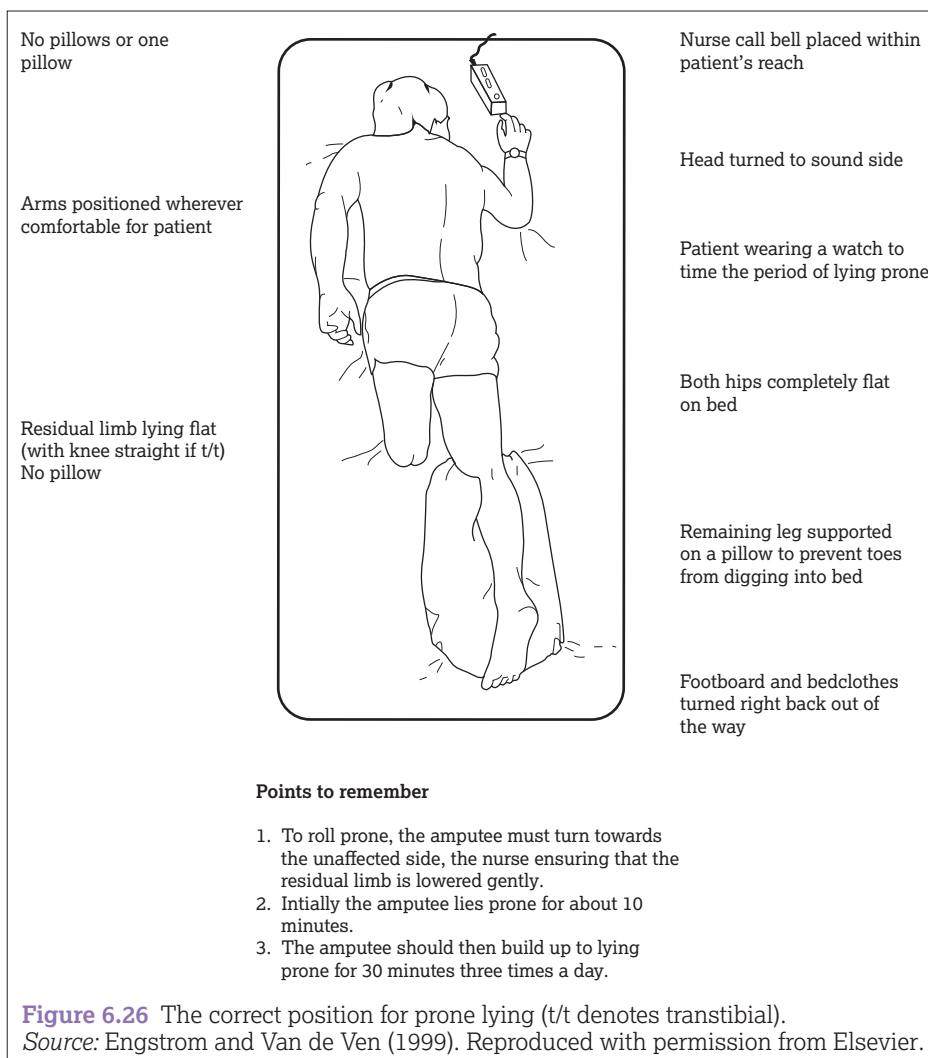

The same principles apply as outlined earlier in the chapter. The main considerations following both upper and lower limb amputation are balance and pain issues. If a lower limb amputee has a prosthesis, ensure that this is correctly applied and fitted prior to standing and mobilizing the patient.

Complications

1 *Limb contracture* can occur due to:

- a** immobility
- b** alteration in muscle balance around the joints
- c** pain
- d** habit.

In order to help prevent limb contracture, the patient will require adequate analgesia to control pain. It is also important to help

patients increase awareness of the positions they adopt with their stump, particularly those which may lead to limb contracture. The physiotherapist may recommend that the patient adopts certain positions for periods during the day to help prevent contractures, such as prone-lying for above-knee amputees (Figure 6.26).

- 2 *Ongoing phantom limb pain.* This can be a persistent problem and will need referral to the pain team for appropriate management.
- 3 *Wound infection or delayed healing.* Review by medical team for appropriate management.

Chapter 7

Nutrition, fluid balance and blood transfusion

Procedure guidelines

- 7.1** Fluid input: measurement 259
- 7.2** Fluid output: monitoring/measuring output if the patient is catheterized 261
- 7.3** Fluid output: monitoring/measuring output if the patient is not catheterized 261
- 7.4** Fluid output: measuring output from drains 262
- 7.5** Fluid output: monitoring output from gastric outlets, nasogastric tubes, gastrostomy 263
- 7.6** Fluid output: monitoring output from bowels 263
- 7.7** Fluid output: monitoring output from stoma sites 264
- 7.8** Measuring the weight and height of the patient 269
- 7.9** Feeding an adult patient 276
- 7.10** Nasogastric intubation with tubes using an internal guidewire or stylet 281
- 7.11** Removal of a nasogastric tube 287
- 7.12** Percutaneous endoscopically placed gastrostomy (PEG) tube care 288
- 7.13** Radiologically inserted gastrostomy (RIG) tube care 290
- 7.14** Removal of T-fasteners 290
- 7.15** Checking the balloon volume on a balloon gastrostomy 291
- 7.16** Jejunostomy feeding tube care 292
- 7.17** Enteral feeding tubes: administration of feed 294
- 7.18** Enteral feeding tubes: administration of medication 296
- 7.19** Enteral feeding tubes: unblocking 298
- 7.20** Blood product request 312
- 7.21** Blood sampling: pre-transfusion 313
- 7.22** Blood components: collection and delivery to the clinical area 314
- 7.23** Blood component administration 316

Overview

Good nutrition, the supply of optimal nutrients and fluid to meet requirements, is an essential component of health, with poor nutrition contributing to ill health and prolonged recovery from illness or disease. It is therefore crucial that the nutritional status of all patients is assessed and considered during the whole of the patient's care. This chapter addresses how fluid and nutrition can influence body composition, how to identify patients who are malnourished or at risk of malnutrition and, most importantly, how the patient's nutritional needs can be met.

254

The provision of food and fluids to patients is an integral part of basic care. In normal circumstances, adequate nutritional intake enables the body to maintain homeostasis of body composition and function but in disease states this balance can be altered. The majority of patients will achieve adequate nutrition through the oral route of diet and fluids but, for some, additional artificial nutritional support or products such as blood will be required to maintain optimal body composition and function. This chapter describes how the patient's needs can be assessed and met through oral, enteral and parenteral routes of nutrition, fluid or blood products.

Fluid balance

Definition

In the human homeostatic state, the intake of fluids equals fluid excreted from the body, thereby maintaining optimal hydration. In nursing practice, this term refers to the procedure of measuring fluid input and output to determine fluid balance (Marieb and Hoehn 2010, Scales and Pilsworth 2008).

Anatomy and physiology

Body composition

The human body is made up of approximately 60% water (this varies with age, gender and percentage of fatty tissue) (Rhoda and Porter 2011, Scales and Pilsworth 2008, Tortora and Derrickson 2011). Bodily water/fluid is essential to life and vital for:

- controlling body temperature
- the delivery of nutrients and gases to cells
- the removal of waste
- acid/base balance
- the maintenance of cellular shape (Baumberger-Henry 2008).

Total body water is distributed between two main compartments: intracellular fluid (ICF, within the cell) and extracellular fluid (ECF, outside the cell). ECF is further divided into the intravascular space, within the blood vessels (known as plasma), the interstitial space which surrounds the cells and the transcellular space. The transcellular space contains specialized fluids such as cerebrospinal fluid; these do not readily exchange fluid with other compartments so are rarely considered in fluid management (Bishop 2008, Rhoda and Porter 2011).

Bodily fluid is a composition of water and a variety of dissolved solutes which Marieb and Hoehn (2010) classify as electrolytes and non-electrolytes. Non-electrolytes include glucose, lipids, creatine and urea and are molecules that do not dissociate in solution and have no electrical charge. Electrolytes such as potassium, sodium, chloride, magnesium and bicarbonate all dissociate in solution into charged ions that conduct electricity. Concentration of these solutes varies depending on the compartment in which they are contained; for example, ECF has a high sodium content (135–145 mmol/L) and is relatively low in potassium (3.5–4.5 mmol/L) and ICF is the reverse – high in potassium but lower in sodium (Tortora and Derrickson 2011). The movement and distribution of fluid and solutes between compartments

are controlled by the semi-permeable phospholipid cellular membranes that separate them (Baumberger-Henry 2008).

Transport and movement of water and solutes

Water can readily and passively pass across the membrane and does so by osmosis (Table 7.1) in response to changing solute concentrations (Tortora and Derrickson 2011). The amount of solute in solution determines the osmolarity – the higher the solute concentration, the higher the osmolarity; this is also referred to as the osmotic pressure (or pull). Electrolytes move across the membrane via the protein channels, some by diffusion (see Table 7.1) and also via a passive mode of transport where solutes move towards an area of low solute concentration. Sodium and potassium are an exception to this rule, as they are required to move against the concentration gradient in order to preserve higher intravascular sodium concentrations. Energy is utilized to pump sodium out of the cell via the protein channels and pump potassium back into the cell, known as the sodium/potassium pump (see Table 7.1).

The movement of water and solutes out of the intravascular space and into the interstitial space is dependent on opposing osmotic and hydrostatic pressures (Scales and Pilsworth 2008). Hydrostatic pressure is caused by the pumping action of the heart and the diameter (resistance) of the vessels/capillaries forcing water and molecules that are small enough to pass through the membrane out of the vessel and into the interstitial fluid. Within the vascular system, only the capillaries have semi-permeable membranes and this is where 'filtration' occurs. At the arteriole end of the capillary, the hydrostatic pressure exceeds the osmotic pressure, moving solutes out of the plasma and into the interstitial space. At the venous end, hydrostatic pressure is reduced and the osmotic pressure within the vessel (plasma) is higher so water is pulled back into the vessel and circulating volume (Tortora and Derrickson 2011). The osmotic pressure is provided by plasma proteins that are too large to pass through the membrane even under pressure. Oedema can result if the membranes become permeable to protein; osmotic pressure is then reduced, resulting in excess of water moving into the interstitial space. Pulmonary oedema is caused by this mechanism at the site of the lungs. Sepsis or a systemic inflammatory response is an example of a condition where the capillary membranes become more permeable to protein.

Osmolarity and fluid balance

Sodium is the most influential electrolyte in fluid balance and is the primary cation (positively charged ion) of the ECF. The concentration of sodium in the ECF has the most profound effect on its osmolarity and therefore water balance (Rhoda 2011). If ECF osmolarity increases (for example, with increased intake of sodium, reduced fluid intake, increased loss of fluid), osmoreceptors of the hypothalamus detect very slight changes (1–2% increase) in plasma osmolarity (Marieb and Hoehn 2010) and trigger the thirst response which in turn encourages oral fluid intake in an attempt to restore the balance (Figure 7.1).

Hormonal mechanisms and the kidneys are highly influential in fluid and electrolyte balance and again are also triggered in response to changing osmolarity and/or plasma volumes. Anti-diuretic hormone (ADH) is released from the posterior pituitary gland (in response to stimulus of the osmoreceptors in the hypothalamus) (Tortora and Derrickson 2011) and acts on the tubules and collecting ducts of the kidneys, inhibiting water excretion and encouraging water reabsorption. If plasma osmolarity falls (indicating water excess), these mechanisms are suppressed by a negative feedback loop; the osmoreceptors are no longer stimulated. This in turn inhibits ADH release; renal tubules no longer conserve water and thirst is reduced, leading to a reduction of oral intake and restoration of balance. ADH is also released in the renin-angiotensin response to a reduction in blood pressure (detected by baroreceptors in blood vessels); more detailed information on this mechanism can be found in Chapter 11: Observations.

Table 7.1 Molecule transport modes

Transport mode	Description	Diagram
Osmosis	Movement of water from an area of low solute concentration to an area of high solute concentration	
Diffusion	Movement of solutes from an area of high concentration to an area of low concentration	
Facilitated diffusion	Movement of solutes from an area of high concentration to an area of low concentration, facilitated by a carrier molecule (e.g. glucose only enters the cell carried by insulin)	
Active transport	Movement of solutes against the concentration gradient from an area of low concentration to an area of high concentration. This transport requires energy synthesized within the cell (i.e. the sodium/potassium pump)	

Aldosterone is a mineralocorticoid secreted by the adrenal cortex in response to increased osmolarity and/or decreased blood pressure (part of the renin-angiotensin system). It acts on the renal tubules, initiating the active transport of sodium (and hence water) from the tubules and collecting ducts back into the plasma and circulating volume (Baumberger-Henry 2008).

These homeostatic mechanisms are very effective in maintaining fluid and electrolyte balance in health and act to compensate

for fluid imbalances to ensure effective cellular function. However, these compensatory mechanisms are not sustainable and will eventually fail if ill health or imbalance persists. For example, in continued haemorrhage, the body will compensate by conserving water and vasoconstricting vessels in an attempt to increase blood pressure and volume. Failure to replace lost fluids, improve volume and therefore perfusion will eventually lead to cellular and organ dysfunction which in turn lead to organ failure and possible death (Goldstein 2012).

Dehydration is a particular concern in ill health as often fluid intake is reduced (poor appetite, nil by mouth, nausea) and often coincides with an increased output (vomiting, diarrhoea, haemorrhage, drains, fever). The elderly are at particular risk of dehydration as the effectiveness of the thirst response diminishes with age (Mentes 2006, Welch 2010). When the osmolarity of the ECF increases, it encourages water out of the cell into the ECF, which eventually leads to cellular dehydration, impaired metabolism, disturbed cellular shape and impaired cellular function (Tortora and Derrickson 2011).

If the osmolarity of the ECF falls, water moves into the cell. If this continues, it will lead to water toxicity, causing cells to expand and eventually burst. Care should therefore be taken when administering intravenous fluids (Powell-Tuck et al. 2011), as fluids that are of lower osmolarity than ECF (hypotonic) will cause a shift of water into the cells. Conversely, hypertonic solutions will cause a shift of fluid from the cells, causing dehydration. Maintenance

fluids should usually be isotonic (have the same osmolarity as ECF) (Sheppard and Wright 2006).

Evidence-based approaches

Fluid and electrolyte balance monitoring and management are integral and vital to nursing care (Jevon and Ewens 2007). The fluid balance chart serves as a non-invasive tool to monitor fluid status and guides the prescription and administration of intravenous fluids (Tang and Lee 2010).

Fluid balance charting allows healthcare professionals to carefully monitor the fluid input and output and calculate the fluid balance. This is usually measured over a 24-hour period (Jevon and Ewens 2007). A positive fluid balance indicates that the input has exceeded the output, and a negative fluid balance indicates the reverse, that is, the output has exceeded the input. Although a fluid balance chart is a good indication of fluid balance, it is not an exact measurement, for several reasons. Some losses are insensible such as those from perspiration, respiratory secretions and immeasurable bowel losses. The calculation of fluid balance also relies heavily on the accurate measuring, charting and calculating of input, output and overall balance. For such measurements to be taken accurately, additional interventions such as catheterization may be required. The benefit of accurate fluid balance measurement in the critically or acutely unwell patient must be considered to outweigh the risks associated with such interventions (Callum et al. 1999, NICE 2007, 2013a). Table 7.2 identifies routes and sources of fluid intake and output.

Although a very useful tool, fluid balance charting should not be used in isolation. When considering fluid and electrolyte balance, additional triggers such as physical assessment and monitoring plasma levels of electrolytes should be integral to the observation and care of a patient with actual or potential fluid and electrolyte imbalances (NICE 2007, 2013a, Shepherd 2011b).

Nursing assessment is discussed in detail in Chapter 2: Assessment and discharge, and the assessment of a patient’s fluid status should be an integral part of any admission and subsequent daily assessments, particularly if the patient is critically ill and/or a fluid deficit has been identified. See Table 7.3 for details of what should be included in a fluid status assessment.

Throughout the literature, it is recognized that fluid balance monitoring is often poorly performed by nurses (Bennett 2010,

Table 7.2 Fluid intake and output

Intake	Output
Oral	Urine output
Food and drinks	Normally approx 1500 mL/per day
Normally 2000 mL/per day	
Parenteral/intravenous	Faeces
Maintenance fluids, intravenous infusion, intermittent drugs, flushes	Normally approx 100 mL/per day
Additional to or replaces oral intake	
Enteral	Perspiration
Nasal gastric/nasal jejunostomy, percutaneous gastric jejunostomy feed, flushes	Normally approx 200 mL/day
Additional to or replaces oral intake	Gastric secretions
	Vomit, nasal gastric/gastrostomy drainage
	Additional to normal output
	Wounds and drains
	Additional to normal output
	Insensible losses
	Perspiration, respiratory secretions
	Additional to normal output

Table 7.3 Assessment of fluid status

Assessment	Usual findings	Indications	
Symptoms		Fluid deficit	Fluid overload
History			
To establish any condition, medication or lifestyle that may contribute to or predispose the patient to a fluid imbalance	Differs for each patient	For example, chronic or acute diarrhoea, medication such as diuretics, poor oral fluid intake	Ingestion of too much water/fluid, renal failure/dysfunction
Thirst <i>Ask the patient</i>	Occasional; resolved by taking an oral drink	Unusually thirsty	No thirst, normal
Mucosa and conjunctiva <i>Inspect</i>	Usually moist and pink	Dry and whitened mucosa, dry conjunctiva and 'sunken' eyeballs	Moist, pink and glistening
Clinical signs			
Heart rate	Usual resting 60–100 bpm	Raised	Normal or raised
Peripheral pulse character	Radial pulse is felt just under the skin at the wrist, light palpation with two or three fingers	Thready, difficult to palpate	Bounding, easy to palpate
Blood pressure	Patient's own normal should be used as a guide	Blood pressure will fall if blood volume falls beyond compensatory mechanisms. Patient may experience postural hypotension	Rise in blood pressure, or may remain normal
Central venous pressure	3–10 mmHg	Low	Raised
Respiratory rate	12–20 breaths/min	High, to meet increased oxygen demands of compensatory mechanisms	High, if overload present
Capillary refill	Usually 2–3 seconds	Slower	Faster
Urine output	0.5–1 mL/kg	Low	Increase, if good renal function
Lung sounds, auscultation	Vesicular breath sounds, 'rustling' heard mainly on inspiration	Normal	Additional sounds (crackles) may indicate fluid overload
Skin turgor	Following a gentle pinch, the fold of skin should return to normal	Skin will take much longer to 'bounce' back to normal. Unreliable in elderly who may have lost some elasticity of their skin	May be normal; however, may be oedematous therefore skin remains dented/pinched
Serum electrolyte levels			
Sodium	135–145 mmol/L	Raised	Lowered
Potassium	3.5–5 mmol/L	May be lowered if cause of fluid deficit is gastrointestinal losses	Normal
Urea	2.5–6.4 mmol/L	Decreased	Normal
Creatinine	Male: 63–116 µmol/L Female: 54–98 µmol/L	Normal, but eventually rises with prolonged poor renal perfusion	Normal
<i>This is a basic examination of serum electrolytes in fluid balance. There are several conditions and treatments that may affect these so they should not be used in isolation to assess or treat fluid imbalance.</i>			
Serum osmolarity	275–295 mosmol/kg	Increased	Decreased
Urine osmolarity	50–1400 mosmol/kg	Increased	Decreased
Daily weight	A person's daily weight should be fairly stable; large losses or gains in weight may indicate fluid imbalance	Reduced each day	Increased each day
Temperature	36.5–37.5°C	May be elevated and this may also contribute to the fluid deficit (increased insensible losses)	Normal

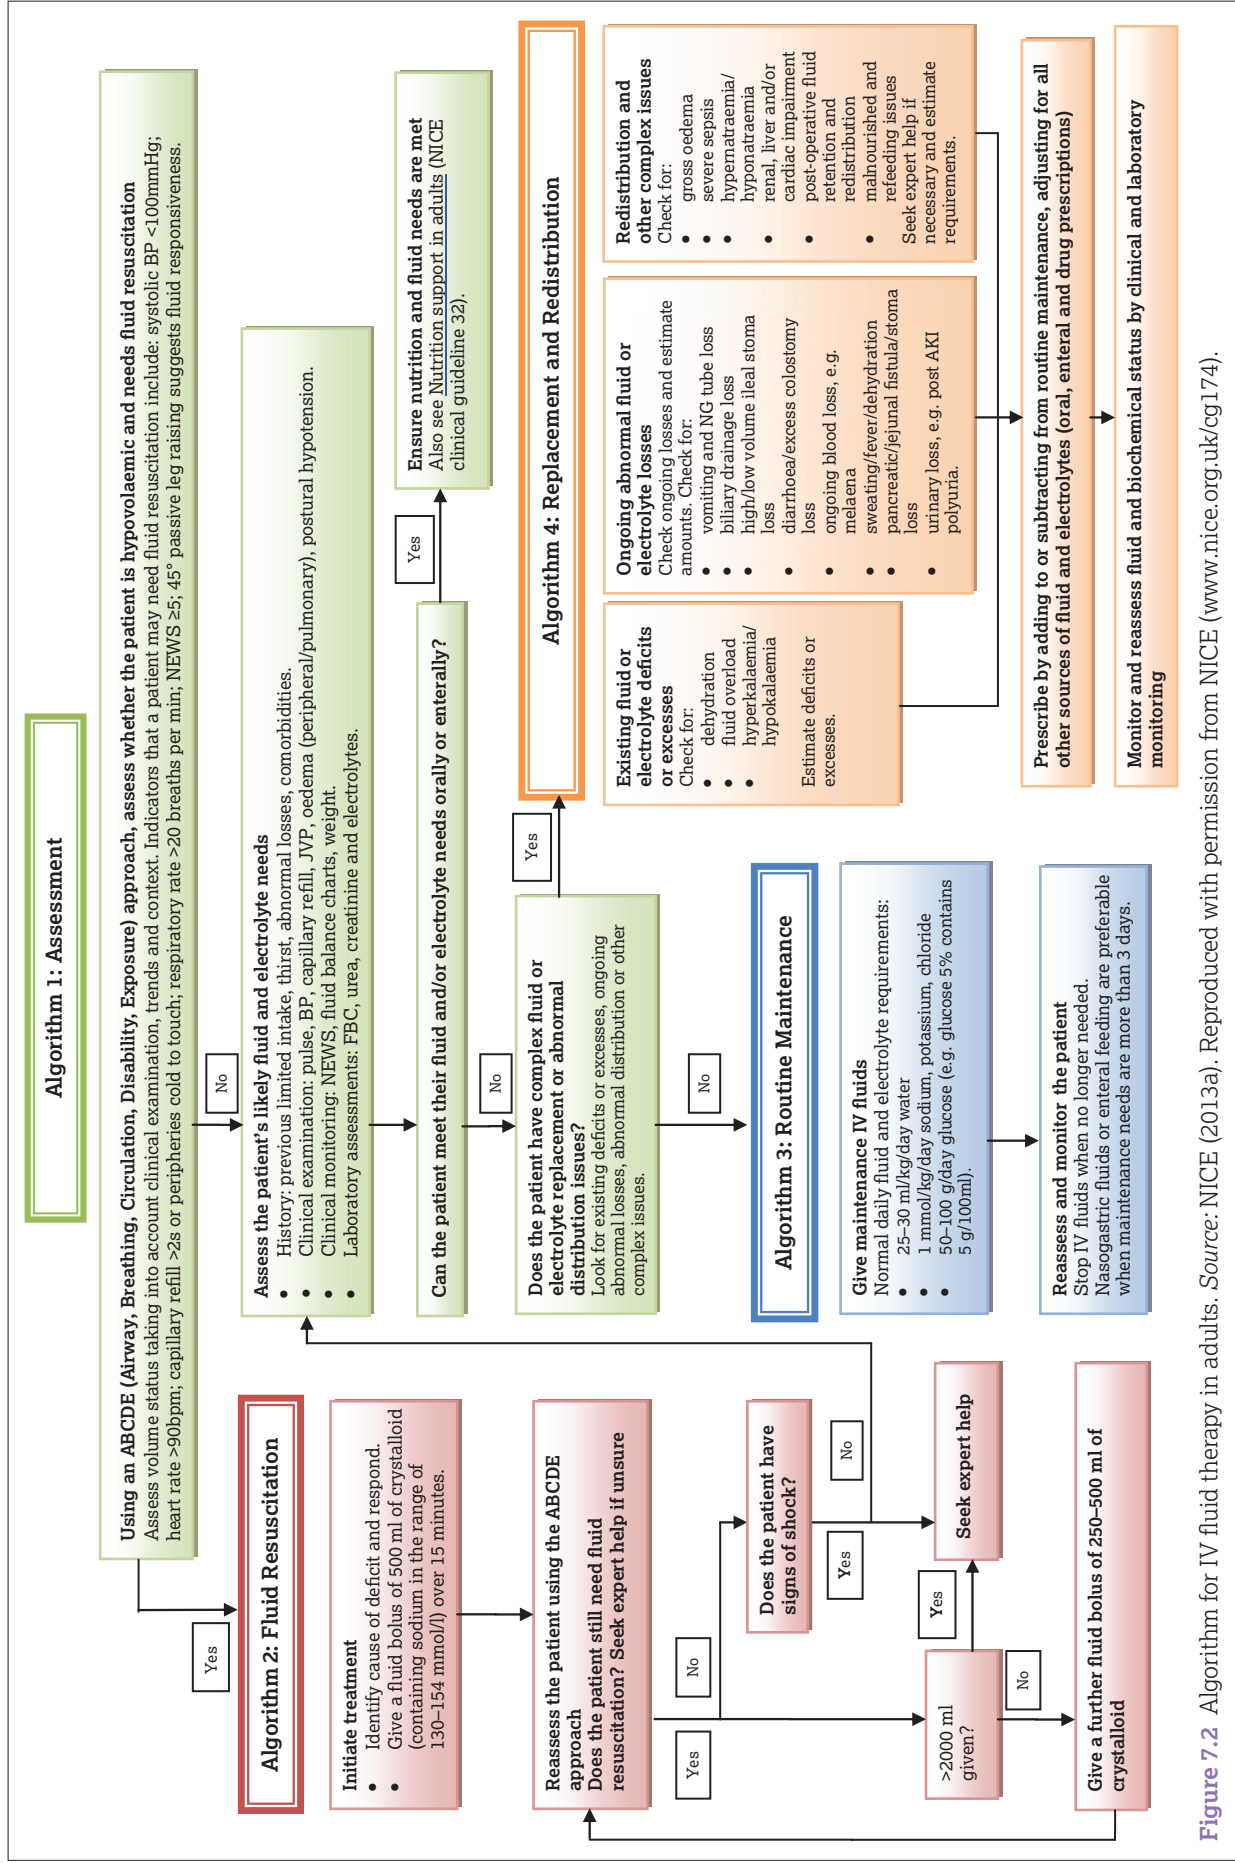

Figure 7.2 Algorithm for IV fluid therapy in adults. Source: NICE (2013a). Reproduced with permission from NICE (www.nice.org.uk/cg174).

Mooney 2007, Shepherd 2011a, NICE 2013a). Alexander and Allen (2011) identify barriers to accurate monitoring of fluid status and suggest that nurses must have a good understanding of the concepts involved in fluid balance in order to recognize or anticipate imbalances. They suggest the use of a fluid management policy to guide both nursing and medical staff and to standardize practice. NICE (2013a) offer guidance on the management of the adult patient in hospital receiving IV fluids; suggesting history taking, full clinical assessment, review of current medications, fluid balance charts and laboratory investigations are all required in order to fully assess the need for IV fluid and/or electrolyte administration.

Understanding of the physiological mechanisms and potential implications will ensure fluid balance charting is carried out with knowledge and thought. Stewart et al. (2009) suggest that these assessment skills should be 'core' for any healthcare professional caring for inpatients. More recently, the British Consensus Guidelines on Intravenous Fluid Therapy for Adult Surgical Patients (Powell-Tuck et al. 2011) and NICE guidance on intravenous fluid therapy in adults (NICE 2013a) has highlighted detrimental effects of fluid overload and therefore the importance of accurate fluid balance monitoring. Recommendations included the need for improved accuracy and for medical staff to review these charts regularly and prior to prescribing any intravenous fluids. Tang and Lee (2010) highlight the implications of incorrect fluid balance calculations (by nurses and doctors), which may lead to under- or overprescribing of fluid administration and therefore affect patient outcome. They suggested that these charts are counterproductive and dangerous unless completed correctly.

NICE (2013a) recommend all patients receiving IV fluids require at least daily assessment of their fluid status and that clinicians are mindful of the electrolyte content of the IV fluids they prescribe.

Within fluid management, and particularly fluid resuscitation, there is an ongoing debate surrounding the benefits of the use of colloids over crystalloid for fluid replacement. Perel and Roberts (2007) conducted a systematic review of the evidence and concluded that there is no apparent benefit to the patient when using colloid rather than crystalloid. Bayer et al. (2012) performed a prospective sequential analysis on the use of both colloid and crystalloid in fluid resuscitation in the septic patient; they found that shock reversal was achieved equally fast with both types of fluid replacement and there was only a marginal reduction in the volume required when using colloid. The UK Adult Resuscitation Guidelines (Resuscitation Council 2005) agree that there is no benefit in choosing colloid over crystalloid but they do recommend that dextrose is avoided due to the redistribution of fluid from the intravascular space and because it may cause hyperglycaemia. Dellinger et al. (2012) provide detailed guidelines on

the management of sepsis and recommend crystalloid as the first choice in fluid resuscitation (Dellinger et al. 2012).

This ongoing debate has led to a wide variation in practice across trusts and even departments. NICE (2013a) have offered clear, standardized guidance with regard to IV fluid administration for the adult patient in hospital (excluding patients with diabetes, severe liver or renal disease, pregnant women and patients under the age of 16 years). A summary and useful form of this guidance can be found in the 'Algorithms for IV fluid therapy in adults' produced by NICE (2013a). See Figure 7.2.

Synthetic colloid fluids containing hydroxyethyl starch have previously been utilized in fluid replacement. However, the benefits of these over the risks have come under scrutiny (Antonelli and Sandroni 2013) and it was decided by the European Medicines Agency (2013) that production and use of these be suspended.

Rationale

Indications

Any patient who has shown signs or symptoms of a fluid imbalance or who has undergone surgery or acute illness that has led to critical care admission should have their fluid intake and output monitored and fluid balance calculated on an hourly basis (Mooney 2007, Tang and Lee 2010). The decision to monitor fluid balance should be a multidisciplinary one; however, it is the responsibility of the bedside nurse to ensure this is done accurately.

Legal and professional issues

The Code (NMC 2015) clearly states that clear and accurate records must be kept; this includes fluid balance charts (Figure 7.3). Nurses should have an understanding of the mechanisms of fluid balance and identify potential imbalances and the problems associated with them.

Pre-procedural considerations

In order to monitor fluid balance, both input and output must be accurately measured. Below are procedural guidelines for measuring input and output. If the patient is awake, able to take oral fluids and is mobile, they must be educated about the fact that their fluid balance is being monitored and each drink must be recorded, as should each episode of passing urine, bowel motion or vomiting and so on. It is helpful to provide a cup with markings showing volume.

It is important to note that patients may have other means of urine output, for example an ileal conduit, ureteric stents, suprapubic catheterization, neobladder. The same concepts can be utilized to measure the output, by attaching a urometer to the catheter or urostomy bag.

Procedure guideline 7.1 Fluid input: measurement

Essential equipment

- Fluid balance chart
- Appropriate pumps for fluid or feeding

Pre-procedure

Action

- 1 Educate the patient about the fact that their fluid input is being monitored and ask them to alert you to any oral intake.
- 2 Obtain fluid balance chart and document patient's name and the date commenced.

Rationale

To ensure the patient is aware of the need to record any oral intake so this can be noted accurately (Baraz et al. 2009, **R4**).

To ensure chart is correctly labelled for the correct patient, allowing accurate documentation (Powell-Tuck et al. 2011, **C**).

(continued)

Procedure guideline 7.1 Fluid input: measurement (*continued*)**Action**

- 3 Ensure pumps available for intravenous fluids, nasogastric/jejunostomy feeds.

Rationale

To enable accurate hourly record of intake (Reid et al. 2004, **E**).

Procedure

- 4 Measure oral fluid intake hourly, noting it on the fluid balance chart (see Figure 7.3).
- 5 Note any enteral or parenteral intake.
- 6 Add together the values for oral, enteral and parenteral intake for the hour.
- 7 Add this value to the cumulative total for intake (see Figure 7.3).

To obtain accurate real-time fluid balance status (Sumnall 2007, **E**).

To obtain accurate real-time fluid balance status and ensure all possible input considered (Smith and Roberts 2011, **E**).

To assess hourly fluid intake (Scales and Pilsworth 2008, **E**).

To assess total intake and enable calculation of the fluid balance (Scales and Pilsworth 2008).

Post-procedure

- 8 Once output totals are calculated (see Procedure guideline 7.6: Fluid output: monitoring output from bowels), subtract output from input.
- 9 Document on chart and in patient's notes.

To calculate fluid balance (Powell-Tuck et al. 2011, **C**).

To ensure accurate documentation (NMC 2010, **C**).

Figure 7.3 Example of a fluid balance chart.

Procedure guideline 7.2 Fluid output: monitoring/measuring output if the patient is catheterized*Essential equipment*

- Urometer
- Measuring jugs (with volume indicators)
- Non-sterile gloves, apron, goggles
- Bedpan/urinary bottles/commode
- Bile drainage bag/gastrostomy drainage bag
- Scales

*Pre-procedure***Action**

- 1 Determine sources of fluid output (see Table 7.2) and note them on the fluid balance chart.

Rationale

To ensure all possibilities have been considered and to ensure accurate (as possible) output determination (Scales and Pilsworth 2008, **E**).

Procedure

- 2 Explain to the patient that it is necessary to monitor their urine output and that you will be doing so every hour.

To ensure the patient is not alarmed by frequent observation and that they are kept informed about current care (Bryant 2007, **E**).

- 3 Attach a urometer to the catheter, using an aseptic technique (see Chapter 3, Procedure guideline 3.10: Aseptic technique).

To allow accurate assessment of hourly urine output, to prevent cross-infection (Fraise and Bradley 2009, **E**).

- 4 Each hour, on the hour, note the volume of urine in the urometer, recording this on the fluid balance chart.

To determine urine output and to keep accurate records of this, thus enabling assessment of fluid balance (Scales and Pilsworth 2008, **E**).

- 5 Empty the urometer into the collection bag (until the bag is full; this will then need emptying).

To ensure urometer is empty for the next hour's determination. **E**

- 6 Add recorded urine output to the other values for output, giving an hourly total.

To allow for fluid balance determination (see Table 7.2). **E**

Post-procedure

- 7 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.

To calculate hourly fluid balance (Levi 2005, **E**).

- 8 Document all values on the chart and any other actions relating to your findings in the patient's notes.

To ensure accurate documentation (NMC 2010, **C**).

Procedure guideline 7.3 Fluid output: monitoring/measuring output if the patient is not catheterized*Essential equipment*

- Measuring jugs (with volume indicators)
- Non-sterile gloves, apron, goggles
- Bedpan/urinary bottles/commode
- Scales

*Pre-procedure***Action**

- 1 Determine sources of fluid output (see Table 7.2) and note on the fluid balance chart.

Rationale

To ensure all possibilities have been considered to ensure accurate (as possible) output determination (Scales and Pilsworth 2008, **E**).

Procedure

- 2 Explain to the patient that it is necessary to measure their urine output.

To ensure that the patient knows that any urine they pass needs to be measured in order to record output and to obtain their co-operation in ensuring accuracy of measurement (Chung et al. 2002, **R4**).

(continued)

Procedure guideline 7.3 Fluid output: monitoring/measuring output if the patient is not catheterized (*continued*)

Action	Rationale
3 Supply the patient with urine bottles and/or bedpans and ask them to use these even if they are able to mobilize to the toilet; ask them to inform you of each episode.	To ensure the urine is kept for measuring and not disposed of (Chung et al. 2002, R4).
4 Use protective equipment for bodily fluids when handling used bottle or bedpan.	To prevent cross-infection (Fraise and Bradley 2009, E).
5 Place bedpan/bottle on to scales, subtracting appropriate value to compensate for weight of item.	To obtain value of urine in millilitres. E
6 If no scales available, use a jug with volume markings; pour urine into jug (using universal precautions), noting level of urine.	To measure urine volume. E
7 Once noted, dispose of urine appropriately.	To prevent contamination and/or cross-infection (Fraise and Bradley 2009, E).
8 Record value on fluid balance chart, adding this to the rest of the output values for the hour.	To determine fluid output for the hour (Sumnall 2007, E).
Post-procedure	
9 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.	To calculate hourly fluid balance (Levi 2005, E).
10 Document all values on the chart and any other actions relating to your findings in the patient's notes.	To ensure accurate documentation (NMC 2010, C).

Procedure guideline 7.4 Fluid output: measuring output from drains**Essential equipment**

- Measuring jugs (with volume indicators)
- Non-sterile gloves, apron, goggles
- Tape and pen

Pre-procedure

Action	Rationale
1 Determine sources of fluid output (see Table 7.2) and note them on the fluid balance chart.	To ensure all possibilities have been considered to ensure accurate (as possible) output determination (Scales and Pilsworth 2008, E).

Procedure

2 Explain to the patient that the output from the drains will be monitored hourly.	To inform the patient about current care and to ensure they are not alarmed by the frequent observations (Bryant 2007, E).
3 If the drain is drainable, empty contents into jug, noting volume; use universal precautions.	To determine volume of fluid drained and prevent cross-infection (Fraise and Bradley 2009, E).
4 If it is not possible to drain the fluid out of the bag, use a suitable pen and mark the level the fluid reaches each hour. Date and time each marking.	To determine drainage each hour. To ensure consistency in reading and to communicate to other members of the multidisciplinary team regarding drainage (Sumnall 2007, E).
5 Note volume/drainage on fluid balance chart.	To determine drainage each hour (Sumnall 2007, E).
6 Add this figure to the rest of the output values for the hour.	To determine accurate total fluid lost each hour (Sumnall 2007, E).

Post-procedure

7 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.	To calculate hourly fluid balance (Levi 2005, E).
8 Document all values on the chart and any other actions relating to your findings in the patient's notes.	To ensure accurate documentation (NMC 2010, C).

Procedure guideline 7.5 Fluid output: monitoring output from gastric outlets, nasogastric tubes, gastrostomy

Essential equipment

- Urometer
- Measuring jugs (with volume indicators)
- Non-sterile gloves, apron, goggles
- Bile drainage bag/gastrostomy drainage bag

Pre-procedure

Action	Rationale
1 Determine sources of fluid output (see Table 7.2) and note them on the fluid balance chart.	To ensure all possibilities have been considered to ensure accurate (as possible) output determination (Scales and Pilsworth 2008, E).

Procedure

2 Explain to the patient that it is necessary to monitor drainage every hour.	To inform the patient of current care and interventions (Bryant 2007, E).
3 Ensure gastric outlet device has a drainage bag attached.	To collect any output for measurement. E
4 If instructed, leave the bag open to drain (this may differ depending on condition).	To enable drainage. E
5 Drain contents into marked jug every hour (if quantity allows), using universal precautions.	To determine volume and prevent cross-infection (Fraise and Bradley 2009, E).
6 Attach a urometer if output is high.	To ensure accurate reading and for ease of measuring. E
7 Note volume on fluid balance chart, adding this value to the rest of the output values for that 1 hour.	To enable determination of fluid balance (Sumnall 2007, E).

Post-procedure

8 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.	To calculate hourly fluid balance (Levi 2005, E).
9 Document all values on the chart and any other actions relating to your findings in the patient's notes.	To ensure accurate documentation (NMC 2010, C).

Procedure guideline 7.6 Fluid output: monitoring output from bowels

Essential equipment

- Measuring jugs (with volume indicators)
- Scales
- Non-sterile gloves, apron, goggles
- Bedpan/commode
- Rectal tube 'Flexiseal' (if required)

Pre-procedure

Action	Rationale
1 Determine sources of fluid output (see Table 7.2) and note them on the fluid balance chart.	To ensure all possibilities have been considered to ensure accurate (as possible) output determination (Scales and Pilsworth 2008, E).

Procedure

2 Explain to the patient that it is necessary to monitor volume of fluid excreted, including that from the bowel, particularly if the stool is loose/watery.	To keep the patient informed about current care and observations, to ensure co-operation in monitoring fluid output (Bryant 2007, E).
3 Provide the patient with bedpans, even if able to mobilize to the bathroom; ask them to place the bedpan over the toilet bowl.	To enable inspection and measurement of fluid lost via the bowel. E
4 If stool is loose enough, this can be transferred into a jug and the volume measured, or use scales.	To quantify fluid output from stool (Scales and Pilsworth 2008, E).

(continued)

Procedure guideline 7.6 Fluid output: monitoring output from bowels (*continued*)

Action	Rationale
5 If the stool is formed and it is not possible to accurately quantify, still note on fluid balance chart that bowels were opened.	To take into account any insensible losses (Mooney 2007, E).
6 A rectal tube may be suitable in some patients; please refer to local policy regarding use of rectal tube. Note any output on the fluid balance chart.	To ensure correct use of tube and to quantify any fluid losses from the bowel. E
7 Add losses to the previous losses for the hour.	To calculate hourly fluid output (Sumnall 2007, E).
Post-procedure	
8 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.	To calculate hourly fluid balance (Levi 2005, E).
9 Document all values on the chart and any other actions relating to your findings in the patient's notes.	To ensure accurate documentation (NMC 2010, C).

264

Procedure guideline 7.7 Fluid output: monitoring output from stoma sites**Essential equipment**

- Measuring jugs (with volume indicators)
- Non-sterile gloves, apron, goggles

Pre-procedure

Action	Rationale
1 Determine sources of fluid output (see Table 7.2) and note them on the fluid balance chart.	To ensure all possibilities have been considered to ensure accurate (as possible) output determination (Alexander et al. 2006, E).

Procedure

2 Explain to the patient that you are monitoring hourly output.	To ensure the patient understands why their stoma is being checked hourly. To ensure they are up to date with current care (Bryant 2007, E).
3 Check that the stoma bag is drainable; if not, change (see Chapter 5: Elimination, Procedure guideline 5.23: Stoma bag change).	To ensure ease of draining bag contents and to reduce the number of times the adhesive flange is removed, in order to protect the skin. E
4 Using protective equipment, empty the contents of the stoma bag into the measuring jug, noting volume.	To determine output from stoma for 1 hour and prevent cross-infection (Fraise and Bradley 2009, E).
5 Dispose of contents using protective equipment, adhering to local policy.	To ensure correct disposal of contents and prevent cross-infection (Fraise and Bradley 2009, E).
6 Note volume of stool on chart; add to other losses for the hour.	To ensure correct documentation of output and allow calculation of fluid balance (NICE 2013a, C).
7 Add hourly total (all outputs) to cumulative output (see Figure 7.3).	To enable fluid balance determination (Sumnall 2007, E).

Post-procedure

8 Once all output has been determined, noted on chart and total hourly output calculated, subtract total output from total input.	To calculate hourly fluid balance. E
9 Document all values on the chart and any other actions relating to your findings in the patient's notes.	To ensure accurate documentation (NMC 2010, C).

Problem-solving table 7.1 Prevention and resolution (Procedure guidelines 7.1, 7.2, 7.3, 7.4, 7.5, 7.6 and 7.7)

Problem	Cause	Prevention	Action
Non-compliance/co-operation from patients.	Usually misunderstanding or lack of education regarding importance of monitoring fluid balance.	Effective patient education and teaching.	Determine effective teaching methods, considering individual needs, for example poor hearing, illiteracy. Re-educate the patient, using appropriate means.
Inability to record input due to lack of pumps to regulate intravenous fluids or enteral feeds.	Not available, unable to use, inappropriate.	Request more equipment from appropriate sources, request training.	Calculate drip rates on free-flowing fluids to ensure correct hourly input calculated.
Insensible losses.	Inability to measure some losses.	N/A	Note on chart if perspiration is excessive or if bowels opened and immeasurable, to highlight possible inaccuracy in fluid balance.
Leaking drains.	Inevitable with some drains.	Inevitable with some drains; however, surrounding opening may require further suturing; request surgical review if necessary.	Utilize stoma bag/wound drainage bag to collect drainage, to enable measurement.
Incorrect fluid balance calculation.	Incorrect fluid input determination. Incorrect fluid output determination. Incorrect calculation.	Appropriate teaching and education for nurses performing these procedures, competency checking.	Ensure nurses are educated appropriately, access information and education if unsure of procedure or technique.

Post-procedural considerations

Every hour, the findings of fluid input/output monitoring should be recorded; any deficit or change in fluid balance should be reported. Any imbalance noted will require action and a management plan. The nurse recording the fluid balance should have an appreciation of the importance of fluid imbalance management and should notify the appropriate person.

Complications

Correct fluid balance monitoring is essential in the successful management of actual or potential fluid balance disturbances (Jevon and Ewens 2007). Over- or underestimation of the fluid status could lead to incorrect management, resulting in fluid overload (hypervolaemia), dehydration (hypovolaemia) (Bryant 2007, Tang and Lee 2010) and/or electrolyte disturbances, all of which will ultimately lead to organ dysfunction.

Fluid overload/hypervolaemia

Underestimating the fluid balance may lead to continued or increased administration of IV fluids, which if monitored incorrectly could result in circulatory overload. Excess IV fluid administration is not the only cause of circulatory overload, which can also result from acute renal failure, heart failure and intake of excessive sodium (Welch 2010).

In health, homeostatic mechanisms exist to compensate and redistribute excess fluids but, in ill health, these mechanisms are often inadequate, leading to increasing circulatory volumes. As the volume within the circulatory system rises, so does the hydrostatic pressure which, when excessive, results in leaking of fluid from the vessels into the surrounding tissues. This is evident as oedema, initially apparent in the ankles and legs or buttocks and sacrum if the patient is in bed. This can progress to generalized oedema, where even the tissues surrounding the eyes become puffy and swollen.

A bounding pulse and an increased blood pressure are also signs of fluid overload, as is an increased cardiac output and raised central venous pressure (Cutler and Cutler 2010).

One of the most dangerous symptoms of fluid overload is pulmonary oedema, which occurs when the hydrostatic pressure within the vessels causes congestion within the pulmonary circulation, increasing the hydrostatic pressure there and causing fluid to leak into the lungs and pulmonary tissues (Casey 2004). This presents with respiratory symptoms, including shortness of breath, increased respiratory rate, a cough (Welch 2010), often associated with pink frothy sputum, and finally reduced oxygen saturations due to inadequate gaseous exchange at the alveolar level (Casey 2004). Left untreated, this can be fatal as the lungs are failing to provide essential cells and organs with oxygen; this would eventually lead to organ dysfunction and then failure.

Cardiac dysfunction can result from fluid overload, not only from the reduced availability of oxygen to the cardiac cells due to the pulmonary oedema, but also from the increase in volume causing the cardiac muscle to stretch, leading to cell damage and possible inability to contract effectively (Treacher 2009).

Treatment of hypervolaemia would involve restricting fluid intake, monitoring electrolytes and using diuretics in an attempt to offload some of the excess fluid (Thomsen et al. 2012). Vasodilators may also be considered to reduce the pressure in the vessels. If these mechanisms fail, it may be necessary to use renal replacement therapy to drive the fluid out of the circulation.

In some cases fluid overload is part of the disease process. However, with effective monitoring and fluid balance recording and assessment, it may be possible to avoid the devastating complications.

Hypovolaemia/dehydration

Dehydration refers to a negative fluid balance, when the fluid output exceeds the fluid intake (Jevon 2010). Overestimation of the fluid balance may lead to inadequate replacement of lost fluids. Dehydration can, however, be caused by a loss of fluids to 'third spaces' such as ascites or lost due to a reduction in colloid osmotic pressure (hypoalbuminaemia) (Casey 2004), losses

which are not easy to account for. Fluid balance charts should therefore always be used in association with physical assessment of the patient, weight measurement and laboratory results.

There are three categories of dehydration (Mentes 2006) – isotonic, hypertonic and hypotonic – each related to the type of fluid and solutes lost. Isotonic describes the loss of both water and sodium from the ECF; hypertonic is excessive loss of water only, which leads to a rise in ECF sodium, causing a shift in fluid from the intracellular space to the extracellular. Hypotonic dehydration results from excessive sodium loss, particularly with the overuse of diuretics (Welch 2010).

266

Dehydration can ultimately cause a reduction in circulating volume (Tortora and Derrickson 2011). As with any change in a homeostatic state, the body in health has the ability to compensate but in ill health these mechanisms are often inadequate. Untreated dehydration will quickly lead to a drop in blood pressure and a rise in heart rate (to compensate for the fall in blood pressure). A fall in blood pressure will firstly lead to inadequate renal perfusion, causing a rise in metabolites, acidosis, acute renal failure and eventual toxæmia. Untreated, other organs will suffer from underperfusion, possibly resulting in ischaemia, organ dysfunction and eventual organ failure (Sumnall 2007).

Additional signs and symptoms of dehydration are thirst, weight loss, decreased urine output, dry skin and mucous membranes, fatigue and increased body temperature (Goertz 2006).

Treatment of dehydration includes the replacement of lost fluid and electrolytes but caution must be exercised. If the dehydration is mild, slower fluid replacement is advised, in order to prevent further complications in shifts in electrolytes. However, if hypovolaemia exists with the signs and symptoms of circulatory shock, low blood pressure and organ dysfunction, aggressive fluid replacement is advised (Jevon 2010, NICE 2013a).

Acute kidney injury

Acute kidney injury (which can be due to a multitude of causes) is a common feature in the acutely or critically unwell patient and will require even more careful approaches to monitoring and maintenance of fluid balance (Goldstein 2012). The National Confidential Enquiry into Patient Outcome and Death (NCEPOD 2009) reviewed the care delivered to patients with acute kidney injury and found that 50% received suboptimal care. NICE responded to these findings by producing guidance for the prevention, detection and management of acute kidney injury (NICE 2013b). The relevant recommendations from this guidance include the need for reliable monitoring of urine output and early recognition of oliguria. These guidelines reinforce the need for accurate and reliable fluid balance monitoring along with health-care professionals understanding the implications of the findings.

Nutritional status

Definition

Nutritional status refers to the state of a person's health as determined by their dietary intake and body composition. Nutritional support refers to any method of giving nutrients which encourages an optimal nutritional status. It includes modifying the types of foods eaten, dietary supplementation, enteral tube feeding and parenteral nutrition (NCCAC 2006).

Anatomy and physiology

The normal process of ingestion of food or fluids is via the oral cavity to the gastrointestinal tract.

Swallowing is a complex activity with voluntary and reflexive components. It is usually described as having four stages and requires intact anatomy and sensorimotor functioning of the cranial nerves (Bass 1997, Butler and Leslie 2012, Logemann 1998). The stages start with the oral preparatory stage which is influenced by the sight and smell of food. Food or liquid is placed in

Figure 7.4 Pharyngeal stage of swallowing.

the mouth and the lips are closed. After chewing and mixing with saliva, it forms a cohesive mass (bolus) that is held on the centre of the tongue. The oral stage of the swallow is initiated as food is moved through the oral cavity towards the pharynx. These swallowing stages are voluntary.

The pharyngeal stage of swallowing, which is involuntary (Figure 7.4), occurs as the food bolus crosses the mandible/tongue base as the palate closes, sealing entry to the nasal cavity and reducing risk of nasal regurgitation. Movement of the tongue base and posterior pharyngeal wall squeezes the bolus down the pharynx. Involuntary movements of the larynx (voice box), vocal cords and epiglottis protect the airway and open the cricopharynx. The bolus travels from the cricopharynx to the gastro-oesophageal junction and peristaltic action then transfers the bolus down the oesophagus (Atkinson and McHanwell 2002, Butler and Leslie 2012).

The gastrointestinal tract is the site where food is ingested, digested and absorbed, thus enabling nutrients to be used by the body for growth and maintenance of body functions. Food ingested is moved along the gastrointestinal tract by peristaltic waves through the oesophagus, stomach, small intestine and large intestine. The passage of food and fluid through the gastrointestinal tract is dependent on the autonomic nervous system, gut hormones such as gastrin and cholecystokinin, the function of exocrine glands such as the parotid, pancreas and liver and psychological aspects such as anxiety. Sphincters situated between the stomach and duodenum, the ileocaecal valves and the anal sphincter also regulate the rate of passage of food and fluids through the tract (Barrett 2014).

Before food can be absorbed, it must be digested and broken down into molecules that can be transported across the intestinal epithelium which line the gastrointestinal tract. This process is dependent on digestive enzymes secreted by the pancreas and lining of the intestinal tract which act on specific nutrients. Bile, from the liver, is required to emulsify fat, thus enabling it to be broken down by digestive enzymes. The absorption of nutrients is dependent on an active, or energy-dependent, transport across the intestinal epithelium lining the digestive tract. Villi, finger-like projections, increase the surface area of the small intestine to aid absorption.

Most nutrients are absorbed from the small intestine although some require specific sites within the gastrointestinal tract; for example, vitamin B₁₂ is absorbed in the terminal ileum. Mucosa shed into the lumen of the intestine is broken down and absorbed along with fluid and electrolytes secreted into the lumen during the process of digestion. The volumes of fluid secreted into the gut are large and may amount to 8–9 litres a day when combined with an oral intake of 1.5–2 litres daily. The majority of fluid is reabsorbed in the small intestine with the remainder being absorbed in the large intestine. Bacteria in the large intestine metabolize non-starch polysaccharides (dietary fibre), increasing faecal bulk and producing short chain fatty acids which are absorbed and metabolized for energy (Brownlee 2011).

Related theory

Bodyweight is the most widely used measure of nutritional status in clinical practice. However, whilst weight provides a simple, readily obtainable and usually fairly precise measure, it remains a one-dimensional metric and as such has limitations. In contrast, an understanding of anatomy and physiology and in particular the changes that can occur in body composition, in addition to frank weight gain or loss, provides valuable clinical insight (Thibault et al. 2012). In the so-called 'two-compartment' model of body composition, bodyweight is described in terms of, firstly, fat-free mass, that is bones, muscles and organs, which includes the hepatic carbohydrate energy store glycogen, and secondly, fat mass or adipose tissue (Thibault et al. 2012). In health, water constitutes up to 60% of total bodyweight. It is distributed throughout the fat-free and fat compartments with approximately two-thirds present as intracellular and one-third as extracellular fluid. Thus, a healthy 70 kg male comprises 42 kg of water which amounts to 60% of total bodyweight. This is made up of 28 litres of intracellular fluid and 14 litres of extracellular fluid. The same 'typical' male contains approximately 12 kg of muscle, also referred to as lean body mass, and 12 kg of fat (Geissler and Powers 2005).

Body composition and nutritional status are closely linked and are dependent upon a number of factors, including age, sex, metabolic requirements, dietary intake and the presence of disease. Depletion of lean body mass occurs in both critical illness and injury and negatively affects functional and immune function and can be associated with increased mortality and length of hospital stay (Carlsson et al. 2013, Jensen et al. 2012, Pichard et al. 2004). Lean body mass tends to decrease with age (Hickson 2006). Shifts in body water compartments are readily observed in conditions such as ascites and oedema (Bedogni et al. 2003). Both of these conditions result from an abnormally increased extracellular water compartment and, despite a gain in total bodyweight, are indicative of worsening outcome.

The physiological characteristics of the different body compartments can be exploited by various assessment tools and techniques to determine changes indicative of nutritional risk (Bedogni et al. 2006). Such changes are masked if weight alone is used as the sole measurement.

Evidence-based approaches

Rationale

Nutritional support, to maintain or replete body composition, should be considered for anybody unable to maintain their nutritional status by taking their usual diet (NCCAC 2006). These include the following.

- Patients unable to eat their usual diet (e.g. because of anorexia, mucositis, taste changes or dysphagia) should be given advice on modifying their diet.
- Patients unable to meet their nutritional requirements, despite dietary modifications, should be offered oral nutritional supplements.

- Patients unable to take sufficient food and dietary supplements to meet their nutritional requirements should be considered for an enteral tube feed.
- Patients unable to eat at all should have an enteral tube feed. Reasons for complete inability to eat include carcinoma of the head and neck area or oesophagus, surgery to the head or oesophagus, radiotherapy treatment to the head or neck, fistulae of the oral cavity or oesophagus or dysphagia due to cerebrovascular accident (CVA).
- Parenteral nutrition (PN) may be indicated in patients with a non-functioning or inaccessible gastrointestinal (GI) tract who are likely to be 'nil by mouth' for 5 days or longer. Reasons for a non-functioning or inaccessible GI tract include bowel obstruction, short bowel syndrome, gut toxicity following bone marrow transplantation or chemotherapy, major abdominal surgery, uncontrolled vomiting and enterocutaneous fistulae. Enteral nutrition should always be the first option when considering nutritional support.

Patients in any group may have an increased requirement for nutrients due to an increased metabolic rate, as found in those with burns, major sepsis, trauma or cancer cachexia (Bozzetti 2001, Thomas and Bishop 2007, Todorovic and Micklewright 2011). Patients should have nutritional requirements estimated prior to the start of nutritional support and should be monitored regularly.

Methods of assessing nutritional status

Before the initiation of nutritional support, the patient must be assessed. The purpose of assessment is to identify whether a patient is undernourished, the reasons why this may have occurred and to provide baseline data for planning and evaluating nutritional support (NCCAC 2006). It is helpful to use more than one method of assessing nutritional status. For example, a dietary history may be used to assess the adequacy of a person's diet but does not reflect actual nutritional status, whereas percentage weight loss does give an indication of nutritional status. However, percentage weight loss taken in isolation gives no idea of dietary intake and likelihood of improvement or deterioration in nutritional status (NCCAC 2006).

Bodyweight and weight loss

Body Mass Index (BMI) or comparison of a patient's weight with a chart of ideal bodyweight gives a measure of whether the patient has a normal weight, is overweight or underweight, and may be calculated from weight and height using the following equation.

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (m)}^2}$$

Tables are available to allow the rapid and easy calculation of BMI (BAPEN 2003a). These comparisons, however, are not a good indicator of whether the patient is at risk nutritionally, as an apparently normal weight can mask severe muscle wasting.

Of greater use is the comparison of current weight with the patient's usual weight. Percentage weight loss is a useful measure of the risk of malnutrition.

$$\% \text{Weight loss} = \frac{\text{Usual weight} - \text{Actual weight}}{\text{Usual weight}} \times 100$$

A patient would be identified as malnourished if they had any of the following:

- BMI less than 18.5 kg/m²
- unintentional weight loss greater than 10% within the last 3–6 months

- BMI less than 20 kg/m² and unintentional weight loss greater than 5% within the last 3–6 months (NCCAC, 2006).

Sick children should have their weight and height measured frequently. It may be useful to measure on a daily basis (Shaw and Lawson 2007). These measurements must be plotted onto centile charts. A single weight or height cannot be interpreted as there is much variation of growth within each age group. It is a matter of concern if a child's weight begins to fall across the centiles or if the weight plateaus.

268

Obesity and oedema may make interpretation of bodyweight difficult; both may mask loss of lean body mass and potential malnutrition (Pennington 1997).

Accurate weighing scales are necessary for measurement of bodyweight. Patients who are unable to stand may require sitting scales or hoist scales.

It is often not appropriate to weigh palliative care patients who may experience inevitable weight loss as disease progresses. Psychologically, it may be difficult for patients to see that they are continuing to lose weight (Shaw 2011). Measures of nutritional status such as clinical examination and current food intake may still be used in addition to measures of bodyweight.

Skinfold thickness and bio-electrical impedance

Skinfold thickness measurements can be used to assess stores of body fat. They are rarely used in routine nutritional assessment due to the insensitivity of the technique and the variation between measurements made by different observers. They are more appropriate for long-term assessments or research purposes and the technique should only be used by practitioners who are practised in using skinfold thickness calipers because of the potential for intra-investigator variation in results (Durnin and Womersley 1974).

Bio-electrical impedance analysis (BIA) is a simple, non-invasive and relatively inexpensive technique for measuring body composition (Janssen et al. 2000). This technique works well in healthy individuals but may be of limited use in some hospital patients with abnormal hydration status (for example, severe dehydration or ascites) and is also less reliable at the extremes of BMI ranges (Kyle et al. 2004, Leahy et al. 2012).

Clinical examination

Observation of the patient may reveal signs and symptoms indicative of nutritional depletion.

- *Physical appearance*: emaciated, wasted appearance, loose dentures, teeth or clothing/jewellery.
- *Oedema*: will affect weight and may mask the appearance of muscle wastage. May indicate plasma protein deficiency and is often a reflection of the patient's overall condition rather than a measure of nutritional status.
- *Mobility*: weakness and impaired movement may result from loss of muscle mass.
- *Mood*: apathy, lethargy and poor concentration can be features of undernutrition.
- *Pressure sores and poor wound healing*: may reflect impaired immune function as a consequence of undernutrition and vitamin deficiencies (Thomas and Bishop, 2007).

Specific nutritional deficiencies may be identifiable in some patients. For example, thiamine deficiency characterized by dementia is associated with high alcohol consumption. Rickets is seen in children with vitamin D deficiency.

A more structured approach can be taken by using an assessment tool such as Subjective Global Assessment (SGA) or patient-generated SGA (PG-SGA) (Bauer et al. 2002). This involves a systematic evaluation of muscle and fat sites around the body and assessment for oedema in the ankles or sacral area in immobile patients. Such an assessment can be used to determine whether the patient is malnourished and can be repeated to assess changes in nutritional status.

Dietary intake

Nutrient intake can be assessed by a diet history (Thomas and Bishop 2007). A 24-hour recall may be used to assess recent nutrient intake and a food chart may be used to monitor current dietary intake. A diet history may also be used to provide information on food frequency, food habits, preferences, meal pattern, portion sizes, the presence of any eating difficulty and changes in food intake (Omran and Morley 2000, Reilly 1996). A food chart on which all food and fluid taken is recorded is a useful method for monitoring nutritional intake, especially in the hospital setting or when dietary recall is not reliable (Thomas and Bishop 2007).

Biochemical investigations

Biochemical tests carried out on blood may give information on the patient's nutritional status. The most commonly used are as follows.

- *Plasma proteins*: changes in plasma albumin may arise due to physical stress, changes in circulating volume, hepatic and renal function, shock conditions and septicemia. Plasma albumin and changes in plasma albumin are not a direct reflection of nutritional intake and nutritional status as it has been shown that they may remain unchanged despite changes in body composition (NCCAC 2006). In addition, albumin has a long half-life of 21 days, so it cannot reflect recent changes in nutritional intake. It may be useful to review serum albumin concentrations in conjunction with C-reactive protein (CRP), which is an acute-phase protein produced by the body in response to injury or trauma. CRP greater than 10 mg/L and serum albumin less than 30 g/L suggest 'illness' (Elia 2001). Prealbumin and retinol binding protein levels are more sensitive measures of nutrition support, reflecting recent changes in dietary intake rather than nutritional status. However, they may be expensive to measure and are not measured routinely in hospital.
- *Haemoglobin*: this is often below haematological reference values in malnourished patients (men 13.5–17.5 g/dL, women 11.5–15.5 g/dL). This can be due to a number of reasons, such as loss of blood from circulation, increased destruction of red blood cells or reduced production of erythrocytes and haemoglobin, for example due to dietary deficiency of iron or folate.
- *Serum vitamin and mineral levels*: clinical examination of the patient may suggest a vitamin or mineral deficiency. For example, gingivitis may be due to a deficiency of vitamin C. Goitre is associated with iodine deficiency, and muscle weakness and cramps may be caused by magnesium deficiency (Thomas and Bishop 2007). Serum vitamin and mineral levels are rarely measured routinely, as they are expensive and often cannot be performed by hospital laboratories.
- *Immunological competence*: total lymphocyte count may reflect nutritional status (Gibson 2005) although levels may also be depleted with malignancy, chemotherapy, zinc deficiency, age and non-specific stress (Thomas and Bishop 2007).

If a patient is considered to be malnourished by one or more of the above methods of assessment then referral to a dietician should be made immediately (NCCAC 2006).

Methods for calculation of nutritional requirements

The body requires protein, energy, fluid and micronutrients such as vitamins, minerals and trace elements to function optimally. Nutritional requirements should be estimated for patients requiring any form of nutritional support to ensure that these needs are met.

Energy requirements may be calculated using equations such as those derived by Henry (2005), which take into account weight, age, sex, activity level and clinical injury, for example post surgery, sepsis or ventilator dependency. An easier and more appropriate method is to use bodyweight and allowances based on the patient's clinical condition (Table 7.4). Careful adjustments may be necessary in cases of oedema or obesity, in order to avoid overfeeding (Horgan and Stubbs 2003).

Table 7.4 Guidelines for estimation of patient's daily energy and protein requirements (per kilogram bodyweight) (guidelines not always appropriate for patients who are severely ill)

Factor	Measurement
Energy (kcal)	25–35
Energy (kJ)	105–146
Protein (g)	0.8–1.5
Fluid (mL)	35 (18–60 years) 30 (>60 years) (plus 2–2.5 mL per °C in temperature above 37°C)

Source: Todorovic and Micklewright (2011). Reproduced with permission from PENG – Parenteral and Enteral Nutrition Group (www.peng.uk.com) of the British Dietetic Association (www.bda.uk.com).

Fluid and nitrogen (or protein) requirements can be calculated in a similar way. If additional nitrogen is being given in situations where losses are increased, for example due to trauma, GI losses or major sepsis, then additional energy intake is required to assist in promoting a nitrogen balance. Improvement in nitrogen balance is the single nutritional parameter most consistently associated with improved outcome, and the primary goal of nutrition support should be the attainment of nitrogen balance (Gidden and Shenkin 2000). Additional fluid of 500–750 mL is necessary for every 1°C rise in temperature in pyrexial patients (Thomas and Bishop 2007).

Vitamin and mineral requirements calculated as detailed in the Committee on Medical Aspects of Food Policy (COMA) Report 41 on dietary reference values (COMA and DH 1991) apply to groups of healthy people and are not necessarily appropriate for those who are ill. A patient deficient in a vitamin or mineral may benefit from additional supplements to improve a condition. Macronutrient and micronutrient requirements for children are also listed in the COMA Report. Calculations are usually done with the reference nutrient intake (RNI). The child's actual bodyweight, not the expected bodyweight, is used when calculating requirements. This is to avoid excessive feeding.

Methods for measuring height and weight of an adult patient

Taking an accurate height and weight of a patient is an essential part of nutrition screening. Accurate measurements of bodyweight may also be required for estimating body surface area and

calculating drug dosages, such as for anaesthesia and chemotherapy. All patients should have height and weight measured on admission to hospital and weight should be measured at regular intervals during their hospital stay according to local policy and individual clinical need.

Pre-procedural considerations

Check that the patient is able to stand or sit on the appropriate scales. The patient should remove outdoor clothing and shoes before being weighed and having height measured.

When obtaining a height measurement, check that the patient is able to stand upright whilst the measurement is taken. For patients who are unable to stand then height may be determined by measuring ulna length and using conversion tables. If neither height nor weight can be measured or obtained, BMI can be estimated using the mid upper arm circumference (MUAC) (BAPEN 2003a). It may not be possible to weigh patients who cannot be moved or are unable to sit or stand. Alternative methods to obtain weight should be explored, for example bed scales which can be placed under the wheels of the bed, scales as an integral part of a bed or a patient hoist with weighing facility.

Equipment

Scales

Scales (either sitting or standing) must be calibrated and positioned on a level surface. If electronic or battery scales are used then they must be connected to the mains or have appropriate working batteries prior to the patient getting on the scales.

Stadiometer

These are devices for measuring height and may be mounted on weighing scales or wall mounted.

Tape measure

Required if estimating height from ulna length or MUAC. The tape measure should use centimetres, be disposable or made of plastic that can be cleaned with a detergent wipe between patient uses.

Assessment tools

Identification of patients who are malnourished or at risk of malnutrition is an important first step in nutritional care. There are a number of screening tools available which consider different aspects of nutritional status. National screening initiatives have demonstrated that 28% of patients admitted to hospital were found to be at risk of malnutrition – high risk (22%) and medium risk (6%) (BAPEN 2009). Particular diagnoses, such as cancer, increase the risk of malnutrition.

Procedure guideline 7.8 Measuring the weight and height of the patient

Essential equipment

- Scales
- Stadiometer (preferably fixed to the wall)

Optional equipment

- Tape measure

Pre-procedure

Action	Rationale
1 Position the scales for easy access and apply the brakes (if appropriate).	To ensure that the patient can get on and off the scales easily and to avoid accidents should the scales move. E
2 Ask the patient to remove shoes and outdoor garments. The patient should be wearing light indoor clothes only (see Action figure 2).	Outdoor clothes and shoes will add additional weight and make it difficult to obtain an accurate bodyweight. E

(continued)

Procedure guideline 7.8 Measuring the weight and height of the patient (*continued*)**Procedure**

Action	Rationale
3 Ensure that the scales record zero, then ask the patient to stand on scales (or sit if using sitting scales). Ask the patient to remain still and check that the patient is not supporting any weight on any object, for example wall, stick or feet on the floor.	To record an accurate weight (NMC 2010, C).
4 Note the reading on the scale and record immediately, taking care that it is legible. Check with the patient that the weight reflects their expected weight and that the weight is similar to previous weights recorded. This may require conversion of weight from kg to stones and pounds or vice versa.	To check that the weight is correct. If the weight is not as expected then the patient should be reweighed. E
5 Ensure that the patient has removed their shoes and then ask them to stand straight with heels together. If the stadiometer is wall mounted, the heels should touch the heel plate or the wall. With a freestanding device the person's back should be toward the measuring rod.	Shoes will provide additional height and make the measurement inaccurate. E To ensure that the patient is standing upright. If the person does not have their back against the measuring rod then the measuring arm may not reach the head. E
6 The patient should look straight ahead and with the bottom of the nose and the bottom of the ear in a parallel plane. The patient should be asked to stretch to reach maximal height.	To ensure an accurate height is measured. E
7 Record height to the nearest millimetre.	To record an accurate measurement of the patient's height (NMC 2010, C).
8 To estimate the height of a patient from ulna length, ask the patient to remove long-sleeved jacket, shirt or top.	To be able to access their left arm for measurement purposes. E
9 Measure between the point of the elbow (olecranon process) and the midpoint of the prominent bone of the wrist (styloid process) on the left side if possible (Action figure 9).	To obtain measurement of the length of the ulna. E
10 Estimate the patient's height to the nearest centimetre, using a conversion table.	To estimate the patient's height (BAPEN 2003a, C).
11 To estimate BMI from MUAC, ask the patient to remove long-sleeved jacket, shirt or top.	To be able to access their left arm for measurement purposes (BAPEN 2003a, C).
12 Measure the distance between the top of the shoulder (acromion) and the point of the elbow (olecranon process) – identify the midpoint between the two points and mark the arm (Action figure 12a, 12b).	To obtain measurement of the mid upper arm circumference. E
13 Ask the patient to let the arm hang loosely by their side and, with a tape measure, measure the circumference of the arm at the midpoint (Action figure 13).	To obtain accurate measurement of the mid upper arm circumference. E
14 Document the measurement.	To record an accurate measurement of MUAC (BAPEN 2003a, C).
15 Estimate the patient's BMI using a conversion table.	To estimate the patient's BMI (BAPEN 2003a, C).
Post-procedure	
16 Document height and weight, or estimated BMI, in patient's notes.	To record the accurate measurement of patient's height and weight (NMC 2010, C).

Action Figure 2 Weighing a patient.

Action Figure 9 Measure between the point of the elbow (olecranon process) and the midpoint of the prominent bone of the wrist (styloid process).

Action Figure 12a Identify the midpoint between the two points.

Action Figure 12b Mark the arm.

Action Figure 13 Measure the circumference of the arm at the midpoint using a tape measure.

Problem-solving table 7.2 Prevention and resolution (Procedure guideline 7.8)

Problem	Cause	Prevention	Action
Patient unable to stand on scale.	Poorly positioned scales. Patient balance not sufficient.	Check with patient prior to asking them to stand on scales if they are able to do so. Offer sitting scales if necessary.	Ensure both sitting and standing scales are available in the hospital.
Weight obtained appears too low.	Patient may have put pressure on scales prior to them reaching zero.	Ensure zero is visible before patient touches scales.	Check weight with patient once obtained. Reweigh patient to check correct weight.
Weight obtained appears too high.	Patient may be wearing outdoor clothes or shoes or be carrying a bag, drainage bag and so on. Patient may have fluid retention, for example oedema or ascites.	Ensure that the patient is wearing light indoor clothes before standing on the scales. Check whether patient has fluid retention. Ask patient to empty any drainage bags.	Check weight with patient once obtained. Reweigh patient to check correct weight.
Patient is unable to stand.	Patient is unwell or has physical disability.	Discuss the procedure with patient before undertaking height measurement.	Consider estimating height from ulna measurement.

All patients who are identified as at risk of malnutrition should undergo a nutritional assessment. Subjective global assessment (SGA) and patient-generated SGA (PG-SGA) are comprehensive assessment tools that necessitate more time and expertise to carry out than most screening tests. Some more simple screening tools, including the Malnutrition Universal Screening Tool (MUST) (BAPEN 2003a), based on the patient's BMI, weight loss and illness score, are less time consuming. Other tools may be specific to the patient's age or diagnosis (Kondrup et al. 2003). The most important feature of using any screening tool is that patients identified as requiring nutritional assessment or intervention have a nutritional care plan initiated and are referred to the dietician for further advice if appropriate.

Post-procedural considerations

Consideration must be given to the patient's weight and whether this reflects a change in their clinical condition. The weight may be being used as part of a nutritional screening or assessment or for planning of treatment, for example medication. Any significant changes should be interpreted in the light of potential changes in body composition and incorporated into the patient's care plan. For example, a loss of weight may require further questioning about dietary intake and the commencement of a nutritional care plan.

After taking a measurement of height, it is useful to check with the patient that the figure obtained is approximately the height expected. However, it is important to consider that patients may report a loss in height with increasing years. A cumulative height loss from age 30 to 70 years may be about 3 cm for men and 5 cm for women and by age 80 years it increases to 5 cm for men and 8 cm for women (Sorkin et al. 1999).

Provision of nutritional support: oral

Evidence-based approaches

Rationale

An essential part of providing diet for a patient is to ensure that the patient is able to consume the food and fluid in a safe and

pleasant environment. Some patients may require assistance with feeding or drinking and a system should be in place to ensure that these patients receive the required attention at each mealtime and beverage service, as well as adaptive cutlery or crockery if appropriate. Choice should be encouraged, preferably from a menu. Ideally the menu should be coded to assist patients to select suitable options such as high energy, soft, vegetarian, etc. Meals should be available for patients requiring gluten-free, halal, kosher or texture-modified choices.

It is essential that meals are appetising and strictly comply with any dietary restriction relevant to the patient. For example, those with food allergies, texture modifications, religious or cultural dietary requirements need to be clearly identified with the senior ward nurse, before assistance with feeding commences. Eating and drinking are pleasurable experiences and the psychosocial aspect of this cannot be overestimated. The inability to participate in mealtimes can be socially isolating (Ekberg et al. 2002). Research has highlighted that dysphagia also affects carers due to the impact on social activity and can lead to permanent changes in lifestyle (Patterson et al. 2012).

Patient-centred care requires respect and involvement of the patient in the process of feeding (Care Quality Commission 2010). Supporting the dignity of the patient throughout the process is also imperative to its success and acceptance.

Provision of food and nutrition in a hospital setting

Good nutritional care, adequate hydration and enjoyable mealtimes can dramatically improve the general health and well-being of patients who are unable to feed themselves, and can be particularly relevant to older people (Nutrition Summit Stakeholder Group and DH 2007). Unfortunately, it is evident that assistance with meals for those that require it does not always occur. In the summary of the results for the 2011 national inpatients survey, 15% described the hospital food as 'poor', an increase over 13% in 2010. Of those needing help to eat their meals, 19% did not receive this (Care Quality Commission 2010).

Many factors, including being in hospital, need to be taken into consideration when planning nutritional support. Clinical benchmarking (DH 2010) and clinical initiatives such as protected mealtimes aim to address common problems that patients experience whilst in hospital that impact on food intake.

Box 7.1 Food and nutrition benchmark ('food' includes drinks)

Agreed patient/client-focused outcome: patients/clients are enabled to consume food (orally) which meets their individual needs.

Indicators/information that highlight concerns which may trigger the need for benchmarking activity:

- Patient satisfaction surveys
- Complaints figures and analysis
- Audit results: including catering audit, nutritional risk assessments, documentation audit, environmental audit (including dining facilities)
- Contract monitoring, for example wastage of food, food handling and/or food hygiene training records
- Ordering of dietary supplements/special diets
- Audit of available equipment and utensils
- Educational audits/student placement feedback
- Litigation/Clinical Negligence Scheme for Trusts
- Professional concern
- Media reports
- *Sustainable Food and the NHS* (King's Fund 2005), *Food and Nutritional Care in Hospitals* (Council of Europe 2003)

Factor	Benchmark of best practice
1 Promoting health	People are encouraged to eat and drink in a way that promotes health
2 Information	People and carers have sufficient information to enable them to obtain their food and drink
3 Availability	People can access food and drink at any time according to their needs and preferences
4 Provision	People are provided with food and drink that meets their individual needs and preferences
5 Presentation	People's food and drink are presented in a way that is appealing to them
6 Environment	People feel the environment is conducive to eating and drinking
7 Screening and assessment	People who are screened on initial contact and identified as at risk receive a full nutritional assessment
8 Planning, implementation, evaluation and revision of care	People's care is planned, implemented, continuously evaluated and revised to meet individual needs and preferences for food and drink
9 Assistance	People receive the care and assistance they require with eating and drinking
10 Monitoring	People's food and drink intake is monitored and recorded

Other factors which may influence food intake, such as treatments, surgery and medications, also need to be taken into account when planning nutritional support, as clinical experience shows that these may have a deleterious effect on appetite and the ability to maintain an adequate nutritional intake, although rehabilitation therapy can be helpful in increasing intake (van der Molen et al. 2009).

The *Essence of Care Benchmark for Food and Drink* (DH 2010) sets the standard for best practice with regard to the provision of food and drink in hospital. The document states that people must be enabled to consume food and drink (orally) which meets their needs and preferences. Ten factors affecting intake and benchmarks of best practice are identified to support optimal provision and monitoring of food and drink. These are shown in Box 7.1. The Department of Health and the Nutrition Summit Stakeholder Group have worked together to produce an action plan based on the 10 key characteristics of good nutritional care in hospitals. These are outlined in Box 7.2.

Modification of diet

There are various publications providing initial advice for people requiring modification of diet, such as *Have You Got a Small Appetite?* (NAGE n.d.). See also Table 7.5.

Dietary supplements

If patients are unable to meet their nutritional requirements with food alone then they may require dietary supplements. These may be used to improve an inadequate diet or as a sole source of nutrition if taken in sufficient quantity.

Sip feeds

These come in a range of flavours, both sweet and savoury, and are presented as a powder in a packet or ready prepared in a can, bottle or carton. Sip feeds contain whole protein, hydrolysed fat and carbohydrates. Most are called 'complete feeds' since they provide all protein, vitamins, minerals and trace elements to meet requirements if a prescribed volume is taken (Thomas and Bishop 2007). Others may be aimed at specific needs, for example high protein.

Energy supplements

Carbohydrates

Glucose polymers in powder or liquid form contain approximately 350 kcal (1442 kJ) per 100 g and 187–299 kcal (770–1232 kJ) per 100 mL respectively. Powdered glucose polymer is virtually tasteless and may be added to anything in which it will dissolve, for example milk and other drinks, soup, cereals and milk pudding; liquid glucose polymers may be fruit flavoured or neutral (Thomas and Bishop 2007). Such supplements would be used to increase the energy content of the diet.

Box 7.2 Ten key characteristics of good nutritional care in hospitals

- All patients are screened on admission to identify those who are malnourished or at risk of becoming malnourished. All patients are rescreened weekly.
- All patients have a care plan which identifies their nutritional care needs and how they are to be met.
- The hospital includes specific guidance on food services and nutritional care in its clinical governance arrangements.
- Patients are involved in the planning and monitoring arrangements for food service provision.
- The ward implements protected mealtimes to provide an environment conducive to patients enjoying and being able to eat their food.
- All staff have the appropriate skills and competencies needed to ensure that patients' nutritional needs are met. All staff receive regular training on nutritional care and management.
- Hospital facilities are designed to be flexible and patient centred with the aim of providing and delivering an excellent experience of food service and nutritional care 24 hours a day, every day.
- The hospital has a policy for food service and nutritional care which is patient centred and performance managed in line with home country governance frameworks.
- Food service and nutritional care are delivered to the patient safely.
- The hospital supports a multidisciplinary approach to nutritional care and values the contribution of all staff groups working in partnership with patients and users.

Fat

Fat may be in the form of long-chain triglycerides (LCT) or medium-chain triglycerides (MCT) and comes as a liquid which can be added to food and drinks. These oils provide 416–772 kcal (1714–3181 kJ) per 100 mL; the oils with a lower energy value are presented in the form of an emulsion and those with a higher energy value are presented as pure oil (Thomas and Bishop 2007).

Mixed fat and glucose polymer solutions and powders are available and provide 150 kcal per 100 mL or 486 kcal per 100 g, depending on the relative proportion of fat and carbohydrates in the product.

Products containing MCT are used in preference to those containing LCT where a patient suffers from GI impairment causing malabsorption. Patients require specific advice about their use to ensure that they are introduced into the diet slowly and GI tolerance is assessed (Thomas and Bishop 2007).

Always check with the manufacturer for the exact energy content of products.

Note: products containing a glucose polymer are unsuitable for patients with diabetes mellitus.

Protein supplements

These come in the form of a powder and provide 55–90 g protein per 100 g. Protein supplement powders may be added to any food or drink in which they will dissolve, for example milk, fruit juice, soup, milk pudding.

Energy and protein supplements are not used in isolation as these would not provide an adequate nutritional intake. They are used in conjunction with sip feeds and a modified diet. The

Table 7.5 Suggestions for modification of diet

Eating difficulty	Dietary modification
Anorexia	<p>Serve small meals and snacks, for example twice-daily snack options</p> <p>Make food look attractive with garnish</p> <p>Fortify foods with butter, cream or cheese to increase energy content of meals</p> <p>Use alcohol, steroids, megestrol acetate or medroxyprogesterone as an appetite stimulant</p> <p>Encourage food that patient prefers</p> <p>Offer nourishing drinks between meals. In hospital consider a 'cocktail' drinks round</p>
Sore mouth	<p>Offer foods that are soft and easy to eat</p> <p>Avoid dry foods that require chewing</p> <p>Avoid citrus fruits and drinks</p> <p>Avoid salt and spicy foods</p> <p>Allow hot food to cool before eating</p>
Dysphagia	<p>Offer foods that are soft and serve with additional sauce or gravy</p> <p>Some foods may need to be blended: make sure food is served attractively</p> <p>Supplement the diet with nourishing drinks between meals</p>
Nausea and vomiting	<p>Have cold foods in preference to hot as these emit less odour</p> <p>Keep away from cooking smells</p> <p>Sip fizzy, glucose-containing drinks</p> <p>Eat small frequent meals and snacks that are high in carbohydrate (e.g. biscuits and toast)</p> <p>Try ginger drinks and ginger biscuits</p>
Early satiety	<p>Eat small, frequent meals. In hospital, access an 'out-of-hours' meal service</p> <p>Avoid high-fat foods which delay gastric emptying</p> <p>Avoid drinking large quantities when eating</p> <p>Use prokinetics, for example metoclopramide, to encourage gastric emptying</p>

detailed nutritional compositions of dietary supplements are available from the manufacturers.

Specialist supplements

Supplements designed for specific patient groups are also available, for example, aimed at dementia, chronic obstructive pulmonary disease, renal or dysphagia patients.

Vitamin and mineral supplements

When dietary intake is poor, a vitamin and mineral supplement may be required. This can often be given as a one-a-day tablet supplement that provides 100% of the dietary reference values. Care should be taken to avoid unbalanced supplements or those containing amounts larger than the dietary reference value (FSA and Expert Group on Vitamins and Minerals 2003). Excessive doses of vitamins and minerals may be harmful, particularly as some vitamins and minerals are not excreted by the body when taken in amounts exceeding requirements. Additionally, vitamins and minerals may interact with medication to influence its efficacy; for example, vitamin K may influence anticoagulants such as warfarin.

Patients being discharged from hospital on nutritional supplements

It is important to ensure that patients who require continued oral nutritional supplements in the community are discharged with a suitable supply. The decision on choice of supplement will usually be with the prescriber and should be based on clinical need and patient acceptability. Where more than one suitable option is available, the ease of use in a community setting, likely compliance and the impact on primary care budgets may be factors to be weighed up in the choice of supplement.

Anticipated patient outcomes

It is anticipated that feeding an adult will ensure safe delivery of the meal, in a comfortable environment which the patient feels is a pleasurable and positive experience, promoting adequate nutritional care.

Legal and professional issues

Protected mealtimes should be in place on the wards, whereby all non-essential clinical activities have been discontinued and a calm environment exists (Age Concern 2006). The use of protected mealtimes within hospitals is strongly encouraged by the National Patient Safety Agency which encourages trusts to have an appropriate policy in place to monitor its implementation on the wards and to have a structure in place to report patients missing meals via the local risk management system (NPSA 2007). The Care Quality Commission carried out a dignity and nutrition inspection programme in 2012, and found that protected mealtimes was one of the contributing factors in encouraging support for patients to eat and drink sufficient amounts in hospitals, achieving the standard of 'meeting people's nutritional needs' (Care Quality Commission 2013).

Pre-procedural considerations

Sufficient staff need to be available to support those who need help. Patients who require assistance should be identified through screening and a discreet signal should be evident to identify that further assistance is required, for example a red tray, a coloured serviette or a red sticker (Bradley and Rees 2003).

Assessment and recording tools

Food record charts can provide the essential information that forms the basis of a nutritional assessment and help to

determine subsequent nutritional care. They are therefore a valuable resource for dietitians, nurses and ultimately the patient (Freeman 2002). They can be used to assess whether the patient is eating and drinking enough, thereby enabling action to be taken to encourage intake in those who have a reduced dietary intake.

The objective is to quantify the amount of food and drink (including oral nutritional supplements) consumed by a patient over an agreed time period and, although open to error, it has been demonstrated that this type of record keeping provides more accurate information than methods involving recall (Kroke et al. 1999). In hospital, a patient's intake frequently changes as a result of disease, symptoms, medication, unfamiliar surroundings and food availability. It is frequently not evident how much a patient is eating, particularly on busy wards with regular staff changes.

All screening, including food charts, should be linked to a care plan and documented in the patient's notes (DH 2010, Freeman, 2002, NPSA 2009a). If there is noted weight loss, concerns expressed by staff or from relatives regarding the patient's nutritional intake, particularly where there are difficulties observed with eating and drinking, close monitoring of oral intake is essential. The only exception to this is when a patient is receiving end-of-life care and it has been clarified with the clinical team that active nutritional support is not appropriate.

Food charts should be available on all wards and should be simple to complete. It is often preferable to include on the chart household measures such as tablespoons, slice of bread or hospital portions, to assist with the speed of completion.

Training should be given on how the chart should be completed and preferably should be undertaken by the dietitian or the specialist nutrition nurse, as this will facilitate understanding of the rationale and continuity of recording and improve accuracy. Charts need to be carefully completed over a minimum and consecutive 2- or 3-day period or longer if requested by the dietitian. Some research suggests that information should be collected over at least 7 days in order to estimate protein and energy intake to within $\pm 10\%$ (Bingham 1987).

Specific patient preparations

Before commencing assistance, please discuss this with the patient in order that they understand and consent to assistance being provided. When verbal communication is not possible, non-verbal agreement needs to be obtained wherever possible. Try to engage the patient in the feeding process and interpret and record any preferences or dislikes they may express regarding the meal process.

Make sure the patient has the opportunity to visit the bathroom and wash or clean their hands with an antiseptic wipe and to undertake any appropriate mouthcare prior to eating. Establish whether any medication is to be administered prior to or after feeding which will facilitate the feeding and digestive process. Individual symptoms should be assessed; for example, if patients are nauseous they may benefit from the prescribing of antiemetics or prokinetic agents. Patients who have pancreatic insufficiency may require pancreatic enzyme replacements. All drugs should be correctly prescribed on the drug chart. The timing in relation to feeding is important and antiemetics should be given approximately 30 minutes prior to meal service. Any special equipment, such as cutlery or non-slip mats, that is required for assisting the patient with the meal should be provided. This may require referral to an occupational therapist for an assessment.

Procedure guideline 7.9 Feeding an adult patient

Essential equipment

- A clean table or tray
- Equipment required to assist the patient such as adequate drinking water, adapted cups, cutlery and napkin
- A chair for the nurse or carer to sit with the patient

Pre-procedure

Action	Rationale
1 Explain and discuss feeding with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands, put on apron.	To ensure that the procedure is as clean as possible (Fraise and Bradley 2009, E).
3 Ensure that the patient is comfortable, that is, they have an empty bladder, clean hands, clean mouth and, if applicable, clean dentures. Ensure there are no unpleasant sights or smells that would put the patient off eating.	To make the mealtime a pleasant experience (Age Concern 2006, E).
4 Ensure the nurse or carer is positioned in front or to the side of the patient and sat at the patient's level to assist with feeding.	To enable the patient and helper to see each other and to assist communication. E
5 Ensure that the patient is sitting upright in a supported midline position, preferably in a chair, if it is safe and appropriate, and at a table.	To facilitate swallowing and protect the airway. E
6 Protect the patient's clothing with a napkin.	To maintain dignity and cleanliness. E

Procedure

7 Assist the patient to take appropriate portions of food at the correct temperature but encourage self-feeding. Tailor the size of each mouthful to the individual patient. If possible, each hot course of a meal should be served individually and items which may change in consistency, such as ice cream, served separately.	To make the mealtime a pleasant experience. To maintain textures of foods. To ensure that swallowing is not compromised if the patient feels that they must hurry with the meal (Samuels and Chadwick 2006, E).
8 Allow the patient to chew and swallow foods before the next mouthful. Avoid hovering with the next spoonful.	To maintain the dignity of the patient. E
9 Avoid asking questions when the patient is eating, but check between mouthfuls that the food is suitable and that the patient is able to continue with the meal.	To reduce the risk of aspirating, which may be increased if speaking whilst eating. E
10 Use the napkin to remove particles of food or drink from the patient's face.	To maintain dignity and cleanliness. E
11 Ask the patient when they wish to have a drink. Assist the patient to take a sip. Support the glass or cup gently so that the flow of liquid is controlled or use a straw if this is helpful. Take care with hot drinks to avoid offering these when too hot to drink.	To give the opportunity for the patient to swallow. Hot liquids may scald the patient. E
12 If the food appears too dry, ask the patient if they would like some additional gravy or sauce added to the dish.	To facilitate chewing and swallowing (Wright et al. 2008, E).
13 Observe patient for coughing, choking, wet or gurgly voice, nasal regurgitation or effortful swallow. See Table 7.6 for details of problems that may be experienced by patients.	May indicate aspiration, laryngeal penetration or weakness in muscles required for swallowing (Leslie et al. 2003, E).
14 Encourage the patient to take as much food as they feel able to eat, but do not press if they indicate that they have eaten enough.	To improve nutritional intake but also maintain patient dignity and choice (Wright et al. 2008, E).

Post-procedure

15 After the meal assist the patient to meet hygiene needs, for example, wash hands and face and clean teeth.	To maintain cleanliness and dignity. E
---	---

Table 7.6 Difficulties that may be experienced by patients during eating and drinking and their potential implications

Difficulty experienced	Implications
Coughing and choking during and after eating and/or drinking	Indicates laryngeal penetration or aspiration (Smith Hammond 2008)
Wet or gurgly voice quality	Indicates laryngeal penetration or aspiration (Leslie et al. 2003b)
Drooling/excess oral secretions	Indicates less frequent swallowing and is associated with dysphagia (Langmore et al. 1998). May result from poor lip seal
Nasal regurgitation	Indicates impaired velopalatal seal (Leslie et al. 2003b)
Food/drink pooling in mouth	Indicates lack of oral sensation from intraoral flaps or may be a sign of cognitive impairment (Logemann 1998)
Swallow is effortful	May indicate weakness in muscles required for swallowing (Logemann et al. 2008)
Respiration rate on eating/drinking is increased	Increased respiration rate may be associated with risk of aspiration (Leslie et al. 2003b)
Signs of recurrent chest infections and pyrexia	This may indicate aspiration pneumonia as a consequence of dysphagia (Leslie et al. 2003b)
Patient report of swallowing problems	Patients can be very accurate in self-diagnosis of dysphagia (Pauloski et al. 2002)
Patient reports food sticking	Patients can be very accurate in self-diagnosis of dysphagia (Pauloski et al. 2002)
Additional time required to eat a meal	Taking a long time to eat may indicate dysphagia (Leslie et al. 2003b)
Avoidance of certain foods	Patients will avoid food items that they find difficult to swallow (Leslie et al. 2003b)
Weight loss	Patients may eat less due to difficulty swallowing (Leslie et al. 2003b)
Poor oral hygiene	Aspiration of secretions in those with poor oral hygiene may result in aspiration pneumonia (Langmore 2001)

Post-procedural considerations

Education of patient and relevant others

It is important that volunteers, family members or visitors who wish to assist the patient with feeding are familiar with and trained in the processes listed in Procedure guideline 7.9: Feeding an adult patient (NPSA 2009b). This is to ensure that the family is confident and can safely and effectively assist the patient.

Documentation

It is essential that the plate is not removed before wastage has been recorded and this is relayed to the ward catering staff. If the patient has not managed a reasonable amount of their meal, this needs to be addressed later in the afternoon or evening. It is also important to ascertain whose responsibility it is for completion of the charts to avoid confusion, that is, nurse, healthcare assistant, ward catering staff or patient, as this will vary across institutions. These charts can be used by the dietician or healthcare professional to effectively assess the patient's meal pattern and nutrition intake. Some patients may be able to complete the record themselves if given guidance on what is required. All food record charts that have been reviewed by a healthcare professional should be signed and dated on completion of review.

Difficulties arise when the food chart data are not accurately completed or reviewed, during which time malnutrition and its consequences continue, rather than being quickly identified and addressed.

If there is strong concern about the quantity of food that has been consumed by the patient, this must also be verbally relayed to the nurse in charge, ward dietician and possibly the clinician.

Nutritional management of patients with dysphagia

Definition

Dysphagia is an impairment of swallowing that may involve any structure from the lips to the gastric cardia (Leslie et al. 2003).

Evidence-based approaches

Rationale

Indications

Patients who are at high risk of dysphagia are summarized in Box 7.3.

Goals of clinical assessment

Some patients who are eating and drinking may experience dysphagia. It is important to correctly ascertain the presence of dysphagia and the factors contributing to its possible aetiology. Such patients may be at risk of aspiration and subsequent chest infections and therefore require a referral to a speech and language therapist for a full assessment (Roe 2012). Patients require a nutritional assessment from a dietician with consideration of possible enteral tube feeding if the patient is unable to maintain an adequate nutritional intake or is at risk of aspiration. A suitable swallowing rehabilitation programme should be developed. Patients undergoing surgery or radiotherapy for head and neck cancer should have a baseline clinical swallowing evaluation before treatment (Lazarus 2000, NICE 2004, Patterson and Wilson 2011).

Principles of care

Care will be influenced by the timing of patient referral dependent on their disease and treatment status. Management of the dysphagic patient will be tailored to individual needs and they will require regular reviews to ensure that intervention and management decisions remain appropriate. The nature of the dysphagia may persist, recur or worsen depending on the patient's treatment or disease.

Treatment options may include normal diet with specifically targeted therapy techniques, modified diet, combination of alternative feeding and limited oral intake or nil by mouth. For patients with oropharyngeal dysphagia, dysphagia food texture descriptors have been developed and updated to provide industry and in-house caterers with detailed guidance on categories of food texture, thereby enhancing patient safety (NPSA 2012).

Box 7.3 Patient groups at high risk of dysphagia

- Head and neck cancer patients undergoing surgery and/or radiotherapy/chemoradiotherapy. The risk of dysphagia is increased with multimodal therapy. Side-effects from treatment may affect swallow function, such as xerostomia (dry mouth), odynophagia (pain on swallowing), thick oral secretions, nausea, candidiasis, taste changes, mucositis, fatigue, fibrosis and trismus (reduced mouth opening). Nutritional support with enteral tube feeding may be required.
- Patients with neurological involvement including brain tumours or metastases, other co-morbid neurological disorders, for example cerebrovascular accident, multiple sclerosis, motor neurone disease, Parkinson's disease, myasthenia gravis. Such patients may also have cognitive or behavioural issues which can affect their mood, motivation, feeding and appetite.
- Patients with lung cancer and vocal cord paralysis and respiratory disorders such as chronic obstructive pulmonary disease, including mechanically ventilated patients.
- Tracheostomy patients may present with swallowing problems although frequently their medical diagnosis is the primary cause of dysphagia.
- Gastrointestinal patients may present with oropharyngeal or oesophageal dysphagia.
- Any other patient with significant generalized weakness or other co-morbidities, including palliative care patients.
- Patients with psychogenic dysphagia.
- Laryngectomy patients and particularly pharyngolaryngectomy and pharyngolaryngo-oesophageal patients. Some patients may experience dysphagia due to altered anatomy after surgery.

Source: Adapted from Donzelli et al. (2005), Leder and Ross (2000), Lewin et al. (2001), Roe (2005), Roe et al. (2007), Royal College of Speech and Language Therapists (2006).

For patients undergoing radiotherapy for head and neck cancer, it may be appropriate to implement a programme of prophylactic swallowing exercises (Cappell et al. 2009, Paleri et al. 2014).

Close liaison between the nursing staff, dieticians and members of the MDT is essential. The speech and language therapist (SLT) may recommend that the patient adopts certain compensatory swallow techniques to reduce the risk of aspiration or eliminate discomfort. Exercises or swallow techniques may be given to the patient to rehabilitate their swallow (Lazarus et al. 2002, Lewin et al. 2001, Logemann et al. 1997). It is important for nurses to participate in educational programmes for patients and carers in order to improve awareness of the implications of dysphagia. Nurses may be required to supervise patients with oral intake and encourage their participation with regard to therapy exercises, and reduce other risk factors by encouraging good mouthcare and independent feeding.

Methods of assessment

Clinical swallow assessment

In any patient presenting with a new onset of dysphagia, a medical review is necessary as this may be the first indicator of a change in disease or condition. A subsequent specialist SLT referral is then necessary. The SLT will take a full comprehensive case history including subjective reports, medical, physical and mental status. Surgical and/or disease details will be determined, including where the patient is on the care pathway, for example pre-operative, post-operative, receiving treatment, medication or

Figure 7.5 Oral stage of swallowing.

palliative care. An examination of the oral cavity and cranial nerve assessment will be carried out to evaluate motor and sensory function associated with swallowing (Figure 7.5). Food and drink trials may be carried out by the SLT. The clinical swallowing evaluation may include tests such as the 100 mL Water Swallow Test (Patterson and Wilson 2011).

Instrumental swallowing evaluation

Following an initial assessment, the SLT may recommend instrumental assessments to evaluate in detail the nature and extent of any swallowing disorder. Silent aspiration is a particular issue and, in the absence of any overt clinical signs of aspiration or relevant medical history (such as frequent chest infections), instrumental evaluation will be the most appropriate way to identify the problem and its cause. The SLT can implement a range of compensatory strategies during these assessments to optimize swallowing function and minimize the risk of aspiration where possible. By observing swallowing biomechanics, SLTs will be able to define rehabilitation targets. A number of instrumental assessments of swallowing are available but videofluoroscopy (modified barium swallow) and fibreoptic endoscopic evaluation of swallowing (FEES) are the most commonly utilized (Roe 2012). Videofluoroscopy takes place in the X-ray department and involves use of radio-opaque contrast mixed with food (Logemann 1998). FEES involves use of an endoscope passed transnasally, allowing a view of the swallow process while a patient eats and drinks (Langmore 2001). These assessments should be selected on a patient-by-patient basis and in the knowledge that each method has its own particular advantages and limitations (Roe 2012).

Anticipated patient outcomes

Early identification of dysphagia and appropriate management is an essential part of patient care. Appropriate management aims to reduce the incidence of aspiration and the risk of aspiration pneumonia and to help maintain adequate nutrition. If it is not addressed appropriately, it can lead to malnutrition, weight loss and dehydration, aspiration and aspiration pneumonia, low mood and reduced quality of life (Gaziano 2002). Ultimately it may result in increased length of hospital stay (Low et al. 2001). Ensuring the patient has a clear understanding of their swallowing difficulty is essential and may help them to become motivated rehabilitation partners (Roe and Ashforth 2011).

Enteral tube feeding

Definition

Enteral tube feeding refers to the delivery of a nutritionally complete feed (containing protein, fat, carbohydrate, vitamins, minerals, fluid and possibly dietary fibre) directly into the gastrointestinal tract via a tube. The tube is usually placed into the stomach, duodenum or jejunum via either the nose or direct percutaneous route (NCCAC 2006).

Related theory

Enteral feeding tubes allow direct access to the gastrointestinal tract for the purposes of feeding. A nasogastric or nasojejunal tube is placed via the nose and passed down the oesophagus with the feeding tip ending in the stomach (gastric) or small intestine (jejunum) respectively. A gastrostomy tube is placed directly into the stomach allowing infusion of nutrients into the stomach or, alternatively, such tubes may have a jejunal extension passing through the pylorus, allowing feeding into the jejunum (small intestine). A jejunostomy tube allows direct access to the jejunum for feeding. The choice of appropriate tube should be based on the method of insertion and the associated risks, length of time feeding is required, function of the gastrointestinal tract, the physical condition of the patient and body image issues relating to the visibility of the feeding tube, after discussion with the patient. The feeding regimen, care of the tube and stoma will depend on the enteral feeding tube inserted and should be undertaken within the care of a multiprofessional team (Majka et al. 2013, NCCAC 2006).

Evidence-based approaches

Rationale

While the majority of patients will be able to meet their nutritional requirements orally, there is a group of individuals who will require enteral tube feeding either in the short term or on a more permanent basis.

The primary aim of enteral tube feeding is to:

- avoid further loss of bodyweight
- correct significant nutritional deficiencies
- rehydrate the patient
- stop the related deterioration of quality of life of the patient due to inadequate oral nutritional intake (Loser et al., 2005).

Indications

Indications for enteral tube feeding are as follows:

- patient is unable to meet nutritional needs through oral intake alone
- the gastrointestinal tract is accessible and functioning
- it is anticipated that intestinal absorptive function will meet all nutritional needs (NCCAC, 2006)

Pre-procedural considerations

Equipment: types of enteral feed tubes

Nasogastric/nasoduodenal/nasojejunal

Nasogastric feeding is the most commonly used enteral tube feed and is suitable for short-term feeding, that is, 2–4 weeks (NCCAC 2006). Nasogastric tubes must be radio-opaque throughout their length and have externally visible length markings (NPSA 2011). Fine-bore feeding tubes should be used whenever possible as these are more comfortable for the patient than wide-bore tubes. They are less likely to cause complications such as rhinitis, oesophageal irritation and gastritis (Payne-James et al. 2001). Polyurethane or silicone tubes are preferable to polyvinylchloride (PVC) as they withstand gastric acid and can stay in position

longer than the 10–14-day lifespan of the PVC tube (Payne-James et al. 2001). The initial placement of a nasogastric tube should be confirmed with an abdominal X-ray (unless placed under radiological guidance) (NCCAC 2006).

Gastrostomy

A gastrostomy may be more appropriate than a nasogastric tube when enteral tube feeding is anticipated to be greater than 4 weeks. It avoids delays in feeding and discomfort associated with tube displacement (NCCAC 2006).

A gastrostomy tube may be placed endoscopically (percutaneous endoscopically placed gastrostomy; PEG) or radiologically (radiologically inserted gastrostomy; RIG). They are made from polyurethane or silicone and are therefore suitable for short- or long-term feeding. A flange, flexible dome, inflated balloon or pig-tail sits within the stomach and holds the tube in position.

For long-term feeding (i.e. longer than 1 month), a gastrostomy tube may be replaced with a button which is made from silicone. The entry site for feeding is flush with the skin, making it neat and less obvious than a gastrostomy tube. This is more cosmetically acceptable, especially for teenagers or patients who are physically active, but does require a certain amount of manual dexterity from the patient (Thomas and Bishop 2007). The button is held in place by a balloon or dome inside the stomach (Griffiths 1996). Percutaneous endoscopically placed gastrostomy tubes may be placed while the patient is sedated, thereby avoiding the risks associated with general anaesthesia. However, patients who have compromised airways may require general anaesthesia and appropriate consideration for maintenance of the airway (see Chapter 9: Respiratory care).

Certain groups of patients are not suitable for endoscopy; in these cases a RIG can be used. They are indicated for oesophageal patients with bulky tumours where it would be difficult to pass an endoscope and also for head and neck patients whose airway would be obstructed by an endoscope. There is also documented risk of the endoscope seeding the tumour to the gastrostomy site when it pulls the tube past a bulky tumour, although this is a rare complication (Pickhardt et al. 2002).

Jejunostomy

A jejunostomy is preferable to a gastrostomy if a patient has undergone upper GI surgery or has severe delayed gastric emptying; in some cases it can be used to feed a patient with pyloric obstruction (Thomas and Bishop 2007). Fine-bore feeding jejunostomy tubes may be inserted surgically or laparoscopically with the use of a jejunostomy kit, which consists of a needle-fine catheter. The use of needles and an introducer wire allows a fine-bore polyurethane catheter to be inserted into a loop of jejunum. Alternatively, some gastrostomy tubes allow the passage of a fine-bore tube through the pylorus and into the jejunum. A double-lumen tube allows aspiration of stomach contents whilst feed is administered into the small intestine.

Enteral feeding equipment

The administration of enteral feeds may be as a bolus, intermittent or continuous infusion, via gravity drip or pump assisted (Table 7.7). There are many enteral feeding pumps available which vary in their flow rates from 1 to 300 mL per hour. The following systems may be used for feeding via a pump or gravity drip.

- Feed is decanted into plastic bottles or PVC bags. The administration set may be an integral part of the bag or may be supplied separately. The feed is sterile until opened and decanting feed into reservoirs will increase the risk of contamination from handling (Payne-James et al. 2001). Generally this method is only used for feeds that require reconstitution with water. Malnourished and immunocompromised patients are particularly at risk from contamination and infection so this method of administration should be avoided where possible.

Table 7.7 Methods of administering enteral feeds

Feeding regimen	Advantages	Disadvantages
Continuous feeding via a pump	Easily controlled rate Reduction of gastrointestinal (GI) complications	Patient connected to the feed for majority of the day May limit patient's mobility
Intermittent feeding via gravity or a pump	Periods of time free of feeding Flexible feeding routine May be easier than managing a pump for some patients	May have an increased risk of GI symptoms, for example early satiety Difficult if outside carers are involved with the feed
Bolus feeding	May reduce time connected to feed Very easy Minimum equipment required	May have an increased risk of GI symptoms May be time consuming

- The 'ready-to-hang' system has a plastic bottle or pack attached directly to the administration set. The bottles and packs are available in different types of feeds and sizes for flexibility. This is a closed sterile system which has been shown to be successful in preventing exogenous bacterial contamination (Payne-James et al. 2001).
- For powdered feeds that require reconstitution with water, the feed is decanted into plastic bottles or PVC bags. The administration set may be an integral part of the bag or may be supplied separately. The feed is sterile until opened and decanting feed into reservoirs will increase the risk of contamination of the feed from handling (Payne-James et al. 2001). Malnourished and immunocompromised patients are particularly at risk from contamination and infection so this method of administration should be avoided where possible.

Enteral feeds

Commercially prepared feeds should be used for nasogastric, gastrostomy or jejunostomy feeding. Available in liquid or powder form, they have the advantage of being of known composition and are sterile when packaged. Enteral feeds can be nutritionally complete when given in the advised quantity and can be used as a sole source of nutrition or to supplement the patient's oral intake (Lochs et al. 2006).

Whole protein/polymeric feeds

These contain protein, lipid in the form of LCTs and carbohydrate and so require digestion (Lochs et al. 2006). They may provide 1.0–1.5 kcal/mL (see manufacturer's specifications). As the energy density of the feed increases, so does the osmolarity. Hyperosmolar feeds tend to draw water into the lumen of the gut from the bloodstream and can contribute to diarrhoea if given too rapidly. Fibre may be beneficial for maintaining gut ecology and function, rather than promoting bowel transit time (Thomas and Bishop 2007).

Feeds containing medium-chain triglycerides

In some whole-protein feeds, a proportion of the fat or LCTs may be replaced with MCTs. The feed often has a lower osmolarity and is therefore less likely to draw fluid from the plasma into the gut lumen. MCTs are transported via the portal vein rather than the lymphatic system. These feeds are suitable for patients with fat malabsorption and maybe steatorrhoea (Cummings 2000).

Elemental/peptide feeds

These contain free amino acids, short-chain peptides or a combination of both as the nitrogen source. They are often low in fat or may contain some fat as MCTs. Glucose polymers provide the main energy source. These feeds require little or no digestion and are suitable for patients with impaired GI function, maldigestion or malabsorption (Thomas and Bishop 2007). They are hyperosmolar and low in residue.

Special application feeds

These feeds have altered nutrients for particular clinical conditions. Low-protein and low-mineral feeds may be used for patients with liver or renal failure. High-fat, low-carbohydrate feeds may be used for ventilated patients because less carbon dioxide is produced per calorie intake compared with a low-fat, high-carbohydrate feed. Very high-energy and high-protein feeds may be used where nutritional requirements are exceptionally high, for example burns, severe sepsis. These feeds contain approximately double the amount of energy and protein compared to standard whole-protein feeds (Thomas and Bishop 2007).

Paediatric feeds

These are designed for children 1–12 years old and/or 8–45 kg in weight. The protein, vitamin and mineral profile is suitable for children. Generally they are lower in osmolarity than adult feeds. The whole-protein/polymeric feeds are based on cow's milk but are lactose free. Some of these feeds may contain dietary fibre. These feeds provide 1.0–1.5 kcal/mL for children who require additional energy and protein in a smaller volume. Protein hydrolysed feeds and elemental feeds are used in conditions such as food allergies or malabsorption. The osmolarity of these feeds is higher than whole-protein feeds. They need to be introduced carefully (Thomas and Bishop 2007).

Immune-modulating feeds

There is evidence to show that the addition of glutamine, arginine or omega-3 fatty acids, if given pre-operatively, may benefit post-surgical GI patients by reducing the risk of post-operative infections. These specialized liquids may be given pre- or post-operatively (Braga et al. 2002, Weimann et al. 2006).

Up-to-date information on the exact composition of dietary supplements and enteral feeds can be obtained from the manufacturers.

Enteral tube insertion

Evidence-based approaches

Rationale

It is essential that the position of the nasogastric tube is confirmed prior to feeding to ensure that it has been placed safely in the gastrointestinal tract and has not been inadvertently placed in the lungs. A wire introducer is provided with many of the fine-bore tubes to aid intubation.

Indications

- Patients who require short-term enteral tube feeding (2–4 weeks) as a sole source of nutrition or for supplementary feeding.

Contraindications

- Patients who require long-term enteral tube feeding in whom it may be more appropriate to use a gastrostomy tube.
- Patients with coagulation disorders should have blood clotting checked by the medical team and appropriate blood products administered if required prior to insertion.

Anticipated patient outcomes

The patient has a nasogastric tube inserted comfortably and safely. The position is checked and it is confirmed that the tube is placed in the stomach.

Legal and professional issues

Those passing the nasogastric tube should have achieved competencies set by the local trust. The procedure should be compliant with NPSA recommendations, that is, only using syringes that are compatible with enteral feeding tubes (NHS England 2013, NPSA 2011).

Pre-procedural considerations

Specific patient preparations

The planned procedure should be discussed with the patient so they are aware of the rationale for insertion of a nasogastric tube. The decision to insert a nasogastric tube must be made by at

least two healthcare professionals, including the senior doctor responsible for the patient's care. Verbal consent for the procedure must be obtained from the patient.

Prior to performing this procedure, the patient's medical and nursing notes should be consulted to check for potential complications. For example, anatomical alterations due to surgery, such as a flap repair, or the presence of a cancerous tumour can prevent a clear passage for the nasogastric tube, resulting in pain and discomfort for the patient and further complications. Patients who have recurrent retching or vomiting, swallowing dysfunction or are comatose have a high risk of placement error or migration of the tube so care must be taken when placing a nasogastric tube under these circumstances (NPSA 2011). The assessment of the patient, the risks and patient consent obtained should be clearly documented.

Social and psychological impact

For some patients a nasogastric tube can be distressing. This is not only due to physical discomfort but also people's perceptions of their body image, particularly as this type of feeding tube is highly visible. Some people find that they limit their social activity due to embarrassment, which can lead to feelings of isolation. Others see it as a reminder of ill health which can have an impact on mood. These issues should be discussed with the patient prior to tube insertion. If necessary, the patient should be referred for specialist psychological care (Brotherton et al. 2011).

Procedure guideline 7.10 Nasogastric intubation with tubes using an internal guidewire or stylet

Essential equipment

- Clinically clean tray
- Hypoallergenic tape
- Fine-bore nasogastric tube with internal guidewire or stylet that is radio-opaque through its entire length and has externally visible length markings (NPSA 2011)
- Adhesive patch if available
- Glass of water, if appropriate
- Receiver
- Lubricating jelly
- Sterile water
- CE-marked indicator strips with pH range of 0–6 or 1–11 with gradations of 0.5
- 50 mL enteral syringe

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Arrange a signal by which the patient can communicate if they want the nurse to stop, for example by raising their hand.
- 3 Assist the patient to sit in a semi-upright position in the bed or chair. Support the patient's head with pillows.
Note: the head should not be tilted backwards or forwards (Rollins 1997).
- 4 Select the appropriate distance mark on the tube by measuring the distance on the tube from the patient's earlobe to the bridge of the nose plus the distance from the earlobe to the bottom of the xiphisternum (the NEX measurement) (see **Action figures 4a, 4b**).
- 5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required.
- 6 Follow manufacturer's instructions to activate the lubricant on the tip of tube, for example dipping the end in tap water and/or lubricating the proximal end of the tube with lubricating jelly.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- The patient is often less frightened if they feel that they have some control over the procedure. **E**
- To allow for easy passage of the tube. This position enables easy swallowing and ensures that the epiglottis is not obstructing the oesophagus. **E**
- To ensure that the appropriate length of tube is passed into the stomach (NPSA 2011, **C**).
- Hands must be cleansed before and after patient contact to minimize cross-infection (Fraiese and Bradley 2009, **E**).
- Contact with water activates the coating on the tip of the tube. This lubricates the tube, assisting its passage through the nasopharynx. **E**

(continued)

Procedure guideline 7.10 Nasogastric intubation with tubes using an internal guidewire or stylet
(continued)

Procedure	
Action	Rationale
7 Check that the nostrils are patent by asking the patient to sniff with one nostril closed. Repeat with the other nostril.	To identify any obstructions liable to prevent intubation. E
8 Insert the rounded end of the tube into the clearer nostril and slide it backwards and inwards along the floor of the nose to the nasopharynx. If any obstruction is felt, withdraw the tube and try again in a slightly different direction or use the other nostril.	To facilitate the passage of the tube by following the natural anatomy of the nose. E
9 As the tube passes down into the nasopharynx, unless swallowing is contraindicated, ask the patient to start swallowing and sipping water.	To focus the patient's attention on something other than the tube. A swallowing action closes the glottis and the cricopharyngeal sphincter opens, enabling the tube to pass into the oesophagus (Lamont et al. 2011, E).
10 Advance the tube through the pharynx as the patient swallows until the predetermined mark has been reached (NEX measurement). If the patient shows signs of distress, for example gasping or cyanosis, remove the tube immediately.	The tube may have accidentally been passed down the trachea instead of the pharynx. Distress may indicate that the tube is in the bronchus. However, absence of distress is not sufficient for detecting a misplaced tube (NPSA 2005, C ; NPSA 2011, C).
11 Do not flush any fluid down the NG tube until the position has been checked.	There is a risk of introducing fluid into the lungs if the tube is incorrectly positioned (NPSA 2011, C).

282

Action Figure 4a Measuring for a nasogastric tube: measure from the patient's ear lobe to the bridge of the nose.

Action Figure 4b Measuring for a nasogastric tube: measure from the ear lobe to the bottom of the xiphisternum.

- 12 Secure the tape to the nostril with adherent dressing tape, for example Elastoplast, or an adhesive nasogastric stabilization/securing device (Burns et al. 1995). Alternatively Tegaderm/Deoderm can be applied to the cheek and then covered in Mepore to secure the nasogastric tube; this can help to prevent skin irritation. A hypoallergenic tape should be used if an allergy is present.

To hold the tube in place. To ensure patient comfort. **E**

Post-procedure

- 13 Measure the part of the visible tube from tip of nose and record this and the NEX measurement in the care plan. Mark the tube at the exit site with a permanent marker pen (nares).

To provide a record to assist in detecting movement of the tube (Metheny and Titler 2001, **E**; NPSA 2011, **C**).

- 14 Check the position of the tube to confirm that it is in the stomach by using the following methods. Placement devices for NG tube insertion do not replace the following checks to confirm that the tube is in the stomach.

No fluids must be given via the tube until the correct position of the tube has been confirmed (NPSA 2011, **C**).

To confirm that the tube is in the correct position (NHS England, 2013, **C**).

First-line test method: pH paper

Aspirate 0.5–1 mL of stomach contents and test pH on indicator strips (NPSA 2011; Rollins 1997). When aspirating fluid for pH testing, wait at least 1 hour after a feed or medication has been administered (either orally or via the tube). Before aspirating, flush the tube with 20 mL of air to clear other substances (Metheny et al. 1993). A pH level of between 1 and 5.5 is unlikely to be pulmonary aspirates and it is considered appropriate to proceed to feed through the tube (Metheny and Meert 2004; NPSA 2011).

pH indicator strips should have gradations of 0.5 or paper with a range of 0–6 or 1–11 to distinguish between gastric acid and bronchial secretions and must be CE marked and intended to check gastric aspirate (NPSA 2011, **C**).

To prove an accurate test result because the feed or medication may raise the pH of the stomach (NPSA 2011, **C**).

If a pH of 6.0 or above is obtained or there is doubt over the result in the range of pH 5–6 then feeding **must not** commence until a second competent person checks the reading or retests. The nasogastric tube may need to be repositioned or checked with an X-ray.

There is an increased risk of the nasogastric tube being incorrectly placed (NPSA 2011, **C**).

Do not flush the tube with any form of fluid until the placement of the tube has been confirmed (NHS England 2013).

This may result in fluid being flushed into the lungs (NPSA 2011, **C**).

Second-line test method: X-ray confirmation

Take an X-ray of chest and upper abdomen. The X-ray request form should clearly state that the purpose of the X-ray is to establish the position of the nasogastric tube for the purpose of feeding (NPSA 2011).

X-ray of radio-opaque tubes is the most accurate confirmation of position and is the second-line method of choice in patients for whom it is not possible to confirm correct placement with gastric aspirate and pH indicator strips (NPSA 2011, **C**).

- 15 The following methods **must not** be used to test the position of a nasogastric feeding tube: auscultation (introducing air into the nasogastric tube and checking for a bubbling sound via a stethoscope, also known as the 'whoosh test'), use of litmus paper or absence of respiratory distress.

These tests are not accurate or reliable as a method of checking the position of a nasogastric tube as they have been shown to give false-positive results (Metheny and Meert 2004, **E**; NPSA 2011, **C**).

- 16 X-rays must only be interpreted and the position confirmed by someone assessed as competent to do so. When confirmed, the person interpreting the X-ray must document the tip position in the patient's notes in an entry that is signed with date and time.

To record the position and document that it is safe to feed through this nasogastric tube (NMC 2010, **C**; NPSA 2011, **C**).

- 17 Once placement of the nasogastric tube is confirmed, then the guidewire/stylet can be removed. The internal lubricant of the tube must be activated immediately before the stylet is removed. Follow manufacturers guidelines regarding activation of internal lubricant.

To facilitate easy removal of guidewire/stylet (NHS England 2013, **C**).

Problem-solving table 7.3 Prevention and resolution (Procedure guideline 7.10)

Problem	Cause	Prevention	Action
Unable to obtain aspirate from nasogastric tube.	Tip of tube is not sitting in gastric contents, is against the stomach wall or is not advanced sufficiently into the stomach.	Measure the tube correctly as described in Action 4.	Follow the NPSA flowchart (NPSA 2011). 1 Turn patient onto their left side. 2 Inject 10–20 mL air into the tube using a 50 mL syringe. 3 Wait 15–30 minutes. Advance or withdraw tube by 10–20 cm. 4 Do not use water to flush the tube. 5 Try aspirating again.
pH of greater than 5.5 is obtained.	The nasogastric tube may be placed in the lungs or patient is on acid-inhibiting medication and this may contribute to a higher gastric pH.	Check pH of gastric aspirate about the time of administration of acid-inhibiting medication when gastric pH is likely to be at its lowest.	Check patient's medication and check the position of the tube at the appropriate time.
pH of greater than 5.5 is obtained despite following recommendation about acid-inhibiting medication.	The nasogastric tube may be placed in the lungs.	Check medication.	If initial confirmation cannot be obtained from pH aspirate then tube must be X-rayed as it may be in the lungs.
Initial correct placement is confirmed but subsequent measurements are unable to obtain a pH of less than 5.5.	The following may have happened. The nasogastric tube has become displaced Acid-inhibiting medication is causing pH to be above 5.5 Feed/food is influencing pH of stomach contents.	Follow NPSA guidance on checking the position of the nasogastric tube. This involves additional actions including advancing the tube 10–20 cm and rechecking. Leave for 1 hour and then aspirate and check again.	Undertake risk assessment and document action. The nasogastric tube may need to be repositioned and rechecked with an X-ray.
Unable to place the nasogastric tube.	The patient has altered anatomy. The patient is distressed/not compliant with the procedure.		The nasogastric tube should be placed under X-ray guidance or via endoscopy.

Post-procedural considerations

Immediate care

The position of the nasogastric tube must be checked at initial placement and again prior to the administration of all medication or feed. Failure to confirm the position of the tube in the stomach can lead to the administration of fluid, medication or feed directly into the lungs, resulting in aspiration pneumonia (Figure 7.6).

The position of the nasogastric tube can be checked using two methods.

- *First-line method: testing of gastric aspirate with pH indicator paper.* The use of pH to check the position of the tube is based on an understanding of the pH of body fluids, particularly gastric contents, and the pH scale (Box 7.4). This should have a pH less than 5.5 (NPSA 2011).
- *Second-line method: X-ray.* An X-ray must be used to confirm the position of the tube in patients for whom it has not been possible to confirm the position of the tip of the nasogastric tube by gastric aspirate and pH indicator strips. The X-ray

must be read by medical staff with appropriate training (Law et al. 2013).

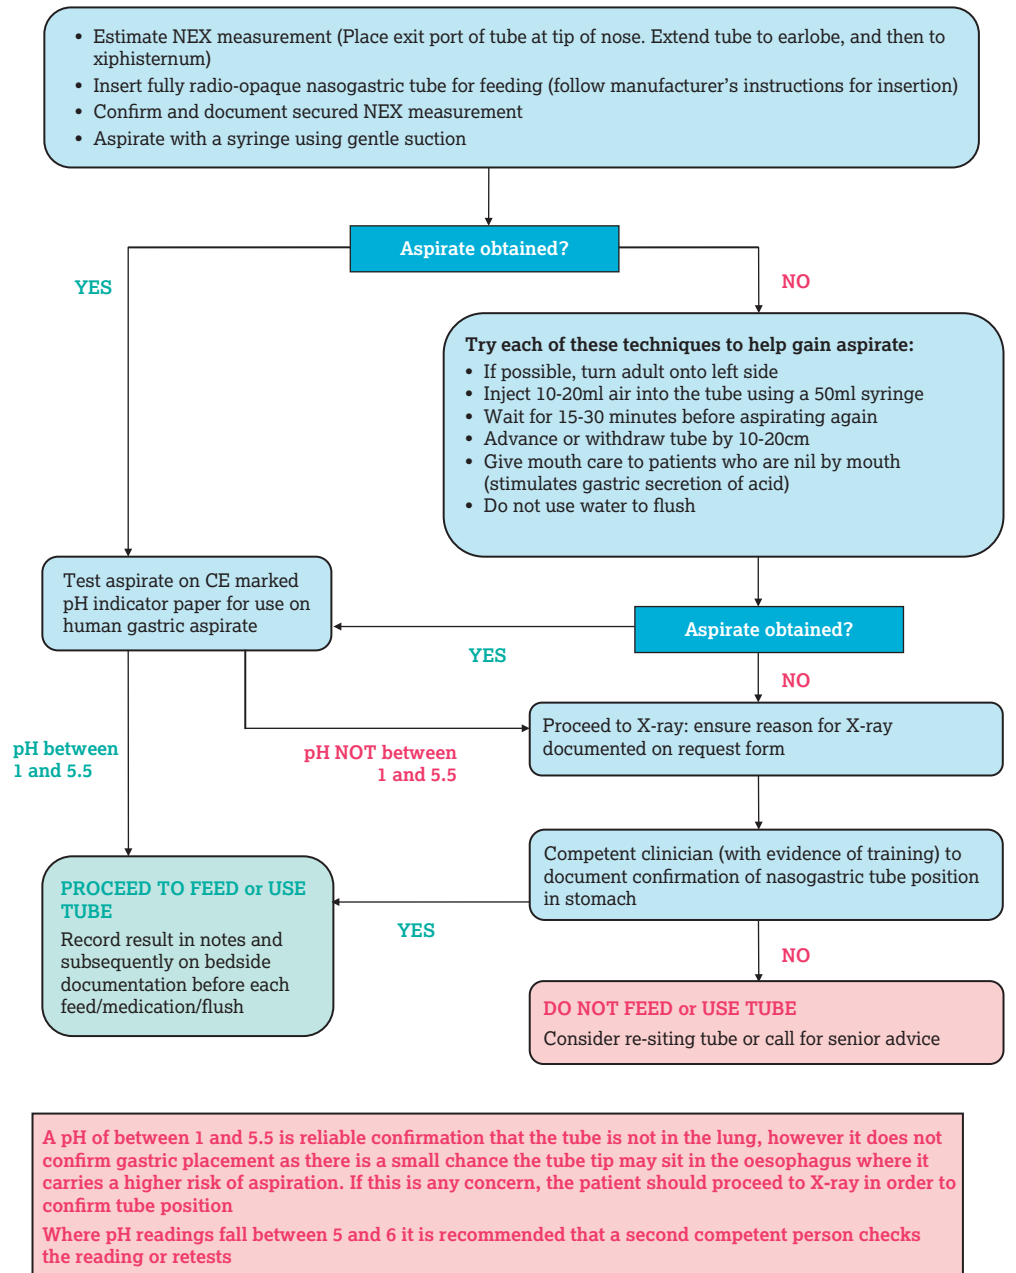

In accordance with NPSA (2011) guidance, the following methods should **not** be used to confirm the position of a feeding tube.

- Auscultation of air insufflated through the feeding tube ('whoosh test').
- Testing the pH of the aspirate using blue litmus paper.
- Interpreting the absence of respiratory distress as an indicator of the correct positioning.
- Monitoring bubbling at the end of the tube.
- Observing the appearance of feeding tube aspirate.

In addition to the initial confirmation, the tube should be checked on a daily basis (see Procedure guideline 7.10: Nasogastric intubation with tubes using an internal guidewire or stylet).

When the nasogastric tube is confirmed to be in the stomach, a mark should be made on the tube at the exit site from the nostril with a permanent marker pen. The length of tube visible from the exit of the nostril to the end of the tube should

Decision tree for nasogastric tube placement checks in **ADULTS**

www.npsa.nhs.uk/alerts

Box 7.4 The clinical importance of the pH scale

The pH scale is a convenient way of recording large ranges of hydrogen ion concentrations without using the cumbersome numbers that are needed to describe the actual concentrations. That is why each step **down** the scale is a 10-fold **increase** in the acidity (a 10-fold **decrease** if going **up** scale). This means that stomach contents of pH 5 have 10 times as much acidity as has lung fluid of pH 6. Not knowing this could place your patient in harm's way.

The midpoint of the scale is 7. This number is related directly to the actual concentration of hydrogen ions in water, which is one ten-millionth units per litre – an extremely small number. One ten-millionth is the same as one divided by 10^7 . So a liquid of pH 6 has one-millionth units per litre, that is, 1 divided by 10^6 , and has 10 times the concentration of hydrogen ions as does pure water. This example shows why as the pH decreases, the hydrogen ion concentration, and thus the acidity, increase. For example, lemon juice and vinegar are acidic with a pH of 2.2 and 3 respectively whereas bleach is alkaline with a low concentration of hydrogen ions and a pH of 11.

In the body, the pH of cells, body fluids and organs is usually tightly controlled in a process called *acid–base homeostasis*. Without this careful regulation of pH or *buffering*, the normal body chemistry cannot take place successfully and illness or in extreme cases death can occur.

The pH of blood is slightly basic with a value of 7.4, whereas gastric acid can range from 5.5 to the highly acidic 0.7 and pancreatic secretions are measured at 8.1. When the pH in the body decreases, that is, it becomes more acidic, *acidosis* can occur, leading to symptoms such as shortness of breath, muscular seizure and coma.

pH also influences the structure and function of many enzymes in living systems. These enzymes usually only work satisfactorily within narrow pH ranges. Thus pepsin, a stomach enzyme, works best at pH 2. In the duodenum, trypsin functions best at around pH 7.5–8.0. Generally, most human cell enzymes work best in a slightly alkaline medium of about 7.4.

Keeping the cellular pH at the correct level is very important and in the case of *unregulated diabetes*, high blood sugar levels occur, leading to acidic conditions that rapidly destroy enzymes and cells. Consequently regular blood sugar monitoring is crucial for diabetics.

In living systems, pH is therefore more than just a measure of hydrogen ion concentration as it is critical to life and the many biochemical reactions that have to take place to maintain a person in optimum health.

be measured in centimetres and recorded along with the NEX measurement. This is to help detect if the nasogastric tube has become displaced. See Figure 7.7 for an X-ray of a correctly inserted nasogastric tube, Figure 7.8 for information on the test precision and test risk when checking the position of a nasogastric tube, and Figure 7.9 for checks when using pH indicator sticks.

Ongoing care

Once the nasogastric tube has been confirmed to be in the stomach, feeding may commence. The tube should be kept patent by regular flushing before and after feed and medication. Preferably only liquid medication should be used as tablets may block the lumen of the tube (BAPEN 2003b). Tablets should only be crushed if no alternative liquid preparation is available. Always check with a pharmacist as some medication should not be crushed – see Procedure guideline 7.16: Jejunostomy feeding tube care.

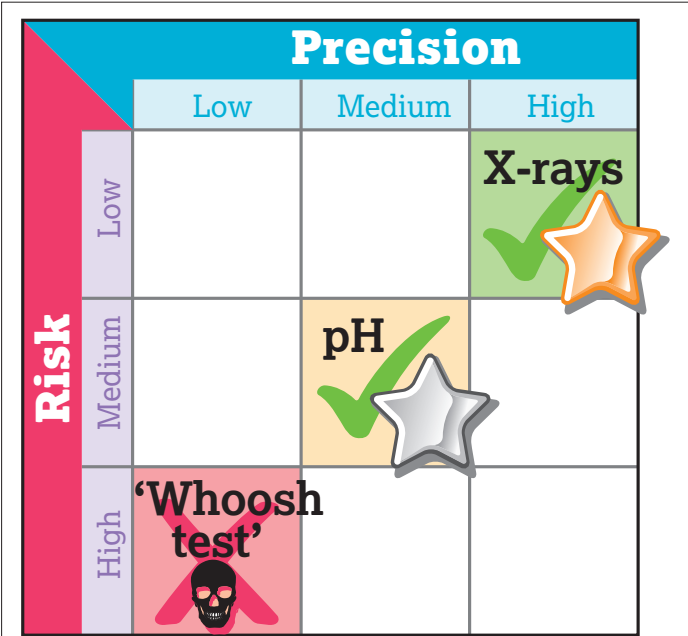

Figure 7.8 Test precision and test risk: the connection. Source: Reproduced with permission from the ECRI Institute (www.ecri.org.uk) and The Royal Marsden NHS Foundation Trust.

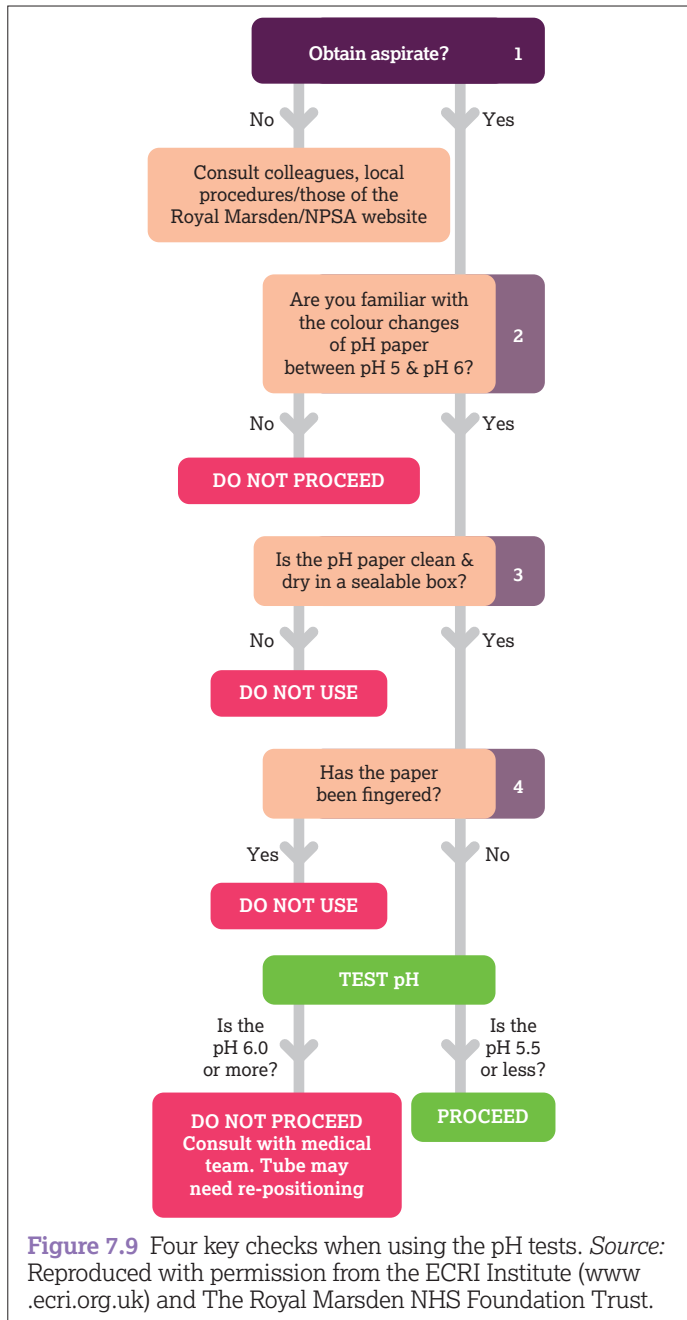

Figure 7.9 Four key checks when using the pH tests. *Source:* Reproduced with permission from the ECRI Institute (www.ecri.org.uk) and The Royal Marsden NHS Foundation Trust.

The position of the tube must be checked with pH testing and recorded on a chart kept at the patient's bedside (NPSA 2011):

- before administering each feed
- before giving medication
- following episodes of vomiting, retching or coughing as it is likely the tube may be displaced
- following evidence of tube displacement (e.g. the tube appears visibly longer).

If a pH of below 5.5 is not obtained then it is highly likely that the tube has become displaced. The medical team should be contacted as the tube may need to be replaced. For further details on checking nasogastric tubes, please refer to the full NPSA guidance or local policy.

Education of patient and relevant others

If appropriate, the patient may be taught how to check the position of the nasogastric tube. They should be made aware that if they feel the tube has moved, it must not be used for feeding until its position has been confirmed by one of the methods described.

Complications

Nasal erosion

Prolonged nasogastric feeding or use of a wide-bore tube can lead to nasal erosion (Ripamonti and Mercadante 2004). In this case it is advised that the tube is removed and replaced in the opposite nostril. If feeding is to be long term then a gastrostomy/jejunostomy should be considered.

Displacement of tube

A tube can accidentally be pulled out, particularly if a patient is restless or distressed. It can also be coughed or vomited out of place. In this situation the position of the tube should be checked. If it is not possible to confirm that the tube remains within the stomach then it should be removed and a new tube placed (NPSA 2011).

Enteral tube removal

Pre-procedural considerations

A nasogastric tube may be removed because it has become dislodged or displaced or if it is no longer required for feeding. If it is being removed and not being replaced then it is essential that the multidisciplinary team is in agreement that the patient is able to meet their fluid and dietary requirements through the oral route and that their ability to swallow is safe and without risk of aspiration.

Procedure guideline 7.11 Removal of a nasogastric tube

Essential equipment

- Dressing pack containing gauze and sterile gloves
- Apron
- 0.9% sodium chloride solution

Pre-procedure

Action

- 1 Explain the procedure to the patient.
- 2 Assist the patient to sit in a semi-upright position in the bed or chair. Support the patient's head with pillows.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

To allow for easy removal of tube. **E**

(continued)

Procedure guideline 7.11 Removal of a nasogastric tube (*continued*)

Action	Rationale
3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required. Apply apron and clean gloves.	Hands must be cleansed before and after patient contact to minimize cross-infections (Fraiese and Bradley 2009, E).
Procedure	
4 Remove any tape securing the nasogastric tube to the nose.	To assist in removal of nasogastric tube. E
5 Using a steady and constant motion, gently pull the tube until it has been completely removed.	To remove the nasogastric tube. E
Post-procedure	
6 Remove gloves and dispose of waste.	To reduce the chance of equipment being reused. E
7 Clean the nose and face to remove any traces of tape.	To ensure patient comfort and dignity. E
8 Document removal of nasogastric tube in care plan and patient's notes.	To ensure adequate records and to enable continued care of patient (NMC 2010, C).

Post-procedural considerations

Once the nasogastric tube has been removed then oral intake of food and fluids should be monitored on a fluid balance chart and a food record chart to ensure that the patient is meeting their daily requirements.

Enteral tube care**Evidence-based approaches****Percutaneous endoscopically placed gastrostomy tube care**

The first change of dressing should be performed 24 hours after PEG placement or earlier if indicated, for example if the site is bleeding (Loser et al. 2005). Until granulation of the stoma canal has taken place, the dressing should be changed daily using aseptic technique. The wound should be inspected for bleeding, erythema, secretion, induration, allergic skin reaction, and so on (Loser et al. 2005). This will help maintain skin integrity and detect any problems early, for example infection or skin breakdown.

Radiologically inserted gastrostomy tube care

After 24 hours and during initial daily change of dressing, the wound should be inspected and skin changes should be carefully noted. The site should be checked for bleeding, erythema, secretion or allergic skin reaction. For the first 10 days after the

gastrostomy has been inserted, the site should be checked daily to ascertain skin integrity and detect any problems early, for example infection or skin breakdown. Most forms of local infection can be readily treated by cleaning the stoma site using aseptic technique and daily change of dressings (Loser et al. 2005). Antibiotics may be required in some instances. This procedure should be done by a nurse in hospital or suitably trained individual in the community (e.g. community or practice nurse, general practitioner).

Jejunostomy feeding tube care

Care of the exit site should be performed daily to maintain skin integrity and detect any problems early, for example infection or skin breakdown. Most forms of local infection can be readily treated by cleaning the stoma site using aseptic technique and daily change of dressings (Loser et al. 2005). Antibiotics may be required in some instances.

Pre-procedural considerations

Prior to performing this procedure, the patient's medical and nursing notes should be consulted to identify tube placement date and method, and any infection control issues. The endoscopist's instructions should be noted, including any specific detail with regard to post-placement care, for example suture removal, tube rotation, checking the volume of the balloon (if appropriate) and dressing changes.

Procedure guideline 7.12 Percutaneous endoscopically placed gastrostomy (PEG) tube care**Essential equipment**

- Sterile procedure pack containing gallipot, low-linting gauze
- Dressing (absorbent, for example Lyofoam)
- 0.9% sodium chloride solution

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).

Procedure

- | | |
|---|--|
| 2 Remove dressing if in place. Observe peristomal skin and stoma site for signs of infection, erythema, irritation or excoriation. Observe tube and consider how it is being kept in place, and note the presence of any sutures, external fixation plates, clamps or balloon ports. | To gain access to stoma site. To detect complications early and instigate appropriate treatment (Lynch and Fang 2004, R5).
To minimize the risk of accidental displacement of tube. E |
| 3 Note the number of the measuring guide on the tube closest to the end of the external fixation device. If the stoma tract has formed (14 days post insertion), loosen the tube from the fixation device and ease the device away from the abdomen. The external fixation plate should be subjected to very low traction, without tension, to maintain contact of the stomach with the abdominal wall. If the tube is less than 14 days post insertion then do not loosen the fixation device. | To ensure the gastrostomy tube is reattached to the fixation device in the correct position (Loser et al. 2005, C). |
| 4 Clean the stoma site with a sterile solution such as 0.9% sodium chloride using a circular outward motion. Use low-linting gauze to dry the area thoroughly. | To minimize the risk of cross-infection and ensure stoma site is thoroughly cleaned (Fraise and Bradley 2009, E ; Lynch and Fang 2004, R5). |
| 5 After 14 days once the tract has been formed, rotate the gastrostomy tube 360°. | To prevent the tube adhering to the sides of the stoma tract (Bumpers et al. 2003, R4). |
| 6 Gently push the external fixation device against the abdomen, checking the measurement guide. | To enable the gastrostomy tube to be reattached to the fixation device. E |
| 7 Gently but firmly pull the gastrostomy tube and attach to the fixation device. The numbered position mark at the gastrostomy exit site will be noted in the medical and nursing notes. The fixation device should remain at the same length, so that gentle traction on the tube allows 0.5 cm give but no more for the first 14 days. | To ensure that the tube is correctly secured. E |
| 8 Ensure the correct point on the measuring guide on the tube is placed closest to the end of the fixation device. | To ensure that the tube is correctly secured. If the patient gains weight, the external fixation device should be released slightly to prevent pressure necrosis of the stoma site (Loser et al. 2005, C). |

Post-procedure

- | | |
|---|---|
| 9 The dry dressing should be replaced daily using aseptic technique until the stoma site has no erythema or exudates or any other signs of infection. Most forms of infection can be readily treated by means of antiseptic measures and daily change of dressing using aseptic techniques (Loser et al. 2005). Do not replace the dressing with an occlusive type. | To encourage wound healing. E
To prevent air getting to the stoma as this may cause infection (Lynch and Fang 2004, R5) or abdominal discomfort. |
| 10 Do not use bulky dressings, particularly under the external fixation device. | To avoid increasing the pressure on the internal retention disc or retention balloon and increasing the risk of tissue necrosis and ulceration occurring in the stomach (Cappell et al. 2009, E). |
| 11 If the patient complains of pain/discomfort, administer analgesia. If this is persistent, liaise with medical team and/or request a gastroenterology review. | To monitor for signs of peritonitis or potential complications following insertion of gastrostomy tube (NPSA 2010, C). |

Problem-solving table 7.4 Prevention and resolution (Procedure guideline 7.12)

Problem	Cause	Prevention	Action
Displaced bumper (PEG).	Excessive tension being applied to tube, either when moving external fixator or by overtightening.	Support the tube beneath the fixator when moving.	Liaise with medical team.
Tube failure.	Prolonged use of clamp without moving faulty tube.	Regular tube care and review. Change position of clamp regularly.	Liaise with medical team to arrange replacement.
Tube blockage.	Inadequate tube flushing or overuse for administering medications.	Regular tube flushing. Avoid/minimize use of tube for medications.	See Procedure guideline 7.19: Enteral feeding tubes: unblocking

Procedure guideline 7.13 Radiologically inserted gastrostomy (RIG) tube care*Essential equipment*

- Sterile procedure pack containing gallipot, low-linting gauze
- Dressing (absorbent, e.g. Lyofoam)
- Sterile 0.9% sodium chloride

*Pre-procedure***Action**

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

Procedure

- 2 Remove post-procedural dressing if in place. Observe peristomal skin and stoma site for signs of infection, erythema, irritation or excoriation.

To gain access to stoma site. To detect complications early and instigate appropriate treatment (Lynch and Fang 2004, **R5**).

- 3 Observe tube and consider how it is being kept in place, and note the presence of any sutures, external fixation plates, clamps or balloon ports.

To minimize the risk of accidental displacement of tube. **E**

- 4 Check that the T-fasteners are intact. These will stay in place for approximately 10–14 days after RIG insertion. The timing should be checked with the radiologist if no instructions given. For removal see Procedure guideline 7.14: Removal of T-fasteners.

To stabilize the stomach against the abdominal wall and allow the tract to form without complications (Lang et al. 2013). **E**

- 5 Clean the stoma site with sterile solution such as 0.9% sodium chloride using a circular outward motion.

To minimize the risk of cross-infection and ensure stoma site is thoroughly cleaned (Fraise and Bradley 2009, **E**; Lynch and Fang 2004, **R5**).

- 6 Use low-linting gauze to dry the area thoroughly. Take care not to wet any cotton pads on the T-fasteners.

To ensure stoma site is thoroughly dried (Lynch and Fang 2004, **R5**).

- 7 Remove the T-fasteners 10–14 days after insertion and secure fixation plate 1–2 cm away from the skin (if applicable). Refer to manufacturer's guidelines as to whether the tube should be rotated.

To prevent the RIG tube moving into the stomach (Lang et al. 2013). **E**

- 8 Secure the tube to the skin with hypoallergenic tape. Do not secure near the stoma site.

To prevent the weight of the tube pulling on the exit site. Tape near the stoma site will make it difficult to clean. **E**

- 9 Advise the patient not to use moisturizing creams or talcum powder.

To prevent infection and/or irritation to the skin. **E**

- 10 If this is a balloon gastrostomy, check the water in the balloon on a weekly basis. See Procedure guideline 7.15: Checking the balloon volume on a balloon gastrostomy.

To prevent tube displacement. **E**

Post-procedure

- 11 After T-fasteners have been removed, do not cover the gastrostomy site with a new dressing unless there is a heavy discharge or leakage from the stoma site.

To encourage wound healing. **E**

Procedure guideline 7.14 Removal of T-fasteners

This usually takes place 10 days post gastrostomy insertion, and should be done after inspection of the gastrostomy site.

Essential equipment

- Sterile procedure pack containing gallipot, low-linting gauze, sterile gloves and sterile field
- 0.9% sodium chloride solution
- Sterile metal forceps
- Stitch cutter

*Pre-procedure***Action**

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and reasons for the procedure and gives their valid consent (NMC 2013, **C**).

- | | |
|--|---|
| 2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. | Hands to be cleaned before and after each patient contact (Fraise and Bradley 2009, E). |
| 3 Assist the patient into a supine position if patient is able to. | To ensure patient comfort. E |
| 4 Perform procedure using aseptic technique. | To prevent infection (Fraise and Bradley 2009, E). |

Procedure

- | | |
|--|---|
| 5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required. Apply apron. | Hands must be cleansed before and after patient contact to minimize cross-infections (Fraise and Bradley 2009, E). |
| 6 Prepare a tray or trolley and take it to the bedside. Clean hands as above. Open sterile pack and prepare equipment. | To reduce the risk of contamination of contents (NICE 2012, C). |
| 7 Clean hands as above and apply sterile gloves. | To reduce the risk of cross-infection (Fraise and Bradley 2009, E). |
| 8 Clean the surrounding skin with an appropriate sterile solution such as 0.9% sodium chloride. | To prevent infection and remove excess debris. E |
| 9 Check condition of the surrounding skin. | To assess for any excoriation of the skin. E |
| 10 Lift the external knot of the T-fastener with metal forceps and cut the suture underneath the cuff close to the skin. Remove the cuff and the metallic tag. Repeat on each T-fastener (Action figure 10). | To remove the suture as plastic forceps tend to slip against nylon sutures. E
To ensure removal of fastener. E |
| 11 Clean the skin with appropriate sterile solution such as 0.9% sodium chloride. | To prevent infection and remove excess debris. E |
| 12 After T-fasteners have been removed, secure fixation plate 1–2 cm away from the skin (if applicable). Do not cover the gastrostomy site with a new dressing unless there is a heavy discharge or leakage from the stoma site. | To encourage wound healing. E |
| 12 Record condition of the skin surround the gastrostomy site. | To document care and enable evaluation of the gastrostomy site (NMC 2010, C). |

Action Figure 10 Removing a T-fastener.

The integrity of the water-filled balloon is important in ensuring that the balloon gastrostomy remains in place. This is usually done 1 week post insertion and on a weekly basis whilst the balloon gastrostomy tube is *in situ*. The balloon is deflated and inflated using a syringe via the balloon inflation valve.

Procedure guideline 7.15 Checking the balloon volume on a balloon gastrostomy

Essential equipment

- Sterile procedure pack containing gallipot, low-linting gauze, sterile gloves and sterile field
- Apron
- Two 10 mL Luer-Lok syringes (20 mL syringe required if balloon volume is greater than 10 mL)
- Sterile water

Pre-procedure

- | Action | Rationale |
|--|---|
| 1 Explain the procedure to the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Assist the patient to sit in a semi-upright position in the bed or chair. Support the patient's head with pillows. | To allow for easy access to the gastrostomy tube. E |

(continued)

Procedure guideline 7.15 Checking the balloon volume on a balloon gastrostomy (*continued*)

Action	Rationale
3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the equipment required. Apply apron.	Hands must be cleansed before and after patient contact to minimize cross-infections (Fraiese and Bradley 2009, E).
4 Prepare a tray or trolley and take it to the bedside. Clean hands as above, open sterile pack and prepare equipment.	To reduce the risk of contamination of contents (NICE 2012, C).
5 Clean hands as above and apply sterile gloves.	To reduce the risk of cross-infection (Fraiese and Bradley 2009, E).
6 Discontinue the feed.	To ensure that the procedure can be undertaken without spillage of feed. E

Procedure

7 Slide the external retention flange up the tube, away from the abdomen and push the tube 2–3 cm into the abdomen.	To ensure that the balloon is inflated in the stomach and not in the tract. E
8 Following manufacturer's guidelines, attach a syringe to the inflation valve of the balloon gastrostomy. Withdraw all the water from the balloon. Discard the water and syringe.	To ensure that the balloon is completely deflated. E
9 Note the volume on the side of the inflation valve of the balloon gastrostomy. Draw up the required volume of sterile water in a new syringe.	To ensure that the correct volume of fluid is inserted into the balloon. E
10 Attach syringe containing sterile water and reinflate the balloon with 5 mL or 20 mL (volume is indicated on the side of the inflation valve).	To ensure that the balloon is not over- or underfilled. E
11 Gently pull back the gastrostomy tube until the balloon can be felt against the stomach wall. Slide the external retention device along the tube until it sits comfortably against the abdomen.	To ensure that the balloon and the external retention device are returned to the correct position. E

Post-procedure

12 Ensure that the skin surrounding the tube is clean and dry.	To promote patient comfort. E
13 Dispose of all equipment in accordance with local policy.	To reduce the chance of equipment being reused. E
14 Record condition of the skin surrounding the gastrostomy site.	To document care and enable evaluation of the gastrostomy site (NMC 2010, C).

Procedure guideline 7.16 Jejunostomy feeding tube care**Essential equipment**

- Sterile procedure pack containing gallipot, low-linting gauze
- Sterile 0.9% sodium chloride

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).

Procedure

2 Remove post-procedural dressing if in place. Observe peristomal skin and stoma for signs of infection, erythema, irritation or excoriation. Observe tube and consider how it is being kept in place, and note the presence of any sutures or external fixation plates.	To gain access to stoma site. To detect complications early and instigate appropriate treatment (Lynch and Fang 2004, R5). To minimize the risk of accidental displacement of tube. E
3 Clean the stoma site with sterile solution such as 0.9% sodium chloride using a circular outward motion.	To minimize the risk of cross-infection and ensure stoma site is thoroughly cleaned (Fraiese and Bradley 2009, E ; Lynch and Fang 2004, R5).
4 Use low-linting gauze to dry the area thoroughly.	To ensure stoma site is thoroughly dry (Lynch and Fang 2004, R5).
5 Secure the jejunostomy tube to the skin with hypoallergenic tape. The site may be covered with a dry dressing or left uncovered.	To prevent the weight of the tube pulling on the exit site. E

Local policy and guidelines (where available) should be identified and followed.

Post-procedural considerations

Immediate care

Local protocols should specify the observations to be taken in the immediate post-operative recovery period. These should include frequency and observation of blood pressure, pulse, respiration and pain score in addition to checks of the stoma site for bleeding, leakage of gastric contents or tube displacement (NPSA 2010). If the patient is complaining of pain or there are signs of peritonitis or tube displacement, contact the medical team immediately. Peritonitis manifests as abdominal pain, fever and a raised white cell count in the initial days after placement. Transient external leakage of the stomach contents from the puncture canal can suggest that internal leakage is also occurring (NPSA 2010).

If there is pain on feeding, prolonged or severe pain post procedure or fresh bleeding, or external leakage of gastric contents then the feed should be stopped immediately. The patient should be reviewed by a senior clinician and the following considered: computed tomography (CT) scan, contrast study or surgical review (NPSA 2010).

Additional complications that may occur in the immediate period after gastrostomy insertion include aspiration pneumonia, haemorrhage and wound infection. Colonic perforation is rare but may occur during the procedure and is likely to lead to peritonitis.

All assessment and care given should be clearly documented, including details of any observations noted and dressings used. The timing of future assessments should be planned to ensure that relevant aspects of care are followed up; for example, if a swab is taken to ascertain whether there is an infection, this needs to be followed up to monitor the stoma site and in order to act on the results of microbiology culture.

The patient should be advised not to use moisturizing creams or talcum powder around the stoma site. The grease in creams can cause the external retention device to slip, allowing movement of the tube and increasing the risk of hypergranulation, leakage and infection (Haywood 2012). Creams and talcs can affect the tube material, causing it to stretch or leak.

Once the stoma site has healed (approximately 10 days post insertion), it is no longer necessary to perform an aseptic technique. Use soap and water to clean the stoma site and ensure the area around the stoma is dried thoroughly. The tube tip should be cleaned daily using water and a small brush (Loser et al. 2005).

Where the enteral feeding tube has been placed to allow nutritional support, the patient's feeding regimen should be checked. If there is no feeding regimen, liaise with dietetic staff as needed or contact the medical team.

Ongoing care

To reduce the risk of tube blockage, the patient's medication should be reviewed where the tube is required for drug administration. Liaise with both medical team and pharmacist to discuss the patient's prescription and alternative routes/medication.

Education of patient and relevant others

The need for patient and/or carer teaching should be considered in patients with newly inserted enteral feeding tubes and discharge planning should be initiated. If a patient is discharged within 72 hours of gastrostomy insertion, the patient and their carers must be provided with appropriate local contacts and out-of-hours telephone numbers for urgent aftercare advice and warned of the danger signs that need urgent attention. These include pain on feeding, new bleeding or external leakage of gastric contents (NPSA 2010).

Complications

Infection

Infection can occur at the time of placement or be due to inappropriate site care, particularly prior to tract maturation. Patients who are immunocompromised may be at increased risk of infection. Initial care after insertion should be carried out using aseptic technique during the daily dressing change until the tract is fully mature. If there are any signs of reddened skin or infection then a swab should be taken and sent off for microbiology culture and sensitivity. Appropriate antibiotic prescribing may be required depending on the condition of the stoma site and the microbiology results from the swab (Loser et al. 2005).

Pain or discomfort post insertion

If the patient experiences pain or discomfort following insertion of the tube, they should be assessed using an appropriate pain scale. Analgesia should be prescribed and administered. The site should be observed regularly for signs of infection. If pain is described as worse on feeding, feed or medication delivery should be stopped immediately. The patient should be reviewed by a senior clinician and the following considered: CT scan, contrast study or surgical review (NPSA 2010).

Pressure necrosis

Excessive tightening of the external fixator device may cause pressure necrosis around the stoma site. The external fixator should be adjusted whilst the patient is sitting up, where possible. If the external fixator is adjusted whilst the patient is lying down then it is necessary to ensure that it is applied 1–2 cm from the skin surface.

The stoma site should be reviewed regularly and the patient and carer taught how to adjust and reposition the external fixator. This is particularly important if the patient has gained weight as this may cause pressure on the fixator.

Hypergranulation

Excess movement of the enteral feeding tube within the tract may stimulate the growth of granulation tissue. Ensure that the fixation plate is firm but not too tight on the abdomen to minimize movement of the tube. If the tube does not have an external fixator plate then consider placing one to stop excessive movement of the tube (Lynch and Fang 2004).

Buried bumper

In enteral feeding tubes that have a bumper as the retention device, the retention bumper may become buried in the intestinal wall. The external fixator should be released and the tube pushed in approximately 2 inches and rotated fully both clockwise and anticlockwise. Ensure this is rotated regularly according to manufacturer's instructions (Lynch and Fang 2004).

Peristomal leakage

It is important to examine the tube site for causes of peristomal leakage. Contributory factors may be delayed gastric emptying, buried bumper and infection. Ensure correct management of the stoma area, including checking the internal balloon weekly if this is the method of tube retention. If there is delayed gastric emptying, investigate and treat the cause of this. Avoid use of bulky dressings under the external fixator. Consider skin care and use protective cream or spray if necessary. Liaise with medical colleagues and consider the need for antacid medication to reduce skin excoriation (Lynch and Fang 2004, Westaby et al. 2010).

Pneumoperitoneum

This is a known complication of the insertion procedure when air is present in the abdominal cavity. The patient's medical team must be contacted immediately if the patient is

complaining of increased pain or pyrexia or has signs of an acute abdomen.

Unplanned removal of tube

A gastrostomy or jejunostomy that is accidentally removed within 14 days of insertion requires immediate attention (Westaby et al. 2010). It should be replaced endoscopically or radiologically as soon as possible as a mature tract has not developed in this period (Lynch and Fang 2004).

The patient's medical team or nutrition nurse must be contacted immediately, as the stoma site can heal over within 2 hours. The leakage of gastric contents into an immature tract carries the risk of infection. Place a dry dressing over the stoma to prevent stomach contents leaking onto skin.

Administration of enteral tube feed

Pre-procedural considerations

Prior to using enteral feeding tubes for medication or feed administration, it is vital to know where in the gastrointestinal tract the tube tip lies. This may be difficult in patients who have tubes placed in other organs or where there is little visible difference externally between gastrostomy, gastrojejunostomy or jejunostomy tubes. Where available, the tube size, type, insertion date and method should be clearly documented. If this information is unavailable, the tube should be aspirated and the pH used to differentiate between gastric or small bowel placement. If there are sutures securing the external fixator to the patient's abdomen, these should not be removed until it has been confirmed that they are not required to keep the tube in position.

Procedure guideline 7.17 Enteral feeding tubes: administration of feed

Essential equipment

- 50 mL enteral or catheter-tipped syringe
- Commercial ready-to-hang feed

Optional equipment

- Tap water or sterile water (for jejunostomy tubes or for patients who are immunosuppressed) (NICE 2003). Water should be fresh and kept covered

Pre-procedure

Action

1. Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

Procedure

- 2 Check the date on the feed container.
- 3 Shake the feed container gently.
- 4 Take a new giving set from a sealed package and ensure that the roller clamp/tap is closed.
- 5 Screw the giving set tightly onto the feed container.
- 6 Hang the container upside down from the hook on a drip stand.
- 7 Open the roller clamp/tap and prime the feed to the end of the giving set. (Follow instructions for individual pump.)
- 8 Feed the giving set into the pump as directed by the manufacturer's instructions.
- 9 Set the rate of the feed as directed by the manufacturer's instructions and according to the patient's feeding regimen.
- 10 Set the dose of the feed as directed by the manufacturer's instructions and according to the patient's feeding regimen.
- 11 Flush the feeding tube with a minimum of 30 mL of water or sterile water in an enteral syringe by attaching to the end of the feeding tube. Depress the plunger on the syringe slowly.
- 12 Remove the end cover from the giving set and connect to the feeding tube.
- 13 Commence administration of feed.

To ensure that the feed has not passed its expiry date. **E**

To ensure the feed is evenly dispersed, therefore reducing the risk of blocking the giving set. **E**

To avoid accidental spillage of feed from end of administration set. **E**

In order to pierce the seal on the container and maintain a sealed system (Matlow et al. 2006, **C**).

To avoid backflow of intestinal contents into the feed container (Matlow et al. 2006, **E**).

This ensures that air is not fed into the stomach when feeding commences. **E**

To connect the giving set to the pump device. **E**

To ensure the correct rate of feed is administered. **E**

To ensure that the correct dose of feed is administered. **E**

To ensure the patency of the feeding tube (BAPEN 2003b, **C**).

To ensure that the feed is delivered via the enteral feeding tube. **E**

To ensure that the feed is delivered via the enteral feeding tube. **E**

Post-procedure

- 14 Dispose of any equipment that is no longer required.
- 15 Document the time that the feed commenced and the rate of administration.

To reduce the chance of equipment being reused and to reduce cross-contamination with new equipment. **E**

To ensure accurate documentation of nutritional and fluid intake (NMC 2010, **C**).

Problem-solving table 7.5 Prevention and resolution (Procedure guideline 7.17)

Problem	Cause	Prevention	Action
Pump alarms with 'occlusion' or 'empty'.	The feed may have finished. There may be a blockage in the giving set or feeding tube.	Ensure the feed container was shaken well before feeding. Ensure the giving set was not bent when feeding was commenced. Ensure that the roller clamp/tap is fully open. Flush the feeding tube as directed before commencing.	Straighten any kinks in the giving set. Ensure that the giving set is fixed correctly around the rotor. Open the roller clamp/tap fully. Check that the feeding tube is not blocked. Disconnect from the feeding tube and run the feed into a container; if feed runs and there is no alarm, this indicates that the pump is working properly and the feeding tube is probably blocked.
Pump alarms with 'low battery'.	This indicates that the pump battery needs to be recharged and that there is approximately 30 minutes of power remaining.	Keep pump plugged in and charged.	Connect to the mains power and continue to feed.
Unable to prime giving set.	The roller clamp/tap may not be fully open. There may be a fault with the giving set. If a drip chamber is present then feed may not have run into this.	Ensure that the roller clamp/tap is fully open when beginning to prime the giving set.	Open the roller clamp/tap fully. Squeeze some feed into the drip chamber if applicable. Try with a new giving set.
Continuous audio alarm and all visual displays go blank.	The pump may require servicing.	Ensure it is serviced regularly.	Send to equipment library or manufacturers for servicing.

Post-procedural considerations

Immediate care

As soon as the feed commences, check that it appears to be running without problems and is at the correct rate. Monitor this regularly throughout the feed administration.

Monitor the patient for signs of nausea/abdominal discomfort within the first hour and every 2–4 hours during feed administration. This may not be possible if the feed is given overnight and the patient is asleep.

Ongoing care

If appropriate, the patient should be taught how to follow the procedure of setting up the enteral feeding equipment. They should be confident with the maintenance of the equipment and be aware of how to troubleshoot.

Complications

Aspiration

This may occur due to regurgitation of feed, poor gastric emptying or incorrect placement of a nasogastric tube. The risk of this can be reduced by:

- the use of prokinetics which encourage gastric emptying, for example metoclopramide
- checking the position of the tube before feeding
- ensuring the patient has their head at a 45° angle during feeding. If the patient is in bed then this can be achieved through raising the head of the bed and ensuring the patient has sufficient pillows for support (Thomas and Bishop 2007).

Nausea and vomiting

This could be caused by a number of factors. It could be related to disease or a side-effect of treatment or a medication such as

antibiotics or analgesia. A combination of poor gastric emptying and rapid infusion rates could also stimulate nausea and vomiting. Nausea and vomiting can be better controlled through the use of antiemetics, a reduction in the infusion rate or a change from bolus to intermittent feeding.

Diarrhoea

This could be a result of:

- medications such as antibiotics, chemotherapy or laxatives
- disease or treatment, for example pancreatic insufficiency, bile acid malabsorption
- gut infection, for example *Clostridium difficile*
- poor tolerance to the feed.

Antidiarrhoeal agents could be used if a person is experiencing diarrhoea as a side-effect of medication. If possible, an alternative medication should be found that does not cause diarrhoea. In the case of antibiotics, these should be stopped as soon as possible (Thorson et al. 2008). When the diarrhoea is disease related, the underlying problem should be treated; that is, if a person has pancreatic insufficiency they should be provided with a pancreatic enzyme supplement and/or peptide-based feed.

Avoiding microbiological contamination of the feed or equipment will help to reduce the risk of diarrhoea. This will involve keeping the equipment clean and, when feeding, maintaining a sealed system.

A stool sample should be sent to check for any gut infection. If the sample is found to be positive then the infection should be treated appropriately.

If all the above have been ruled out, the dietician can review the osmolality, fibre content and infusion rate (Todorovic and Micklewright 2011).

Constipation

Constipation could be caused by inadequate fluid intake, immobility, bowel obstruction or the use of opiates or other medications causing gut stasis.

Methods to improve symptoms of constipation include:

- checking fluid balance and increasing fluid intake if necessary
- providing laxatives/bulking agents
- if possible, encouraging mobility
- if in bowel obstruction, discontinuing enteral feeding (Todorovic and Micklewright 2011).

296

Abdominal distension

This could be caused by poor gastric emptying, rapid infusion of feed, constipation or diarrhoea. Possible ways to improve distension include:

- gastric motility agents
- reducing the rate of infusion
- encouraging mobility if possible
- treating constipation or diarrhoea.

Blocked tube

Blockage can be a result of inadequate flushing or failure to flush the feeding tube or administration of inappropriate medications via the tube. For ways to unblock a feeding tube refer to Procedure guideline 7.19: Enteral feeding tubes: unblocking.

Enteral feeding tubes: administration of medication

Evidence-based approaches

Rationale

Indications

- Patients requiring medications who are not able to take oral preparations due to dysphagia.
- Where possible, medications should be administered in liquid or soluble form. Alternatively, some preparations can be given in sublingual form.

Contraindications

- Not all medications can be administered through an enteral tube due to risk of blockage.
- If the medication has an enteric coating or is a slow-release preparation, it should not be crushed.
- Some medications may be harmful to the administrator and advice from a pharmacist is required.
- If a number of different medications are required, always administer separately. Do not mix medications unless advised to do so by a pharmacist.

Procedure guideline 7.18 Enteral feeding tubes: administration of medication

Essential equipment

- 50 mL enteral syringe
- Mortar and pestle or tablet crusher if tablets are being administered (BAPEN 2003b)

Optional equipment

- Tap water or sterile water (for jejunostomy tubes or for patients who are immunosuppressed) (NICE 2003). Water should be fresh and kept covered

Pre-procedure

Action

- 1 Check whether patient can take medication orally, whether medication is necessary or if it can be temporarily suspended.
- 2 Consider whether an alternative route can be used, for example buccal, transdermal, topical, rectal or subcutaneous.
- 3 Check drug is absorbed from the site of delivery.
- 4 Clean hands with bactericidal soap and water or alcohol-based handgel. Put on non-sterile gloves.

Rationale

- If patient can take medication orally this reduces the risk of tube blockage (BAPEN 2003b, **C**).
- If patient can take medication via an alternative route this reduces the risk of tube blockage (BAPEN 2003b, **C**).
- Some drugs may not be absorbed directly from the jejunum (BAPEN 2003b, **C**).
- To minimize cross-infection and protect the practitioner from gastric/intestinal contents (Fraise and Bradley 2009, **E**).

Procedure

- 5 Stop the enteral feed and flush the tube with at least 30 mL of water (sterile water for jejunostomy administration), using an enteral syringe.
- To clear the tube of enteral feed as this may cause a blockage or interact with medications. Sterile water should be used for jejunostomy tubes as the water is bypassing the protective acidic environment of the stomach. **E**

Where there is an absolute contraindication for medicine to be taken with feed:

- 6 Stop the feed 1–2 hours before and 2 hours after administration (this will depend on the drug); for example, for phenytoin administration, stop feed 2 hours before and for 2 hours after.
 - 7 Consult with the dietician to prescribe a suitable feeding regimen.
- To avoid interaction with enteral feed. **E**
- To ensure that the patient's nutritional requirements are met in the time available around medicine administration (BAPEN 2003b, **C**).

8 Prior to preparation, check with the pharmacist which medicines should never be crushed.	Some medications are not designed to be crushed. These include: <i>modified-release tablets</i> : absorption will be altered by crushing, possibly causing toxic side-effects <i>enteric-coated tablets</i> : the coating is designed to protect the drug against gastric acid <i>cytotoxic medicines</i> : this will risk exposing the practitioner to the drug (BNF 2014, C).
9 Prepare each medication to be given separately. Volumes greater than 10 mL may be drawn up in a 50 mL syringe and administered via the tube. For small volumes (less than 10 mL) follow step 12. <i>Either</i> : <i>Soluble tablets</i> : dissolve in 10–15 mL water. <i>Or</i> : <i>Liquids</i> : shake well. For thick liquids mix with an equal volume of water. <i>Or</i> : <i>Tablets</i> : crush using a mortar and pestle or tablet crusher and mix with 10–15 mL water.	To avoid interaction between different medications and to ensure solubility (BAPEN 2003b, C).
10 Never add medication directly to the enteral feed.	To avoid interaction between medicines and feed (BAPEN 2003b, C).
11 Administer the medication through the tube via a 50 mL syringe. Do not use a three-way tap or syringe tip adaptor. Rinse the tablet crusher or mortar with 10 mL water, draw up in a 50 mL syringe, and flush this through the tube.	To ensure the whole dose is administered (BAPEN 2003b, C). To ensure that intravenous syringes are not connected to an enteral feeding system (NPSA 2011, C).
12 If volumes of less than 10 mL are required, the dose should be measured in a 10 mL oral syringe. The plunger of a 50 mL syringe should be removed and the 50 mL syringe connected with the enteral tube. The dose should then be administered into the barrel of the 50 mL syringe and the 10 mL syringe rinsed with water, which should also be administered via the barrel of the 50 mL syringe.	To ensure the whole dose is administered (BAPEN 2003b, C).
13 If more than one medicine is to be administered, flush between drugs with at least 10 mL of water to ensure that the drug is cleared from the tube.	To avoid interactions between medicines (BAPEN 2003b, C).
14 Flush the tube with at least 30 mL of water following the administration of the last drug.	To avoid medicines blocking the enteral tube (BAPEN 2003b, C).
15 If the patient is on fluid restriction or for a paediatric patient, consult the dietician and pharmacist about the quantity of water to be given before and after medication.	To ensure that the patient does not exceed their fluid restriction or requirements (BAPEN 2003b, C).
Post-procedure	
16 Remove and dispose of any equipment.	To reduce the risk of cross-infection. E
17 Record the administration on the prescription chart.	To maintain accurate records (NMC 2010, C).

Problem-solving table 7.6 Prevention and resolution (Procedure guideline 7.18)

Problem	Cause	Prevention	Action
Tube became blocked with medication.	Medication had not been administered in the correct composition and/or the tube was not flushed adequately.	Ensure that the guidance from the pharmacist is followed correctly. Ensure that the tube is flushed before and after administration.	See Procedure guideline 7.19: Enteral feeding tubes: unblocking on how to unblock a feeding tube.
Unable to administer required medication.	It is in a form that cannot be crushed or dissolved.	Ensure that the pharmacist and medical team are aware that all medications need to be administered via an enteral tube.	Contact the medical team or pharmacist to seek advice on an alternative medication.

Post-procedural considerations

Immediate care

The tube patency should be checked to ensure that the medication has not caused a blockage. This could be done by flushing the tube.

The patient should be monitored to ensure that there are no side-effects of the medication administered.

Ongoing care

In order to avoid complications and ensure optimal nutritional status, it is important to monitor the following in patients on enteral tube feeds:

- oral intake
- bodyweight
- urea and electrolytes
- blood glucose
- full blood count
- fluid balance
- tolerance to feed, for example nausea, fullness and bowel activity
- quantity of feed taken
- care of tube
- care of stoma site (where appropriate).

Education of the patient and relevant others

If the patient is going home with the enteral tube in place, it should be ensured that the patient is educated and confident with administering their medication. If this is not possible then the patient should be referred to a healthcare professional, such as a community nurse, who can undertake this aspect of care.

Home enteral feeding

Some patients who are established on tube feeding in hospital also require enteral tube feeding at home. A multidisciplinary approach is needed for a successful discharge, usually involving a dietician, doctor, ward nurse, community nurse and general practitioner. The patient's circumstances and the ability of the patient or carers to manage the feed must be considered when discharge is being planned. Adequate time should be allowed in the hospital setting for patients to become fully accustomed to the techniques of feed administration and care of the feeding tube, prior to discharge home. Patients should also be given written information to reinforce the education they receive prior to discharge (BAPEN 2003a).

Support in the form of the general practitioner, community nurse and community dietetic services should be established before discharge. A multidisciplinary discharge meeting may be of benefit to both the patient and the professionals involved. Many of the commercial feed companies organize for the patient's feed and equipment to be delivered to their home, after consultation with the local community services (BAPEN 2003b). The hospital or community dietician can arrange this. Early notification of discharge is essential as it usually takes a minimum of 7 days to set this up.

Termination of enteral tube feeding

It is important to ensure that an individual is able to meet their nutritional requirements orally prior to termination of the feed. Enteral tube feeding may be discontinued when oral intake is established (NCCAC 2006). It may be useful to maintain an overnight feed while the patient is establishing oral intake.

Enteral feeding tubes: unblocking

Enteral feeding tubes may become blocked. See Procedure guideline 7.19 for unblocking an enteral feeding tube.

Procedure guideline 7.19 Enteral feeding tubes: unblocking

Essential equipment

- 50 mL enteral syringe
- Tap water or sterile water (for jejunostomy tubes or for patients who are immunosuppressed) (NICE 2003).
Water should be fresh and kept covered
- To obtain lukewarm water (40–45°C), put three-quarters of a cup (120 mL) of cold drinking tap water (sterile water for jejunostomy and for immunosuppressed patients) into a plastic cup and add a quarter of a cup (40 mL) of boiling water

Optional equipment

- Sterile water (for jejunostomy tubes)

Pre-procedure

Action

- 1 Always flush the enteral tube before and after administration of feed and medication with at least 30 mL of water (sterile water for jejunostomy and for immunosuppressed patients).
- 2 Examine the tube for kinks.

Rationale

- To avoid the tube blocking. Sterile water should be used for jejunostomy tubes as the water is bypassing the protective acidic environment of the stomach. **E**
- To ensure that this is not the cause of the blockage (Pickering 2003, **E**).

Procedure

- 3 Draw up 30 mL of water in a 50 mL enteral syringe and attempt to flush/withdraw fluid from the tube.
To dissolve any medication or soften any feed plugs in the tube. To prevent hot water being administered via the feeding tube (BAPEN 2003b, **C**).
- 4 Flush tube only with 50 mL water.
To remove blockage and acidic fluids such as carbonated drinks that may cause feed to clot (BAPEN 2003b, **C**).
- 5 If tube is still blocked, consider use of a proprietary product designed to unblock tube. Follow manufacturer's instructions.
To break down plug. Such products contain digestive enzymes which may break down a protein plug but they may not unblock a tube blocked with medication (manufacturer's recommendation, **C**).

6 If all of the above are unsuccessful then the enteral tube will need to be replaced.

To ensure continued enteral access for the administration of feed, fluids and medication. **E**

Post-procedure

7 Document the procedure in the patient's notes.

To record that the tube was unblocked (NMC 2010, **C**).

Problem-solving table 7.7 Prevention and resolution (Procedure guideline 7.19)

299

Problem	Cause	Prevention	Action
Cracked/split tube.	Too much pressure applied whilst flushing tube.	Avoid too much pressure whilst flushing tube and take care with a syringe smaller than 50 mL.	If tube cracks or splits then it must be replaced.

Parenteral nutrition

Definition

Parenteral nutrition (PN) is the direct infusion into a vein of solutions containing the essential nutrients in quantities to meet the daily needs of the patient (Shaw 2008, Singer et al. 2009).

Related theory

The basic components of a PN regimen are provided by solutions including the following.

- *Amino acids (nitrogen source)*. Commercially available solutions provide both essential amino acids, usually in proportions to meet requirements, and non-essential amino acids, such as alanine and glycine. They may also contain conditionally essential amino acids such as glutamine for use in critical care (Singer et al. 2009).
- *Glucose (carbohydrate energy source)*. Glucose is the carbohydrate source of choice. It provides 3.75 kcal/g (15.5 kJ/g) and usually provides 50% of non-nitrogen energy.
- *Fat emulsion (fat energy source)*. Fat generates 9 kcal/g (37 kJ/g) and its inclusion in PN is necessary to provide essential fatty acids. Fat usually provides 50% of non-nitrogen energy. Nitrogen:non-nitrogen energy is usually provided in the ratio of 1:150–200. An insufficient energy supply from carbohydrate and fat will encourage the use of nitrogen for energy.
- *Electrolytes*, for example sodium, potassium, calcium, magnesium and phosphate.
- *Vitamins and minerals*. Both water-soluble and fat-soluble vitamins are required as part of a standard bag.
- *Trace elements*, for example zinc, copper, chromium, selenium (Singer et al. 2009).

Evidence-based approaches

Rationale

Parenteral nutrition should only be used when it is not possible to meet nutritional requirements via the gastrointestinal tract. PN is an invasive and relatively expensive form of nutrition support and, in inexperienced hands, can be associated with risks from catheter placement, catheter infections, thrombosis and metabolic disturbance. Careful consideration is therefore needed when deciding to whom, when and how this form of nutrition support should be given (Braga et al. 2009, NCCAC 2006). It should be planned and managed by healthcare professionals with the relevant expertise (NCEPOD 2010). Whenever possible, patients

should be aware of why this form of nutrition support is needed and its potential risks and benefits.

Parenteral nutrition may be used in combination with enteral nutrition where some gut function is present but this is insufficient to meet nutritional requirements, for example in intestinal failure where the patient can eat but absorptive capacity may be insufficient to maintain nutritional status.

Indications

The indications for parenteral nutrition are:

- failure of gut function (e.g. with obstruction, ileus, dysmotility, fistulae, surgical resection or severe malabsorption) to a degree that definitely prevents adequate gastrointestinal absorption of nutrients
- the consequent intestinal failure has either persisted for several days (e.g. >5 days) or is likely to persist for many days (e.g. 5 days or longer) before significant improvement (Bozzetti et al. 2009, Braga et al. 2009, NCCAC 2006).

Examples of the use of PN include for patients with prolonged gastrointestinal ileus, intractable vomiting, multiorgan failure where requirements cannot be met by the enteral route and proximal high-output fistula.

Contraindications

If the gut can be used or an attempt to use it has not yet been considered, then PN should be withheld pending the outcome of using the enteral system. PN should also not be used if the perceived risk to the patient outweighs the benefits anticipated (NCCAC 2006).

Contents of parenteral nutrition

Parenteral nutrition provides nutrients in a form that can be used directly by the body when they are infused intravenously. Nitrogen (protein) is provided as free amino acids in a ratio designed to meet requirements for essential amino acids. Specific amino acid profiles may be used for some disease states. Energy is usually provided from carbohydrate and fat. Carbohydrate is present as glucose and fat is provided as a lipid emulsion providing essential fatty acids. The lipid source may be provided by long-chain, medium-chain triglycerides or fish oil containing omega-3 fatty acids with different manufacturers using various lipid blends. Fluid, electrolytes, vitamins, minerals and trace elements are also provided by parenteral nutrition (Singer et al. 2009).

Choice of a parenteral nutrition regimen

Parenteral nutrition is usually administered from a single infusion container in which all the requirements for a 24-hour feed are pre-mixed. Such infusions are available as standard ready-prepared bags that require mixing and the addition of vitamins, minerals and trace elements or individual bags may be made to a particular prescription and purchased from a compounding unit.

The regimen for a particular patient should be formulated according to their needs for energy and nitrogen, electrolytes and fluid. The majority of commercial vitamin and mineral preparations aim to meet both short- and long-term requirements although appropriate monitoring is required to ensure that nutritional requirements are met in the longer term as clinically indicated by the monitoring guidelines. Standard PN regimens may be suitable for some patients who require short-term nutritional support or do not appear to have excessively altered nutritional requirements.

The choice of such regimens depends on the patient's body-weight and nutritional requirements. To allow for the possible need to vary the constituents of the infusion in response to changes in the patient's electrolyte or nutritional requirements, PN solutions should be ordered daily. Once compounded, most PN preparations last up to 7 days (Weinstein and Plumer 2007) and need to be stored in a refrigerator. However, some triple-chamber PN bags can be stored at ambient temperatures and require mixing prior to administration. These bags generally require the addition of vitamins, minerals and trace elements under aseptic conditions.

Parenteral nutrition should be introduced slowly in the seriously ill or injured, with no more than 50% of requirements given in the first 24–48 hours due to the risk of refeeding syndrome (NCCAC 2006).

Methods of administration

The traditional method of access is via a central venous catheter. Central venous access is required because PN solutions are hyperosmolar and there is a risk of thrombophlebitis associated with feeding into peripheral veins (Shaw 2008). However, it has been shown that, with care and attention, peripheral veins can be used to provide short-term peripheral PN (NCCAC 2006). This would be via a midline or peripheral cannula. For the administration of PN, the device should be placed in the largest vein possible, usually in the forearm away from a joint, with rotation of the site every 48–72 hours (Shaw 2008). For insertion, see Chapter 14: Vascular access devices.

A skin-tunnelled catheter is the choice for long-term nutrition but peripherally inserted central cannulas (PICCs) or non-tunnelled central venous catheters can also be used in the short term. The number of lumens will depend on the patient's peripheral venous access and the number of additional therapies required. It is recommended that the minimum number of lumens is used but if additional intravenous access is required then a double- or triple-lumen catheter should be inserted and then one lumen should be dedicated for use with PN. If using a single-lumen device, routine blood sampling and additional infusions should be carried out independently, using a separate cannula if necessary (Davidson 2005).

For setting up an infusion, see Chapter 12: Medicines management, Procedure guideline 12.24: Medication: continuous infusion of intravenous drugs.

Post-procedural considerations

Ongoing care

Administration sets should always be changed every 24 hours (Loveday et al. 2014, NICE 2012, O'Grady et al. 2011). Existing injection sites on the administration set should never be used for giving additional medications as PN is incompatible with numerous medications. Drugs may bind to the nutrients or the PN bag, reducing their availability. If any additional medications, blood products or central venous pressure (CVP) readings are required

then they should be given or taken via a separate lumen or via a peripheral device (NCEPOD 2010).

A volumetric infusion pump must be used to ensure accurate delivery of PN. No bag should be used for longer than 24 hours (BNF 2014).

If the infusion must be discontinued, the catheter should be flushed to maintain patency. The risk of infection increases if the infusion is disconnected from the central venous device; therefore, it is not advisable to disconnect PN until the whole daily requirement has been administered (NCEPOD 2010).

During intravenous feeding, monitoring is necessary to detect and minimize complications. Once feeding is established and the patient is biochemically stable then the frequency of monitoring may be reduced if the clinical condition of the patient permits (Table 7.8).

Home parenteral nutrition

There are a few indications for home PN. It may be necessary in patients who have complete intestinal failure or insufficient functioning bowel to maintain an adequate nutritional status via the enteral route, for example short bowel syndrome due to Crohn's disease or a high-output fistula.

This is a complicated and specialist treatment, requiring 24-hour access to advice and support, and should be co-ordinated through a specialist centre.

No patient should be considered for home PN without a multi-disciplinary discussion with the patient and the formulation of a clear management plan. If continuation of hospital-initiated PN is considered essential, the implications must be discussed with the multiprofessional team, including the medical consultant, dietetics, pharmacy, IV therapy team, complex discharge co-ordinator and patient (Staun et al. 2009).

There is national guidance on the training, provision and appropriate support for such patients, which should be consulted prior to any discharge of patients receiving PN (NHS 2009). However, in England there is a developing national clinical network of expert regional units to provide support for patients requiring home PN to ensure that their needs are met appropriately (NHS 2009). Patients require an extensive period of specialized training to manage PN in the home environment and this should be undertaken by such units and clinical teams.

It is important that all members of the multidisciplinary team, including the dietician, nurse, doctor, pharmacist, catering department and community services, are involved in the patient's nutritional care to ensure a thorough and co-ordinated approach to nutritional management (NCCAC 2006).

Termination of parenteral nutrition

Parenteral nutrition should not be terminated until oral or enteral tube feeding is well established (NCCAC, 2006). PN should be weaned off to half rate before stopping, to prevent rebound hypoglycaemia, as well as to ensure adequate nutritional intake via an alternative route. It is important that all members of the multidisciplinary team are involved in the decision to terminate PN and that enteral intake is monitored sufficiently.

Complications

Metabolic complications should be detected by appropriate monitoring. Some of the more common complications are as follows.

Fluid overload

This may occur when other blood products and fluids are given concurrently. It may be possible to reduce the volume of a 24-hour bag of PN while maintaining the nutritional content. A pharmacist and dietician can advise on the feasibility of creating such regimens.

Impaired liver function

Long-term parenteral nutrition and the lack of enteral nutrition may contribute to altered liver function and cholestasis. Liver

Table 7.8 Monitoring in nutrition support

Parameter	Frequency of monitoring	Rationale	Interpretation
Catheter entry site	Daily	Signs of infection/inflammation	Interpret with knowledge of infection control
Skin over insertion site and tip of cannula or midline catheter	Daily	Signs of thrombophlebitis	
General condition	Daily	To check tolerance of feed and that feed and route continue to be appropriate	
Temperature/blood pressure	Daily, then as needed	Sign of infection, fluid balance	
Sodium, potassium, urea, creatinine	Baseline, then daily until stable, then 1–2 times a week	Assessment of renal function, fluid status	Interpret with knowledge of fluid balance and medication Urinary sodium may be helpful in complex cases with gastrointestinal fluid loss
Glucose	Baseline, then 1–2 times daily until stable (more if needed), then weekly	Glucose intolerance is common	Good glycaemic control is necessary
Magnesium, phosphate	Baseline, then daily if risk of refeeding syndrome, then three times a week until stable, then weekly	Depletion is common and under-recognized	Low concentrations indicate poor status
Liver function tests	Baseline, then twice weekly until stable, then weekly	Abnormalities common during PN	Complex. May be due to sepsis, other disease or nutritional intake
Calcium, albumin	Baseline, then weekly	Low or high levels may occur	Correct measured serum calcium concentration for albumin Hypocalcaemia may be secondary to magnesium deficiency Low albumin reflects disease, not protein status
C-reactive protein	Baseline, then 2 or 3 times a week until stable	Assists interpretation of protein, trace element and vitamin results	To assess the presence of an acute-phase reaction The trend of results is important
Zinc, copper	Baseline, then every 2–4 weeks depending on results	Deficiency is common, especially with increased losses	People most at risk when anabolic Zinc decreases and copper increases in acute-phase reaction
Selenium	Baseline if risk of depletion, further testing depending on this	Deficiency is likely in severe illness and sepsis, or long-term nutrition support	Decreases in acute-phase reaction Long-term status better assessed by glutathione peroxidase
Full blood count	Baseline, then 1 or 2 times a week until stable, then weekly	Anaemia due to iron or folate deficiency is common	Effects of sepsis may be important
Iron, ferritin	Baseline, then every 3–6 months	Iron deficiency is common in long-term PN	Iron status is difficult to assess in acute-phase reaction Iron decreases, while ferritin increases
Folate, vitamin B ₁₂	Baseline then every 2–4 weeks	Iron deficiency is common	Serum folate/B ₁₂ sufficient with full blood count
Manganese	Every 3–6 months if on home PN	Excess provision to be avoided, more likely in liver disease	Red blood cell or whole blood better measure of excess than plasma
Vitamin D	Six-monthly if on long-term PN	Low levels if housebound	Requires normal kidney function for effect
Bone densitometry	On starting home PN, then every 2 years	Diagnosis of metabolic bone disease	Together with lab tests for metabolic bone disease

Source: Adapted from NCCAC (2006).
PN, parenteral nutrition.

function may be influenced by the total amount of glucose that is administered, the quantity and composition of lipid in parenteral nutrition, the type of administration, i.e. over 24 hours, and any underlying hepatic pathology (Staun et al. 2009).

Hyperglycaemia

This may occur due to stress-induced insulin resistance or carbohydrate overload. A simultaneous sliding scale insulin infusion may be required. Failure to recognize hyperglycaemia may result in osmotic diuresis.

302 Hypoglycaemia

Abrupt cessation of PN may result in a rebound hypoglycaemia. A reduction in infusion to half the rate prior to stopping the infusion may help prevent this occurring.

Azotaemia

Raised plasma urea may indicate renal dysfunction or dehydration. Alterations in the nitrogen and non-protein energy content of the PN may be required, or an increase in fluid input (Payne-James et al. 2001).

Hypophosphataemia

This is associated with excessive glucose infusion and the refeeding syndrome in malnourished patients (Marvin et al. 2008, NCCAC 2006). It is necessary to correct phosphate levels by providing additional phosphate prior to feeding. Phosphate levels should be monitored daily at the start of feeding.

Other complications such as metabolic acidosis, electrolyte disturbances, hypernatraemia, hypokalaemia and hypomagnesaemia may require a review of the PN solution, rate of administration, additional fluids, blood products and drugs.

Transfusion of blood and blood components

Definition

Blood transfusion is the administration of a blood component- or plasma-derived product to the patient (Gray et al. 2007). Blood is a raw material from which different therapeutic products are made (McClelland 2007).

Anatomy and physiology

ABO and Rh blood groups

In 1901, Landsteiner discovered that human blood groups existed and developed the ABO system which marked the start of safe blood transfusion (Bishop 2008). There are four principal blood groups: A, B, AB and O. Each group relates to the presence or absence of surface antigens on the red blood cells and antibodies in the serum which dictate blood compatibility (Table 7.9).

People with the blood group **AB** have red cells with A and B surface antigens, but they do not have any anti-A or anti-B immunoglobulin M (IgM) antibodies in their serum. Therefore, they are able to receive blood from any group, but can only donate to other people from group AB.

People with group **O** red cells do not have either A or B surface antigens but they do have anti-A and anti-B IgM antibodies in their serum. They are only able to receive blood from group **O**, but can donate to A, B, O and AB groups.

People with group **A** red cells have type A surface antigens, and they have anti-B IgM antibodies in their serum. They are only able to receive blood from groups **A** or **O** and can only donate blood to people from A and AB groups.

People with group **B** red cells have type B surface antigens and they have anti-A IgM antibodies in their serum. They are therefore only able to receive blood from groups **B** or **O** and can only donate blood to people from B and AB groups.

Table 7.9 Red cell compatibility

Group	Antigens	IgM antibodies	Compatible donor for	Compatible recipient of
A	A	Anti-B	A AB	A O
B	B	Anti-A	B AB	B O
AB	A and B	None	AB	A B AB O
O	None	Anti-A Anti-B	A B AB O	O

In addition to the ABO system, the Rh blood group was discovered in 1940; again, these are surface antigens and they are another essential system used in transfusion therapy (Mollison et al. 1997). The Rh D antigen is the most immunogenic of the Rh antigens (Porth 2005). Approximately 85% of Caucasians have the D antigen and are therefore Rh positive and 15% lack the D antigen and are Rh negative (Daniels 2013). There has now been identification of several hundreds of red cell transfusion-related antigens, and antibody production can happen after contact with non-self blood antigens, usually due to transfusion or pregnancy (Zwaginga and van Ham 2013).

Related theory

Blood group incompatibility

The transfusion of ABO incompatible red cells can lead to intravascular haemolysis where the recipient's IgM antibodies bind to the corresponding surface antigens of the transfused cells (McClelland 2007). Complement activation results in lysis of the transfused cells and the haemoglobin that is released precipitates renal failure, with the fragments of the lysed cells activating the clotting pathways, which in turn leads to the development of disseminated intravascular coagulation (DIC) (Mollison et al. 1997). Transfusion of Rh D-positive cells to a Rh D-negative individual will result in immunization and the appearance of anti-D antibodies in at least 30% of recipients (Daniels 2013). If the person is immunized then on any subsequent exposure to D antigen-positive red cells, extravascular haemolysis occurs when rhesus antibody-coated red cells are destroyed by macrophages in the liver and spleen (McClelland 2007). This can present as a severe immediate or delayed haemolytic transfusion reaction (Daniels 2013).

A patient's Rh status is of particular importance if they are female and of child-bearing potential requiring a transfusion and during pregnancy. Immunization can happen by two processes: transfusion of D-positive cells into someone who is D negative or in pregnancy when transplacental passage of fetal red cells exposes the mother to D-positive cells. When the mother is Rh D negative and the developing fetus is Rh D positive, the exposure to fetal blood can stimulate anti-D activation in the mother. Anti-D is one of the red cell antibodies which can cross the placenta and cause haemolysis of the fetal blood which results in haemolytic disease of the fetus and newborn (HDFN) (McClelland 2007, Norfolk 2013).

Blood groups in haemopoietic stem cell transplantation

The human leucocyte antigen (HLA) is used to determine compatibility for organ transplantation, including bone marrow and peripheral blood stem cells. However, because ABO blood groups and HLA tissue types are determined genetically, it is not uncommon to find a suitable HLA donor who is ABO and/or Rh incompatible with the recipient. In such circumstances, major transfusion reactions can be avoided by red cell and/or plasma depletion of the donor cells in the laboratory before reinfusion (Mollison et al. 1997). However, collection of peripheral stem cells by apheresis usually results in a product that is already significantly red cell depleted and so further red cell depletion in the laboratory is not necessary (McKenna and Clay 2005).

Evidence-based approaches

The transfusion of blood components is a complex multistep process involving personnel from diverse backgrounds with differing levels of knowledge and understanding. Errors made in the process of transfusion present a significant risk to patients.

Although there is little evidence to support the efficacy of set procedures to manage this risk, current professional opinion has been provided by the British Committee for Standards in Haematology (BCSH) in collaboration with the Royal College of Nursing (RCN) and the Royal College of Surgeons of England (RCS) (BCSH 2009, Gray and Illingworth 2005). As a result of this guidance, every hospital should have a policy for the administration of blood and blood components, including identification of the patient, blood sampling, special blood requirement requests, processing of blood samples, the storage, collection and transportation of blood components, administration of blood components and the care and monitoring of the transfused patient. Furthermore, hospitals are also required to manage and report any

adverse events or near misses, with a statutory requirement to hold a record of every step of the transfusion process, including the final fate of each blood product, for 30 years (James 2005). Only staff authorized to do so should be involved at any stage in the transfusion process.

Nurses in the UK are normally the healthcare professionals ultimately responsible for the bedside check and arguably have the final opportunity to prevent errors occurring when patients receive blood transfusions (Wilkinson and Wilkinson 2001). Errors in the requesting, collection and administration of blood components (red cells, platelets and plasma concentrates) lead to significant risks for patients. Since its launch in 1996, the Serious Hazards of Transfusion (SHOT) scheme has continually shown that 'wrong blood into patient' episodes are a frequently reported transfusion hazard. These wrong blood incidents are mainly due to human error arising from misidentification of the patient during blood sampling, blood component collection and delivery or administration which can lead to life-threatening haemolytic transfusion reactions and other significant morbidity (BCSH 2009). In the 2013 SHOT report (Bolton-Maggs et al. 2014) the cumulative data submitted since 1996 were analysed to assess likelihood of preventability. It was found that half of all reports are adverse events caused by human error, such as assuming patient identity and not following the correct checking processes. See Figure 7.10.

The National Comparative Audits (NCA) of bedside transfusion practice (2003, 2005, 2009 and 2011) show that patients continue to be placed at risk of avoidable complications of transfusion through misidentification and inadequate monitoring.

Rationale

Blood transfusion is an essential part of modern medicine and potentially a life-saving intervention. However, its use should be appropriate and limited when possible through the following

Figure 7.10 Cumulative data for SHOT categories 1996/7–2013, n=13,141.

Source: Adapted from Bolton-Maggs et al. (2014). Reproduced with permission from SHOT (www.shotuk.org).

strategies: early diagnosis and treatment of conditions that may eventually require a transfusion, optimal patient management using evidence-based approaches to transfusion and assessing the possibility of alternative treatments such as pharmacological interventions, good surgical and anaesthetic techniques (WHO 2011).

Recent publications and legislation have created greater awareness of the need to continue to improve transfusion practice in many ways. Blood and blood components are no longer regarded as safe unlimited resources. There are risks inherent in transfusion practice and therefore unnecessary exposure to blood components should be avoided. This is of particular importance for patients who may only have one transfusion in their lifetime, such as surgical patients. However, all patients should only receive a transfusion when it is absolutely necessary. Furthermore, the appropriate use of components is essential for the conservation of blood supplies. Regularly updated guidance on the safe appropriate use of blood and blood components is available online at www.transfusionguidelines.org.uk and these should be consulted in collaboration with local hospital and blood transfusion service guidelines.

Indications for red cells

Anaemia is defined as a haemoglobin concentration in blood that is below the expected value, when age, gender, pregnancy and certain environmental factors, such as altitude, are taken into consideration. In general, anaemia is a consequence of one or more of the following generic causes:

- increased loss of red blood cells
- decreased production of red blood cells
- increased destruction of red blood cells
- increased demand for red blood cells
- increased production of abnormal red blood cells

which may be due to nutritional deficits, blood loss, kidney disease, medication or chronic diseases (Fields and Meyers 2006, Moftah 2005). The cause of anaemia should be ascertained and possible effective treatment options explored, such as treatment of iron deficiency before the patient is transfused with red cells (BCSH 2001).

A minimum transfusion trigger has not been well established because of the variability of patient co-morbidities and anaemia tolerance. Evidence suggests that most patients can safely tolerate anaemia of 70 g/L of Hb in the absence of active bleeding (Tolich 2008). A systematic review of the evidence for restrictive red cell transfusions practice concluded that the evidence was in favour of restrictive transfusion triggers in the majority of patients and that a haemoglobin threshold of 70 or 80 g/L lowers the number of red cells units transfused. The review also concluded that restrictive transfusion thresholds had no adverse associations with mortality, cardiac morbidity and length of hospital stay (Carson et al. 2012). However, surveys of the UK population show that most blood recipients are relatively elderly; many will have cardiovascular disease and may be less tolerant of low haemoglobin levels than younger, fitter patients. In this group of patients, consider adopting a higher transfusion trigger of 80 g/L (BCSH 2001). Patients who have cardiovascular disease, renal disease, low albumin concentration or are of low weight (in particular, the elderly and children) may also be more susceptible to congestive cardiac failure due to volume overload when blood and other fluids are infused (McClelland 2007, Norfolk 2013). There were six patient deaths reported to SHOT in 2010 which were attributed to overtransfusion and transfusion-associated cardiac overload (TACO). One of the recommendations from the SHOT report 2010 was that the existing BCSH guidelines for the administration of blood components should be supplemented with advice on how to prevent TACO. This addendum to the guidelines was published in August 2012 and makes several recommendations such as only transfusing single units of red cells when possible,

assessment of fluid balance and reducing the amount of blood transfused in low bodyweight patients (BCSH 2012a).

Indications for platelets

Platelet transfusions are indicated in the prevention and treatment of haemorrhage in patients with thrombocytopenia or platelet function defects (BCSH 2003). Thrombocytopenia can be defined as a platelet count below the normal range for the population and this is usually considered to be between 150 and $450 \times 10^9/L$ (Sekhon and Roy 2006). Thrombocytopenia is usually due to either decreased platelet production or increased destruction. Not all thrombocytopenic patients require a platelet transfusion and in some cases it may be contraindicated. Patients who have chronic stable thrombocytopenia due to such conditions as myelodysplasia and aplastic anaemia often do not require a transfusion and do not experience haemorrhage even with platelet counts below $10 \times 10^9/L$ (BCSH 2003). In prophylactic situations there are various thresholds, depending on the reason for the transfusion and presence of risk factors for bleeding; see Table 7.10 for adult thresholds for transfusion and Table 7.11 for paediatric thresholds.

In all cases of prophylactic platelet transfusions, the patient should receive one adult therapeutic dose (one pool or pack) and then be reassessed. Giving double dose platelet transfusions does not decrease the risk of the patient bleeding (Slichter et al. 2010). There should be careful assessment of the need for a platelet transfusion as the effectiveness and the platelet rise following the transfusion will start to reduce as the number of platelet transfusions increases (Slichter et al. 2010), and following the transfusion, the platelet effectiveness should be evaluated by checking the increment. One adult dose of platelets in a 70-kg adult typically gives a rise of $20\text{--}40 \times 10^9/L$ and the sample to check the count can be taken 10 minutes after completion of the transfusion (O'Connell et al. 1988).

Blood donation and testing

All blood donated in the UK is given voluntarily and without remuneration. The successful selection of a donor must protect them from any harm that may be caused by the donation process and also protect the possible recipient of components derived from the donor's blood. Donors of blood for therapeutic use should be in good health; if there is any doubt about their suitability, the donation should be deferred and they should be fully assessed by a designated medical officer. All donors of blood or its components (via apheresis) should be assessed in accordance with the Joint UKBTS/NIBSC Professional Advisory Committee (JPAC) donor selection guidelines (JPAC 2013). The assessment of fitness to donate includes a questionnaire relating to general health, lifestyle, past medical history and medication. Donation may be temporarily or permanently deferred for a variety of reasons including cardiovascular disease, central nervous system diseases, malignancy and some infectious diseases, all of which are detailed in the JPAC (2013) guidelines. Donors are also screened for risk of exposure to transmissible infectious diseases, and specific guidance is provided for donors receiving therapeutic drugs.

Prevention of transmission of infection is determined by donor selection criteria and laboratory testing. In the UK, all blood donations are tested for infections which could be passed on to the recipient. However, concern about transfusion-related variant Creutzfeldt-Jakob disease (vCJD) transmission is now supported by clinical evidence (Ludlam and Turner 2006) and in 2011 a prototype blood test for diagnosis of vCJD in symptomatic individuals was developed by the Medical Research Council (MRC) Prion Unit. It is hoped that this will lead to the development of a screening test for asymptomatic vCJD prion infection (Edgeworth et al. 2011). At present, donor exclusion criteria remain an important precautionary measure for all infection including vCJD (Cervenkova and Brown 2004). Since April 2004 all individuals who have received a blood component since January 1980 are excluded

Table 7.10 Indications for use of platelet transfusions in adults

Indication	Transfusion indicated (threshold provided)/not indicated
Routine prophylactic use	
Reversible bone marrow failure	$10 \times 10^9/L$
Chronic bone marrow failure, peripheral destruction/consumption, abnormal platelet function	Not indicated
Prophylactic use in the presence of risk factors for bleeding (e.g. sepsis, antibiotic treatment, abnormalities of haemostasis)*	
Reversible/chronic bone marrow failure	$20 \times 10^9/L$
Peripheral destruction/consumption, abnormal platelet function	Not indicated
Prophylactic use pre-procedure except eyes or brain	
Reversible/chronic bone marrow failure and platelet destruction/consumption if urgent/other therapy failed	
Bone marrow aspirate and trephine	Not indicated
Epidural anaesthesia	$80 \times 10^9/L$
All other procedures [†]	$50 \times 10^9/L$
Abnormal platelet function	
Bone marrow aspirate and trephine	Not indicated
All other procedures in selected patients if alternative therapy failed/contraindicated	Not possible to state threshold
Prophylactic use pre-procedure involving eyes or brain	
Reversible/chronic bone marrow failure and platelet destruction/consumption if urgent/other therapy failed	$100 \times 10^9/L$
Abnormal platelet function in selected patients if alternative therapy failed/contraindicated	Not possible to state threshold
Therapeutic use	
Massive transfusion, all patient indication categories except platelet function defects where not possible to state threshold [‡]	$75 \times 10^9/L$
For patients with multiple trauma or central nervous system injury	$100 \times 10^9/L$

Source: NCA Platelet Working Group (2012). Reproduced with permission from National Comparative Audit Platelet Working Group at NHS Blood and Transplant (http://hospital.blood.co.uk/safe_use/platelet_education_resources).

*BCSH guidelines for multiple myeloma recommend a threshold count of 30 with bortezomib treatment.

BCSH guidelines for aplastic anaemia recommend a threshold count of 30 during treatment with anti-thymocyte globulin and a threshold count of 20 if pregnant or fever.

[†]American Society for Hematology immune thrombocytopenia guidelines recommend a threshold count of 80 for major surgery.

[‡]Thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia platelet transfusion contraindicated unless life-threatening haemorrhage.

Table 7.11 Differences/additions to indications in Table 7.10 for neonates and older children

Indication	Transfusion indicated (threshold provided)/not indicated
Routine prophylaxis in neonates	
Stable preterm or term infant	$20 \times 10^9/L$
Sick preterm or term infant	$30 \times 10^9/L$
Small preterm infant	Higher threshold, not specified
Neonatal alloimmune thrombocytopenia	$30 \times 10^9/L$
Prophylactic use for children in the presence of risk factors	
Additional risk factors include severe mucositis, local tumour infiltration, platelet count likely to fall to $<10 \times 10^9/L$ before next evaluation, anticoagulation therapy	$20 \times 10^9/L$
Severe hyperleucocytosis or DIC with induction therapy for leukaemia	$40 \times 10^9/L$
DIC	$20 \times 10^9/L$
Prophylactic pre-procedure	
ECMO	$100 \times 10^9/L$
Lumbar puncture or indwelling line insertion in children	$40 \times 10^9/L$

DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation.

from donating blood due to the risk of transmitting vCJD (DH 2013). When a donor has been successfully screened, they must validate the information they have provided and record that they have given consent to proceed.

Cell salvage and autologous transfusion

Since the 1980s there has been interest in autologous transfusion (blood and blood components collected from an individual and intended solely for subsequent autologous transfusion to that same individual) (Blood Safety and Quality Regulations 2005). This has largely been attributed to high-profile infection risks: human immunodeficiency virus (HIV), hepatitis C and more recently vCJD (James and Harrison 2002). However, autologous transfusion is not risk free, with 42 cases of adverse events being reported to SHOT in 2011, all related to intraoperative and post-operative cell salvage (SHOT 2011a). Autologous transfusion is contraindicated in certain circumstances. Furthermore, there has been significant concern about the efficacy of some methods (Carless et al. 2004, Henry et al. 2002). Three principal methods of autologous transfusion exist.

Pre-operative autologous donation (PAD)

This technique is rarely undertaken and not currently recommended unless the clinical circumstances are exceptional, such as the patient has a rare blood group and allogeneic blood would be difficult to obtain (BCSH 2007). This requires the patient to donate up to four units of blood whilst simultaneously taking iron supplements in the month preceding surgery. However, the efficacy of this method has been questioned by systematic review (Henry et al. 2002) and it is only indicated in very specific circumstances such as patients with very rare blood types, patients donating bone marrow and fit patients who have a significant fear of receiving allogeneic blood products such that it is preventing them from seeking necessary surgery (James 2004). This technique can only be carried out in organizations licensed as blood establishments by the Medicines and Healthcare Products Regulatory Agency (MHRA).

Acute normovolaemic haemodilution (ANH)

This technique is not currently encouraged and the effectiveness of the procedure is unproven (McClelland 2007). It involves the donation of up to three units of blood immediately prior to surgery. The patient is then given crystalloids to dilute the circulating volume. This method is only indicated for surgery where considerable blood loss is expected on the principle that the number of red cells lost will be reduced and the patient's autologous whole blood can be returned after surgery.

Intraoperative cell salvage (ICS)

Blood loss during surgery is collected, anticoagulated, filtered and held in a sterile reservoir. The collected blood is then processed, washed and suspended in 0.9% sodium chloride for return. Although ICS is not without risks, such as embolism, bacterial contamination and enhanced inflammatory responses through reinfusion of inflammatory mediators (Harrison 2004), it has been recommended as the most effective form of autologous transfusion to assist in the conservation of blood supplies (James 2004). Cell salvage has been shown to be effective in reducing the requirement for perioperative allogeneic blood transfusion in orthopaedic, cardiac and vascular surgery (Carless et al. 2010). The effectiveness of intraoperative cell salvage to minimize a patient's exposure to allogeneic blood is dependent on the amount of blood lost during surgery. However, if this blood can be retrieved and reinfused, thus preventing a transfusion, then it has been shown to be an effective strategy which should be widely available (Thompson 2005).

Post-operative cell salvage

Where there is a predictable blood loss following elective surgery, the blood is collected in the wound drain and then reinfused to

the patient through special equipment. The blood can be passed through a filter incorporated into the cell salvage post-operative equipment or washed before returning to the patient and this has become almost routine for some surgical practice (Hamer 2005a, McClelland 2007). The main surgical area of use is orthopaedic surgery, in particular replacement knee surgery, and is safe and clinically beneficial (Hamer, 2005b).

Several cases have been reported to SHOT (2011a) where the autologous blood had not been labelled with the correct patient identification and in some cases this had not been noted by staff in the clinical area prior to reinfusion (SHOT 2011a). SHOT highlighted that it is still critical to maintain correct patient identification in autologous transfusion. In 2006 a UK cell salvage group was founded to support the implementation of cell salvage; more information and advice can be found on the Better Blood Transfusion Appropriate Use of Blood Toolkit at www.transfusinguidelines.org.uk.

Blood component donation

Donors of blood components by automated apheresis are subject to the same selection criteria used for donating whole blood and any exception to this must be decided by a designated medical officer. Apheresis can be used to collect plasma, red cells and platelets. Leucopheresis procedures are used for the collection of granulocytes, lymphocytes and peripheral blood progenitor cells (James 2005). Over 80% of the platelets issued in the UK are now from single donor, apheresis collection as part of a Department of Health requirement to reduce the risk of vCJD transmission (NHSBT 2011, SaBTO 2009).

Appropriate use of donated blood components

Donated blood components are a precious gift; they are not a limitless resource and must be used appropriately. The BCSH has guidelines in place for the use of red cell, platelet, fresh frozen plasma (FFP), cryoprecipitate and cryosupernatant transfusions, available on the BCSH website: www.bcsghguidelines.com.

The decision to transfuse must be based on a thorough clinical assessment of the patient and their individual needs. Each blood component should only be given after careful consideration, when there is valid clinical indication or when there are no alternative treatment options available (Oldham et al. 2009).

Blood and blood components have varying shelf-lives and storage requirements. The range of components currently available, indications for use and recommendations for administration are listed in Table 7.12. Clinical indications for use are also provided by the BCSH (BCSH 2012b, Murphy et al. 2001, O'Shaughnessy et al. 2004).

Anticipated patient outcomes

Blood component transfusion can be a life-saving and life-enhancing treatment when used appropriately and when patients are cared for safely and by knowledgeable, skilled practitioners (Oldham et al. 2009).

Legal and professional issues

Blood safety and quality in the UK

Approximately 3.4 million blood products are administered in the UK every year (SHOT 2011a). The transfusion of blood and its components is usually safe and uneventful; however, there are associated risks and there have been significant developments over recent years to improve the quality and safety of transfusion practice in the UK. The Blood Safety and Quality Regulations came into effect in February 2005 and were fully implemented on 8 November 2005. These Regulations cover the collecting, testing, processing, storing and distributing of blood and blood components (Blood Safety and Quality Regulations 2005). The official government agency with jurisdiction for these regulations is the MHRA.

Table 7.12 Blood, blood components and blood products used for transfusion

Type	Description	Indications	Cross-matching	Shelf-life	Average infusion time	Technique	Special considerations
Red cells in optimal additive solutions (SAGM)*	Red cells with plasma removed: 100 mL additive fluid used as replacement to give optimal red cell preservation; haematocrit 60–65% leuco-depleted	Correction of anaemia	ABO and Rh compatible (not necessarily identical)	35 days at 2–6°C	1–2 hours/unit Transfusion to be completed within 4 hours of component's removal from storage	Give via a blood administration set	If more than half blood volume is replaced with red cells in SAGM, use of FFP should be considered to replace clotting factors
Washed red blood cells	Red cells centrifuged and resuspended twice in 0.9% sodium chloride Leuco-depleted	Correction of anaemia where patient may react to plasma components, for example in IgA deficiency	As above	Prepared by non-sterile process, used within 24 hours Closed system preparation, used within 72 hours	1–2 hours/unit	As above	–
Frozen red blood cells	Red cells of very rare phenotype Leuco-depleted	To treat patients with very rare antibody	As above	Stored frozen cells: up to 10 years Use within 12 hours of thawing	2–3 hours/unit	As above	–
White blood cells (buffy coat or apheresed granulocytes) [†]	Mainly granulocytes obtained by leucophoresis or by 'creaming off' the white blood cell layer from fresh blood	To treat patients with life-threatening granulocytopenia	As above	24 hours after preparation Stored at room temperature	60–90 minutes/unit	Administer via a blood administration set	White blood cell infusion induces fever, may cause hypotension, rigors and confusion Treat symptoms and reassure patient White cell component is always irradiated to prevent initiation of transfusion-associated graft-versus-host disease (TA-GVHD) <i>Do not</i> give to patients receiving amphotericin B. Indications for granulocyte transfusions should be when possible benefits are thought to outweigh considerable hazards of the treatment option (Brozovis et al. 1998)

(continued)

Table 7.12 Blood, blood components and blood products used for transfusion (*continued*)

Type	Description	Indications	Cross-matching	Shelf-life	Average infusion time	Technique	Special considerations
Platelets*	Platelets in 200–300 mL plasma May be pooled from 5 donors or apheresed from a single donor Leuco-depleted	To treat thrombocytopenia either for prophylaxis to prevent bleeding or therapeutically to treat bleeding	No cross-matching necessary	Up to 7 days after collection Storage is at 22°C, with continuous gentle agitation	20–30 minutes/unit	Administration using a platelet or blood component administration set Use a new set for each transfusion Do not use micro-aggregate filters	General guide to use: use in chronic bone marrow failure for routine prophylaxis is not indicated Platelets are not clinically indicated for a bone marrow aspirate and trephine regardless of the cause of thrombocytopenia. See Tables 7.10 and 7.11
Fresh frozen plasma	Citrated plasma separated from whole blood	To treat multi-factor deficiencies associated with severe bleeding and/or DIC FFP is not indicated in DIC without bleeding or for the immediate reversal of warfarin	No cross-matching necessary	3 years at <–25°C Once thawed, kept at 4°C, to be used as soon as possible but within 24 hours	15–45 minutes/unit (approx. 250 mL), more rapid infusion may be indicated in major haemorrhage	Administer rapidly via a blood administration set	FFP should be considered if patient has received more than half their blood volume in red cells, to prevent dilutional hypocoagulability The dose given is based on the patient's weight
Albumin 4.5% (HAS)	Solution of albumin from pooled plasma in a buffered, stabilized 0.9% sodium chloride diluent Supplied in 250 mL or 500 mL bottle	To treat hypovolaemic shock or hypoproteinaemia due to burns, trauma, surgery or infection Sourced outside UK to reduce risk of transmission of vCJD	Unnecessary Not blood group specific	5 years at room temperature Kept in dark	30–60 minutes/unit	Administer via a standard solution administration set	The solution should be crystal clear with no deposits
Albumin 20% (HAS)	Heat-treated, aqueous, chemically processed fraction of pooled plasma	To treat hypovolaemic shock or hypoproteinaemia due to burns, trauma, surgery or infection To maintain appropriate electrolyte balance	Unnecessary	5 years at room temperature Kept in dark	30–60 minutes/unit	Administer via a blood administration set undiluted or diluted with 0.9% sodium chloride or 5% glucose solution Slower administration is advised if a cardiac disorder is present to avoid gross fluid shift	The solution should be crystal clear with no deposits

Cryoprecipitate	Cold-insoluble portion of plasma recovered from FFP: rich in factor VIII, von Willebrand's factor and fibrinogen	Hypofibrinogenaemia, in acute DIC with bleeding and surgery prophylaxis with fibrinogen <1.5 g/L Sever liver disease with bleeding and in cases of massive transfusion	No cross-matching necessary	3 years at <-25°C Use immediately after thawing	Available as single donor units or as pooled units (5 single donor units), typical adult dose is two pooled packs, administered at 10–20 ml/kg/hr, 30–60 minutes as a pooled unit	Administer via blood administration set
Solvent detergent treated FFP (SD-FFP)	FFP prepared from pools of donations and the solvent detergent process inactivates bacteria and most encapsulated viruses	Guidelines recommend use in treating thrombotic thrombocytopenic purpura: patients are plasma-exchanged daily to reduce circulating von Willebrand's factor	No cross-matching necessary	4 years at <-18°C Once thawed transfuse	Time depends on machine; average ±2.5 hours	Via apheresis machine
Licensed medicinal product Octaplas®						

DIC, disseminated intravascular coagulation; FFP, fresh frozen plasma; HAS, human albumin solution; INR, international normalized ratio; SAGM, saline, adenine, glucose and mannitol; vCJD, variant Creutzfeldt-Jakob disease.

*Most commonly used blood components.

[†]See leucocyte depletion.

The principal requirements of these Regulations in relation to transfusion practice are as follows.

- **Traceability:** there must be a full audit trail from the donor to the recipient so hospitals must have a system to record and retain information on the fate of each unit of blood/blood component for a period of 30 years.
- **Haemovigilance:** an organized surveillance procedure relating to serious adverse or unexpected events or reactions. The reporting of such events can be done via the online Serious Adverse Blood Reactions and Events (SABRE) system which is maintained by the MHRA. This will usually be done by a designated member of laboratory staff or transfusion practitioner and therefore clinical staff must ensure that all incident reporting is conducted in line with hospital policy.

The Blood Safety and Quality Regulations (2005) defines such events as follows.

- A **serious adverse event** is defined as an unintended occurrence associated with the collection, testing, processing, storage and distribution of blood or blood components that might lead to death or life-threatening, disabling or incapacitating conditions for patients or which results in, or prolongs, hospitalization or morbidity.
- A **serious adverse reaction** is defined as an unintended response in a donor or in a patient associated with the collection or transfusion of blood components that is fatal, life-threatening, disabling or incapacitating, or which results in or prolongs hospitalization or morbidity (Blood Safety and Quality Regulations 2005).

Prior to these regulations, Better Blood Transfusion initiatives aimed to ensure that such guidance became an integral part of NHS care, making blood transfusion safer, ensuring that all blood used in clinical practice is necessary and improving the information both patients and the public receive about blood transfusion (DH 2007). Therefore it is a key requirement that all staff involved in the process of transfusion maintain their awareness of all appropriate guidance.

Competencies

The transfusion of any blood component carries with it the potential for reaction and risk (SHOT 2005). All staff involved in the transfusion of blood and/or blood components must have the knowledge and skills to ensure the process is completed safely. Therefore, the nurse caring for those receiving transfusion therapy must do so within his or her sphere of competence, always acting to minimize risk to the patient (NMC 2015).

Practitioners must understand the theory and reasoning behind the necessity to follow the correct transfusion procedures and practices (Pirie and Gray 2007). In November 2006, the NPSA, the Chief Medical Officer's National Blood Transfusion Committee (NBTC) and SHOT, working in collaboration, developed strategies aimed at ensuring that blood transfusions are carried out safely, and issued the Safer Practice Notice (SPN) No. 14, *Right Patient, Right Blood*. One of the key action points in this Notice was for all NHS and independent sector organizations involved in administering blood transfusions to develop and implement an action plan for competency-based training and assessments for all staff involved in blood transfusions. In 2009, BCSH recommended that blood components must only be administered by a registered healthcare professional who has been trained and competency assessed to NPSA SPN 14 standard and that all staff involved in transfusion in the clinical area must have a minimum of a 2 yearly training (BCSH 2009).

There are three key principles which underpin every stage of the blood component transfusion process:

- patient identification
- documentation
- communication (BCSH 2009).

Consent

In 2010 the Advisory Committee on the Safety of Blood, Tissues and Organs (SaBTO) undertook a public consultation on consent for blood transfusion. A total of 14 recommendations were published following the consultation (SaBTO 2011). They recommended that a valid consent for transfusion should be obtained and documented in the patient's record by the healthcare professional. SaBTO has also recommended that those patients who could not be consented before the transfusion should receive information retrospectively. The Good Practice Guidance (SaBTO 2011) outlines that retrospective information can be given at any point during the hospital stay but recommends that it is incorporated in the discharge procedure. The retrospective information should include the risk of a transfusion-transmitted infection and inform the patient that, as they have received a blood component, they can no longer donate blood (SaBTO 2011).

Providing the patient with information before a procedure and ascertaining that the patient understands the procedure and has consented to it is the responsibility of the healthcare professional carrying out the procedure as well as those prescribing it (NMC 2013). A blood component transfusion must be treated as any prescribed medicine; that is, patients (or guardian) must be informed of the indication for the transfusion, advised of the risks and benefits, of alternatives to blood transfusion including autologous transfusion (BCSH 2009), be given the opportunity to ask questions and have the right to refuse to receive it in accordance with local and national guidance (NMC 2013). One of the key objectives of the HSC 2007/001 Better Blood Transfusion was to improve information provided to patients and to ensure that those who are likely to receive a blood transfusion will be well informed of their choices. There are a number of information leaflets issued by the NHS Blood and Transplant Service for both patients and healthcare professionals. Guidance is also available from SaBTO (2011) to ensure that patients have standardized information prior to a transfusion and outlines all the key information that should be provided.

Patients have the right to refuse transfusion and to be treated with respect. Staff must be sensitive to individual patient needs, acknowledging their values, beliefs and cultural background and exploring alternative treatments if appropriate and available (Oldham et al. 2009). There is increasing public concern about blood transfusion safety and the need to accommodate some patients' religious beliefs (John et al. 2008).

Non-medical written instruction to transfuse

Section 130 of the 1968 Medicines Act was amended by Regulation 25 of the Blood Safety and Quality Regulations (BSQR) 2005 (SI 2005 no 50) and this has resulted in blood components being excluded from the Act (Green and Pirie 2009). This removed blood components from the legal definition of medicinal products and they can no longer be legally prescribed by any practitioner. Blood components are therefore authorized and a written instruction is completed for transfusion. The amendment to the Medicines Act also removed the legal barrier to nurses expanding their role to authorize blood components. This does not mean, however, that all nurses can make the decision to transfuse blood components or authorize their use with a written instruction. Green and Pirie (2009) developed a document for nurses and midwives who wished to expand their role. This framework contains clear guidance for the implementation of non-medical authorization of blood components whilst ensuring patient safety. The guidance includes advice on selecting the patient group, selection criteria for nurses and midwives, the education and training to support role development, clinical governance procedures, safe and appropriate practice and how to review and monitor the improvement to local services (Green and Pirie 2009).

Jehovah's Witnesses and other patients who may refuse a blood transfusion

The principles in caring for the patient remain the same regardless of the reason for refusal and there should be a local policy in place to expedite non-blood management for these patients.

The role of blood in Jehovah's Witnesses' spiritual belief is based on scripture and followers are usually well informed on both their beliefs and their rights. Many Jehovah's Witnesses carry information with them regarding any objection and therefore the need to ensure informed consent is very important. Their religious position leads them to refuse red cells, white cells, plasma and platelets. Derivatives of these are seen as a matter of individual patient choice. Staff caring for patients must ensure that they have clearly documented what the patient will accept or refuse and that decisions to consent to or refuse treatment are respected and recorded appropriately (McClelland 2007). Furthermore, in individual circumstances, practitioners should endeavour to consider non-blood or autologous methods as described previously, where appropriate (McClelland 2007). Jehovah's Witness patients usually carry an Advance Directive listing which blood products and autologous procedures are acceptable or not acceptable to them (McClelland 2007, Norfolk 2013). The Jehovah's Witness community has a network of support called the Hospital Liaison Committees (HLCs) and they are available at any time, night and day, to assist with communication between hospital teams and the patient.

Management of massive blood loss

Massive blood loss is defined as a 50% blood volume loss within 3 hours or a rate loss of 150 mL/min (Frakry and Sheldon 1994). Good patient outcomes are dependent on clinical staff recognizing the blood loss early, taking effective action and ensuring efficient communication between the clinical area and the transfusion laboratory (NPSA 2010). To aid the provision of blood in an emergency situation, the majority of hospitals will have an agreed major haemorrhage protocol where all processes required in the provision of emergency blood are clearly stated. This includes how to activate the protocol, what blood component availability will be and how the blood components will be transferred from the laboratory to the clinical area.

In emergency situations, where the need for blood is immediate and the patient's blood group is unknown, it may be necessary to transfuse group O uncross-matched red cells (BCSH 2006). In major haemorrhage situations there is still a need to use group O Rh D-negative blood judiciously as it is a scarce resource. At the earliest opportunity, a sample should be taken from the patient so that blood group determination can take place. Once the laboratory receives the sample, it usually takes no longer than 10 minutes to determine the blood group and then issue group-specific blood (BSCH 2006).

Blood component request

The details on the blood component request form and the sample tube are the only direct contact between the clinical area and the blood transfusion laboratory. The accuracy and completeness of this information are therefore of vital importance (BCSH 2009). Incorrect or inadequate patient identification leading to a sample for blood grouping being taken from, or labelled for, the wrong patient may result in fatal ABO-incompatible transfusions (SHOT annual reports 1996–2011). In the 2011 SHOT report there were 469 instances of wrong blood in tube (WBIT) and five cases where WBIT led to an incorrect blood component being transfused (SHOT 2011a). Inadequately or mislabelled samples are up to 40 times more likely to contain blood from the wrong patient (BCSH 2009). A WBIT is usually identified in the laboratory by comparing the current patient group to previous group results, so the patients most at risk from this error are those who only have one sample sent and blood is issued on that sample. The BSCH (2012) produced guidelines which advocate that when the patient has not had their blood group tested by the current blood transfusion laboratory on a previous occasion, they should have a second separate sample sent before the blood is issued. This guidance does not apply for the emergency provision of blood and when waiting for a second sample to be processed would cause patient harm. It is also not necessary to implement the

recommendation if the hospital has a secure electronic patient identification system in place (BCSH 2012c).

The collection of the blood sample from the patient and the subsequent labelling of the sample tube should be performed as a continuous, uninterrupted event at the patient's (bed)side, involving one patient and one member of staff only (BCSH 2009).

The Chief Medical Officer's National Blood Transfusion Committee for England and North Wales has produced a standardized 'Indication Codes' for transfusion which may be incorporated into the request process (BCSH 2009).

Pre-procedural considerations

Equipment

Intravenous access

Blood components may be administered through a peripheral cannula or via a central venous access device. Where possible, one lumen should be reserved for the taking of blood specimens and blood component administration for the duration of therapy.

Administration sets

All blood components must be transfused through a sterile blood component administration set with an integral mesh filter (170–200 micron). Blood administration sets should be changed at least every 12 hours or after every second unit for a continuing transfusion (Loveday et al. 2014); see local guidance. Administration sets used for blood components must be changed immediately upon suspected contamination or when the integrity of the product or system has been compromised. Platelets and plasma components may be administered through a normal blood administration set or through a platelet set. Platelets should never be administered through an administration set that has previously been used for red cell transfusion or other blood component as this may cause aggregation of platelets in the administration set (McClelland 2007). Administration sets used for blood components must be changed using aseptic technique and observing universal precautions, in line with manufacturer's instructions (RCN 2010).

Infusion devices

Either gravity or electronic infusion devices may be used for the administration of blood components. There are a variety of electronic infusion devices available and it is therefore essential that individuals using any type of infusion device are competent in their use. Only blood component administration sets compatible with the infusion device should be used. Rapid infusion devices that are CE marked may be used when large volumes have to be infused rapidly. Typically, devices can infuse from 6 to 30 L an hour and usually incorporate a blood-warming device (BCSH 2009, McClelland 2007).

Blood-warming devices

The warming of blood and blood components is generally not recommended as it is of limited benefit and can be dangerous. Blood warmers are only indicated when:

- massive, rapid transfusion could result in cooling of cardiac tissue, causing potentially fatal dysrhythmia (McClelland 2007). If the rate of transfusion is greater than 100 mL per minute, blood-warming devices should be used (McClelland 2007)
- transfusion is required by patients with cold agglutination disease (Gray and Illingworth 2005)
- exchange transfusion is indicated in the newborn (Weinstein and Plumer 2007)
- thawing of cryopreserved stem cells prior to transfusion (blood or marrow).

Both water baths and dry heat blood warmers are available. However, whichever device is chosen, the temperature should

be maintained below 38°C. Warming in excess of this can cause haemolysis of red cells and can denature proteins and increase the risk of bacterial infection. Blood warmers must always be used and maintained according to the manufacturer's guidelines. Blood components must *never* be warmed by improvisation, such as putting the pack into hot water, in a microwave or on a radiator, as uncontrolled heating can damage the contents of the pack (Gray and Illingworth 2005, McClelland 2007, Norfolk 2013). The use of water baths also increases the risk of bacterial contamination. Therefore certain safety measures must be adhered to.

- 312
- Water baths must be drained after each use and must be stored dry and empty.
 - The blood warmer should be drained after each use and must be stored dry and empty.
 - When needed, they should be refilled with sterile water.
 - A protective sterile over-bag to thaw blood and blood products reduces the entry of contaminants through microscopic punctures or breaks in the seal.
 - The product should be used immediately after it has been thawed.

All devices should be serviced as per hospital health and safety policies, MHRA and manufacturers' guidelines.

Specific patient preparations

In 2007 the NPSA issued a Safer Practice Notice No. 24, *Standardising Wristbands Improves Patient Safety*, stating that only the following core identifiers should be used on patients' identification bands:

- last name
- first name
- date of birth
- NHS number.

Patients should have their identification confirmed on admission to the unit and one wristband attached to their wrist. If a wristband is removed for any reason, for example to gain intravenous access via a cannula, it is the responsibility of the person removing it to ensure that a correctly completed wristband is then reapplied.

Electronic systems for patient identification and transfusion

Wristbands can now hold patient information in an electronic format such as in a bar code or a radiofrequency identification tag (RFID). Electronic systems offer improved security and patient safety (BCSH 2009, Murphy et al. 2009) by removing the elements of human error from the process. At the point of taking a sample for pre-transfusion testing, the patient is identified through the usual process of stating name and date of birth but there is the

added safety of scanning the bar code or RFID tag on the wristband.

The electronic systems can be used during collection and administration. During administration, the blood component and the wristband are scanned to confirm that it is the right component for the right patient. The Safer Practice Notice No. 14, *Right Patient, Right Blood*, recommended that all NHS trusts and independent sector organizations responsible for administering blood should risk assess their transfusion procedures and look at the feasibility of using bar codes and other electronic identification and tracking systems for patients, samples and blood components.

The nurse must ensure that the patient has been informed of the proposed transfusion and has had an opportunity to raise any concerns, understands the risks and benefits of the transfusion and has agreed to and is available for the transfusion. Pre-transfusion/baseline observations including blood pressure, temperature, pulse and respiratory rate must be undertaken and documented; also ensure that there is patent venous access prior to administering the transfusion (BCSH 2009).

Pre-transfusion/bedside check

While professional accountability must be taken at every stage by the personnel involved, the final barrier to wrong blood administration is at the bedside. The final link is ensuring the right patient receives the right blood and it is therefore essential that the check is performed thoroughly prior to the transfusion of each component (Oldham et al. 2009).

To ensure that each blood component is used to its full advantage, local hospital policy should be followed with regard to correct handling and storage, transportation and administration of blood components. If unused, the component should be returned to the transfusion laboratory as quickly as possible to maximize the opportunity for it to be used for another patient.

The written order for the blood component must be checked to ensure that it is correctly completed and to ensure that it contains the following information.

- Patient core identifiers.
- Date (and time if appropriate) the blood component is required.
- Type of blood component to be administered.
- Any clinical special transfusion requirements, for example irradiated or administration via a blood warmer.
- Volume or number of units to be transfused (exact number in mL for paediatric transfusions).
- Time over which each unit is to be transfused (exact rate or length of time over which the specified volume is to be transfused for paediatric transfusions).
- Any special instructions, for example concomitant drugs required, such as diuretics.
- Signature of the 'prescriber' (BSCH 2009).

Procedure guideline 7.20 Blood product request

Essential equipment

- Blood request form

Procedure

Action

- 1 The following information must be completed on the request form.
 - (a) First name
 - (b) Surname
 - (c) Date of birth
 - (d) Gender
 - (5) Hospital identification number
 - (6) Ward or department

Rationale

Full demographics are required to minimize the risk of patients with the same or similar names being given the incorrect blood component (McClelland 2007, **E**; SNBTS 2004, **C**). Details on the request form must match the enclosed blood sample. Discrepant samples should not be processed (James 2005, **C**).

2 Complete the following clinical information. (a) Diagnosis (b) Reason for request; this should include details of any surgical procedure (c) Number and type of components requested (d) Any special requirements such as irradiated, cytomegalovirus (CMV) negative (e) If group and screen only (f) Date and time required	Enables laboratory staff to assess need against the surgical blood ordering schedule. E Some vulnerable patient groups may have a fatal reaction to wrongly transfused non-irradiated or CMV-positive products (McClelland 2007, E). Negative and positive status should always be written in full and not as + or – as they may get defaced and be incorrectly processed (SNBTS 2004, C). This allows laboratory staff to plan ahead for complex cross-matches to ensure the required products are available at the correct time (SNBTS 2004, C).
3 Each request should also include: (a) the name of the doctor/nurse requesting the components (b) the name and signature of the person who has taken the blood sample.	Every step of the transfusion must be fully traceable and the record held for 30 years (James 2005, C).
4 The following information can also be included if it is available in the patient's clinical record. (a) Patient's blood group (b) Presence of known antibodies (c) Date of last transfusion	This information is useful to laboratory staff. E Negative and positive should always be written in full and not as + or – as they may get defaced and be incorrectly processed (SNBTS 2004, C).

Procedure guideline 7.21 Blood sampling: pre-transfusion

Essential equipment

- Antimicrobial skin cleanser – the recommended solution is 0.5% chlorhexidine in 70% alcohol
- Safety needle/winged infusion device
- Appropriate tubes for blood sample collection
- Gauze
- Hypoallergenic tape
- Non-sterile, well-fitting gloves
- Sharps container

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Take pre-transfusion blood from one patient at a time.	To ensure that samples from different patients are not confused which can have fatal consequences and to minimize this risk (SHOT 2008, C).
3 Check all packaging before opening and preparing the equipment.	To ensure there has been no contamination and all equipment is in date. E

Procedure

4 Before taking the sample, ask the patient to state their first name, surname and date of birth. Cross-check these details against the blood request form. For patients unable to identify themselves, verification can be obtained from a carer or relative if present. This information must match the wristband and request form.	To ensure that the sample obtained corresponds with the request (BCSH 2009, C).
5 Check these details against the patient's identity wristband.	To ensure that the patient is positively identified before obtaining a blood sample (BCSH 2009, C).
6 Check the patient's hospital number on the wristband against that on the blood request form.	To ensure that the sample obtained corresponds with the request (BCSH 2009, C).
7 Obtain the blood sample by direct venepuncture or via central venous access device, in the appropriate tube (see Chapter 10: Interpreting diagnostic tests).	To ensure the correct procedure is followed and an adequate sample is obtained. E

(continued)

Procedure guideline 7.21 Blood sampling: pre-transfusion (*continued*)**Post-procedure****Action**

- 8 Hand-write the sample tube clearly and accurately, ensuring all names are spelled correctly. This should only be done once the sample has been successfully obtained and should be done at the patient's (bed)side.
 - (a) First name
 - (b) Surname
 - (c) Date of birth
 - (d) Gender
 - (e) Hospital identification number
 - (f) Ward or department
 - (g) Date

Rationale

To ensure the sample is labelled with the correct patient details. BCSH guidelines do not recommend the use of labels pre-printed away from the patient's bedside such as addressograph labels (Murphy et al. 2009, **E**). Blood tubes should never be completed in advance as this has been identified as a major cause of patient identification errors (SNBTS 2004, **C**).

314

Procedure guideline 7.22 Blood components: collection and delivery to the clinical area

Removal of blood components from their storage location continues to be identified as a major source of error in the transfusion process (BCSH 2009). Only those staff who are authorized, trained and competent may remove blood components from storage. A guide to the necessary elements of blood pack labelling is shown in Figure 7.11.

Essential equipment

- Documentation containing the patient's three core identifiers – full name, date of birth and hospital number/unique identifying number – must be held by the person removing the component from storage

Pre-procedure**Action**

- 1 Check that the reason for the transfusion has been documented in the patient's notes.
- 2 Check that there is a valid written order for the administration of the component including special requirements – CMV negative or irradiated components.
- 3 Check the patient is aware of and has 'consented' to the procedure.
- 4 Check the patient is available.
- 5 Take baseline observations to include blood pressure, temperature, pulse and respiratory rate.
- 6 Check the patient has patent venous access. If not then ensure appropriate device is inserted.
- 7 Check the patient is wearing an identification wristband.

Rationale

To ensure the transfusion is appropriate and necessary (BCSH 2009, **C**).

To ensure the selected component meets the patient's individual requirements (BCSH 2009, **C**).

To ensure the patient is fully informed (BCSH 2009, **C**).

To avoid delays once the component has been removed from storage. **E**

To ensure that any transfusion reaction can be immediately identified, due to changes in baseline (BCSH 2009, **C**), and managed appropriately (SNBTS 2004, **C**).

To avoid any delay in commencement of the transfusion and adhere to 'cold chain' requirements (BCSH 2009, **C**).

To avoid delays in confirming patient identity (BCSH 2009, **C**).

Procedure

- 8 Where possible, the same person who will administer the component should collect it from storage.
- 9 Remove the component (using electronic or manual method) from storage in accordance with trust policy.
- 10 Remove one component at a time, unless rapid transportation of large quantities is needed or if blood is being transported to remote areas in specifically designed validated blood transport containers. If large quantities are required this must be discussed with the transfusion laboratory and local procedures followed.
- 11 Check the component at the point of removal for correct patient-identifying details. A visual inspection of the component should also be performed to check the expiry date and any signs of leakage, clumping or discoloration.
- 12 Deliver the component to the clinical area where an appropriately trained and competent member of staff should check that the correct blood has been delivered.

To minimize the number of people involved in the process (BCSH 2009, **C**).

To ensure that only authorized, trained and competent staff may collect blood components (BCSH 2009, **C**).

To ensure components are stored in the appropriate conditions. **E**

In order to minimize the risk of incorrectly administering the component to the wrong patient (BCSH 2009, **C**). Expired or damaged products must not be used (McClelland 2007, **E**).

To ensure the correct component has been received for the patient, to comply with traceability and cold chain requirements (BCSH 2009, **C**).

Compatibility label or tie-on tag

The compatibility label is generated in the hospital transfusion laboratory. It is attached to the blood bag and contains the following patient information: Surname, First Name(s), Date of Birth, Gender, Hospital Number/Patient Identification Number, Hospital and Ward.

The blood group, component type and date requested are also included on the label. The unique donation number is printed on the compatibility label; this number must match exactly with the number on the blood bag label.

STOP, SEE BACK OF THIS TAG BEFORE TRANSFUSION	
NHS <small>SCOTLAND ©Scottish National Blood Transfusion Service 2005 V9</small>	
Donation No: G101 606 597 229 N Component: Red Cells Signature 1: _____ Date Given: _____ Signature 2: _____ Time Given: _____	
Peel off label above and place in patient's Medical Records	
Surname: MACDONALD	Forename: MORAG
DOB: 11/07/1956	Gender: FEMALE
25 HILL STREET TOWN CENTRE	
Patient Identity No: 100198E	Date/Time Required: 20/12/2006
Patient Blood Group: O Rh POS	Component: Red Cells
Donation Number: G101 606 597 229 N	
Special Requirements:	
Once transfusion has been started, you must send the completed section below to the Hospital Transfusion Laboratory. This is a legal requirement	
Surname: MACDONALD	Forename: MORAG
Patient Identity No: 100198E	Lab Sample No: 1803905
Donation Number: G101 606 597 229 N	
Component: Red Cells	
Date Given: _____	Time Given: _____
I confirm that the above patient received this blood component Sign and Print Name	

Unique donation number

This is the unique number assigned to each blood donation by the transfusion service and allows follow-up from donor to patient. From April 2001 all donations bear the new 14 digit (ISBT 128) donation number. The unique donation number on the blood bag must match exactly the number on the compatibility label.

Blood group

Shows the blood group of the component
This does not have to be identical with the patient's blood group but must be compatible

Group O patients must receive group O red cells

Expiry date

The expiry date must be checked – do not use any component that is beyond the expiry date

Cautionary notes

This section of the label gives instructions on storage conditions and the checking procedures you are required to undertake when administering a blood component. It also includes information on the component type and volume

RED CELLS IN ADDITIVE SOLUTION
STORE AT 4°C±2°C (SAGM)

INSTRUCTION
Always check patient/component compatibility/identity
Inspect pack for signs of deterioration or damage
Risk of adverse reaction/infection

Special requirements

This shows the special features of the donation, e.g. CMV negative

Figure 7.11 Blood pack labelling.

Procedure guideline 7.23 Blood component administration

Essential equipment

- Written order for blood component transfusion
- Blood administration set with 170–200 µm macroaggregate filter

Pre-procedure

Action	Rationale
1 Check that the component has been correctly 'prescribed', including any special requirements such as irradiated or CMV-negative blood, and if the patient requires any other medications, for example diuretic, premedication.	To prevent incorrect blood component transfused (IBCT) error: ABO incompatibility or non-irradiated CMV-positive products may cause a fatal reaction if transfused (McClelland 2007, E). Negative and positive status should always be written in full and not as + or – as they may get defaced and be incorrectly processed. E
2 Check that the patient's baseline vital signs, temperature, pulse, blood pressure and respirations have been recorded.	To ensure that any transfusion reaction can be immediately identified, due to changes in baseline (E), and managed appropriately (SNBTS 2004, C).
3 Conduct a visual inspection of the component to be used for signs of clumping, discoloration, damage or leaks.	Expired or damaged products must not be used (McClelland 2007, E).
4 If there are any discrepancies at this point do not proceed until they have been resolved.	To ensure an IBCT event does not occur. E
5 Positively identify the patient by asking them to state the following information. (a) First name (b) Surname (c) Date of birth If the patient is unable to positively identify themselves then verification can be given by a carer or relative. This information must match the wristband exactly.	This is the final check of identity which must be performed next to the patient prior to transfusion and is absolutely vital in minimizing the risk of IBCT errors (BCSH 2009, C ; SNBTS 2004, C).
6 Check the details given against the patient's nameband and the patient details on the blood component.	To minimize the risk of error (SNBTS 2004, C).
7 Check that the information on the compatibility label matches the details on the blood component, checking expiry date, unique component donation number, blood group on the component label against the laboratory-produced label. Check special requirements have been met. If there are any interruptions during this checking procedure, the entire process should be restarted from the beginning.	To minimize the risk of error (BCSH 2009, C ; SNBTS 2004, C).
8 If there are any discrepancies at this point do not proceed until they have been resolved.	To ensure an IBCT event does not occur (SHOT 2008, C).

Procedure

9 Prime the set with blood/blood components unless there are concerns about patency of the device, then prime with 0.9% sodium chloride.	Other agents may damage the product components and precipitate transfusion complications (SNBTS 2004, C); for example, dextrose should never be used to prime a set or flush the blood administration set following a transfusion as this can cause haemolysis (SNBTS 2004, C).
10 Set up infusion via a volumetric infusion pump if appropriate. Check the infusion pump and settings prior to use.	To ensure the pump is in working order (BCSH 2009, C). Some older infusion pumps can damage the red cells. Blood administration sets for specific infusion pumps must always be used. If none are available, the standard blood administration set should be used via gravity and the rate monitored as necessary. E
11 Set the desired infusion rate as indicated by the blood component being used and the patient's condition.	The rate of administration is indicated by the patient's clinical condition (SNBTS 2004, C ; Weinstein and Plumer 2007, E) and/or dictated by current guidelines (SNBTS 2004, C).

Either:

Red cell administration can range from 5–10 minutes in acute blood loss to the maximum time of 4 hours (from the time the component is removed from storage) in elderly patients (SNBTS 2004).

Or:

Platelets, fresh frozen plasma and cryoprecipitate should be transfused over 30–60 minutes and must be completed within 4 hours of puncturing the blood component.

- | | |
|---|--|
| 12 Sign the written order 'prescription' as the person administering the component. The unique component donation number, the date and start time should be recorded in the patient's clinical notes. | To ensure that documentation and traceability requirements are met (BCSH 2009, C). |
| 13 Fifteen minutes after the commencement of each component, take and record patient observations – blood pressure, temperature, pulse and respiratory rate. Follow local hospital policy regarding how observations are documented but they should be easily identifiable as being related to the transfusion. | Adverse reactions will often occur during the first 15 minutes of transfusion (Gray and Illingworth 2005, C). Complaints of serious anxiety, transfusion site pain, loin pain, backache, fever, skin flushing or urticaria could be indicative of a serious transfusion reaction (McClelland 2007, E). In such cases the transfusion should be stopped immediately and urgent medical advice sought (SNBTS 2004, C). |
| 14 Observe and monitor the patient throughout the transfusion episode. If there are any concerns, undertake additional observations as appropriate. | To monitor for any adverse reactions (McClelland 2007, E). |
| 15 Record the finish time of each unit. All units must be completed within 4 hours of removal from storage. | Continuation of a transfusion beyond 4 hours increases the risk of transfusion reaction and complications (BCSH 2009, C). |
| 16 Take and record the patient's observations on completion of each unit, ensuring that post-transfusion observations are performed within 60 minutes of completion of the unit. | To ensure the patient's progress is recorded and acts as a baseline for subsequent units (BCSH 2009, C). |

Post-procedure

- | | |
|--|---|
| 17 Record the time the transfusion finished and the volume of the component transfused on the patient's fluid balance chart. | To ensure an accurate record of fluid is maintained as fluid balance monitoring can identify fluid overload in at-risk patients (Weinstein and Plumer 2007, E). |
| 18 Carefully file all transfusion documentation in the patient's clinical record. In line with local policy, return information on the final fate of each blood component to the hospital transfusion laboratory. | To ensure the transfusion episode has been recorded, maintaining the clinical record for patient safety. To comply with Statutory Instrument No. 50, (Blood Safety and Quality Regulations 2005, C), where the final fate of all blood components must be held for a duration of 30 years. |
| 19 Return any unused blood components to the laboratory promptly. | To allow unused components to be reallocated if returned in time. Refer to local guidelines. E |
| 20 If there is any suspicion of a transfusion reaction then the pack should be returned to the transfusion laboratory with full clinical details. If the transfusion is completed uneventfully then the empty pack and administration set should be disposed of according to local policy. | To ensure transfused bags are available in the event of incident investigation (SNBTS 2004, C). Previously it was advocated that empty packs be kept for a period of 48 hours to aid the investigation of severe post-transfusion reactions. The benefits of this are unproven and it is associated with both practical and health and safety concerns (BCSH 2009). |
| 21 For patients receiving ongoing transfusion support, the blood administration set should be changed at least every 12 hours, or after every second unit transfused. Dispose of used set in clinical waste: refer to local guidelines/protocols. | To minimize risk from bacterial contamination (BCSH 2009, C ; McClelland 2007, E ; SNBTS 2004, E). |

Problem-solving table 7.8 Prevention and resolution (Procedure guidelines 7.20, 7.21, 7.22 and 7.23)

Problem	Cause	Prevention	Resolution
Unable to collect patient information.	Unknown unconscious patient.	Do not transfuse unless clinically essential. In a major haemorrhage or emergency situation, give O-negative red cells until the patient is allocated a unique hospital number.	Assign unique hospital identification number to all requests and samples.
	Major incident.	Do not transfuse unless clinically essential. As above if transfusion is essential.	Use unique major incident identification number for all requests and samples. The transfusion laboratory also needs patient gender, minimum identification 'unknown male/female' and patient incident or hospital number. Follow local policy for major incidents.

(continued)

Problem-solving table 7.8 Prevention and resolution (Procedure guidelines 7.20, 7.21, 7.22 and 7.23) (*continued*)

Problem	Cause	Prevention	Resolution
	Patient unable to communicate verbally.	Follow hospital policy for identification of patients unable to confirm identity verbally. Consider the introduction of photo identification card. Ensure interpreting services are available if appropriate.	Confirm identity with a relative or second member of staff (SNBTS 2004).
318 Patient does not have a nameband.	Nameband has been removed or is no longer legible.	Always follow local policy and never use secondary identifiers such as bed numbers, notes or request forms that the patient may be carrying (Murphy 2009). If a member of staff removes a patient's identification band, they are then responsible for ensuring that it is replaced.	All inpatients are required to wear a nameband; therefore, replace nameband and reconfirm identity (NPSA 2005).
	Patient is in an outpatient setting.	Follow hospital policy for the identification of patients.	Ensure patient has a correctly completed identification wristband prior to commencing a transfusion.
Unable to obtain verbal confirmation.	Patient unconscious.	Ensure hospital policy for the identification of unconscious patients is followed.	Confirm identity with a relative or second member of staff or use unique patient identifier.
Patient unable to communicate verbally.	Due to disease or language barrier.	Follow hospital policy for the identification of patients unable to confirm their identity verbally. Consider the introduction of photo identification cards. Ensure interpreting services are available if appropriate.	Confirm identity with a relative or second member of staff (SNBTS 2004). Always follow local policy and never use secondary identifiers such as bed numbers, notes or request forms that the patient may be carrying (Murphy 2009).
Infusion slows or stops.	Venous spasm due to cold infusion.	Apply a heat pad prior to the transfusion to reduce venous spasm.	Apply warm compress to dilate the vein and increase the blood flow.
	Occlusion.	Check patency prior to administration. Always use a pulsatile flush ending with a positive pressure flush.	Flush gently with 0.9% sodium chloride and resume infusion. If occlusion persists, consider resiting cannula. For a central venous access device occlusion, see Chapter 14: Vascular access devices: insertion and management.
Elevation in temperature of less than 2.0°C after commencing a unit of blood with no other symptoms. Temperature falls if the blood is slowed/stopped.	Febrile non-haemolytic transfusion reaction.	Take history to identify whether patient has had a reaction previously.	Observe the patient's temperature, pulse and blood pressure during the transfusion as indicated. If patient has no other signs and symptoms, give paracetamol and continue the transfusion at a slower rate and observe more frequently (Norfolk 2013).

Post-procedural considerations

Immediate care

The patient should be asked to inform a member of staff of any symptoms which may indicate a transfusion-related adverse event, such as feeling anxious, rigors (shivering), flushing, pain or shortness of breath. The patient should be cared for where they can be visually observed and should be shown how to use the nurse call system. The patient should have vital signs monitored as indicated in the Procedure guidelines: however, it may be necessary to take additional observations if clinically indicated, such as if the patient complains of feeling unwell or they develop signs

of a transfusion reaction (Gray and Illingworth 2005). Guidance for the initial recognition of transfusion reactions is provided in Table 7.13.

Many drugs may cause a pyretic hypersensitivity reaction (BNF 2014). There is at present insufficient evidence to allow guidance on the co-administration of drugs with red blood cell transfusion. A lack of clinical reporting of reactions in patients cannot be taken to indicate safe practice: adverse reactions may be attributed to other causes, subclinical haemolysis or agglutination may occur undetected and serious adverse effects may be masked by pre-existing illness in the patient (Murdock et al. 2009).

Table 7.13 Recognition of transfusion reactions

Symptoms/signs	Mild	Moderate	Severe
Temperature	Temperature of $\geq 38^{\circ}\text{C}$ AND rise of $1\text{--}2^{\circ}\text{C}$ from baseline temperature	Temperature of $\geq 39^{\circ}\text{C}$ OR a rise of $\geq 2^{\circ}\text{C}$ from baseline temperature	Sustained febrile symptoms or any new, unexplained pyrexia in addition to clinical signs
Rigors/shaking	None	Mild chills	Obvious shaking/rigors
Pulse	Minimal or no change from baseline	Rise in heart rate from baseline of 10 bpm or more NOT associated with bleeding	Rise in heart rate from baseline of 20 bpm or more NOT associated with bleeding
Respirations	Minimal or no change from baseline	Rise in respiratory rate from baseline of 10 or more	Rise in respiratory rate from baseline of 10 or more accompanied by dyspnoea/wheeze
Blood pressure (hypo/hypertension)	Minor or no change to systolic or diastolic pressure	Change in systolic or diastolic pressure of ≥ 30 mm/Hg NOT associated with bleeding	Change in systolic or diastolic pressure of ≥ 30 mm/Hg NOT associated with bleeding
Skin	No change	Facial flushing, rash Urticaria, pruritus	Rash, urticaria and periorbital oedema Conjunctivitis
Pain	None	General discomfort or myalgia Pain at drip site	Acute pain in chest, abdomen, back
Urine	Clear Normal output		Haematuria/haemoglobinuria Oliguria, anuria
Bleeding	No new bleeding		Uncontrolled oozing
Nausea	None		Nausea or vomiting
All Green	STOP the transfusion but leave connected. Recheck identity of the unit with the patient, inform doctor. If all well, continue at reduced rate for the next 30 minutes and then resume at prescribed rate. Continue to monitor the patient carefully and be alert for other symptoms or signs of a transfusion reaction. Antipyretics may be required.		
1 or more Amber	STOP the transfusion but leave connected, request urgent clinical review, recheck identity of the unit with the patient, give IV fluids. If symptoms stable or improving over next 15 minutes, consider restarting the unit. Antihistamines and/or antipyretics may be required.		
1 or more Red	STOP the transfusion and disconnect, request immediate clinical review, recheck identity of the unit with the patient, give IV fluids, inform the transfusion laboratory, contact the consultant haematologist.		

Note: in all cases where a transfusion reaction is suspected and the transfusion is stopped and disconnected, the implicated unit, complete with giving set, must be returned to the laboratory for further investigation.

Follow your local transfusion policy and contact the transfusion laboratory for further instructions.

Source: Produced by Wales Transfusion Practitioner Group, V2: WBS BBT Team Oct 2012. Based on SHOT (2011b), UK Blood Services (2007) and BCSH Blood Transfusion Task Force (2012d).

Ongoing care

On completion of a blood transfusion episode, observations to include blood pressure, temperature, pulse and respiratory rate should be taken and recorded. The patient's records should be updated to confirm that the transfusion has taken place, including the volume transfused, whether the transfusion achieved the desired effect (either post-transfusion increment rates or an improvement in the patient's symptoms) and the details of any reactions to the transfusion. If intravenous fluids are prescribed to follow the transfusion, these should be administered through a new administration set appropriate for that infusion. The traceability documentation confirming the fate of the component should be returned to the laboratory (Blood Safety and Quality Regulations 2005).

The SHOT report (2008) emphasizes that, on occasion, transfusion reactions can occur many hours and sometimes days after the transfusion is completed. Therefore, for patients receiving a transfusion as a day case, it is important to ensure that they are counselled on the possibility of later adverse reactions and that they have access to clinical advice at all times. The BCSH

recommends that day-case and short-stay patients are issued with a contact card facilitating 24-hour access to appropriate clinical advice, similar to the scheme used for patients receiving chemotherapy treatments on an outpatient basis (BCSH 2009).

Complications

Transfusion-associated graft-versus-host disease

Although rare, transfusion-associated graft-versus-host disease (TA-GVHD) is a serious complication and is often fatal. TA-GVHD is usually caused by an IBCT incident where non-irradiated blood components containing immunocompetent T lymphocytes are given to severely immunocompromised recipients. The donor T lymphocytes engraft and multiply, reacting against the recipient's 'foreign' tissue, causing a graft-versus-host reaction (Davies and Williamson 1998). Onset occurs 1–2 weeks after transfusion (maximum 30 days) and the condition is predominantly fatal (Norfolk 2013). Irradiation (25 gray) of blood and cellular blood components (not required for non-cellular components such as fresh frozen plasma and cryoprecipitate), to

inactivate T lymphocytes (McClelland 2007), is essential in the prevention of TA-GVHD and is especially important in the following recipients:

- fetuses receiving intrauterine transfusions
- patients undergoing or who have undergone blood or bone marrow progenitor cell transplantation
- immunocompromised recipients
- patients with Hodgkin's lymphoma
- patients who have received purine analogues such as fludarabine.

320

The drugs that require the patient to receive irradiated blood components is currently under review and further advice and updates will be published by the BCSH (2012b). At present, the guidelines are being reviewed for patients receiving T cell-depleted agents such as alemtuzumab for non-haematological indications but, while this review is under way, the BCSH recommends that these patients receive irradiated blood components (BCSH 2012b).

Bacterial infections

Contamination of blood and blood components can occur during donation, collection, processing, storage and administration. Despite strict guidelines and procedures, the risk of contamination remains. Most common contaminating organisms are skin contaminants such as staphylococci, diphtheroids and micrococci, which enter the blood at the time of venesection (Barbara and Contreras 2009, Provan et al. 2009). Bacterial contamination can lead to severe septic reaction. Two strategies have been implemented by NHSBT to reduce bacterial infections. First, donor arm disinfection and the diversion of the first 30 mL of each donation to reduce contamination of the blood component by the skin plug from venepuncture. Since 1996, 40 bacterial infections have been reported to SHOT, 33 of these related to platelet transfusions (SHOT 2011a). NHSBT implemented bacterial screening in January 2011, and aerobic and anaerobic cultures are performed on each platelet collection (NHSBT 2011).

Viral infections

Viruses transmissible via blood transfusions can be either plasma borne or cell associated (Barbara and Contreras 2009, Williamson et al. 1999). Plasma-borne viruses include hepatitis B, hepatitis C, hepatitis A (rarely), serum parvovirus B19, and human immunodeficiency viruses (HIV-1 and HIV-2). Cell-associated viruses include CMV, Epstein-Barr virus, human T cell leukaemia/lymphoma viruses (HTLV-1/HTLV-2) and HIV-1/HIV-2.

Human T cell leukaemia/lymphoma virus type 1

Human T cell leukaemia/lymphoma virus type 1 is an oncogenic retrovirus, associated with the white cells that cause adult T cell leukaemia, and is connected with several degenerative neuromuscular syndromes. The enzyme-linked immunosorbent assay (ELISA) has been recommended because of concerns relating to the transmission of the virus via blood transfusion, and the associated long incubation period of adult T cell leukaemia. In the UK all blood is tested for HTLV (JPAC 2013).

Cytomegalovirus

Cytomegalovirus is classified as part of the herpes family and hence has the ability to establish latent infection with reactivation during periods of immunosuppression (Barbara and Contreras 1998, Louis and Heslop 2009). Approximately 50% of the UK population has antibodies to CMV. Therefore it is recognized that the virus may be transmitted by transfusion. Although it poses little threat to immunologically competent recipients, CMV infection in vulnerable patient groups can cause significant morbidity and mortality. For example, CMV pneumonitis carries an 85% mortality rate in blood and bone marrow transplant recipients (Mollison et al. 1997). In March 2012 the Advisory Committee on the Safety of Blood, Tissues and Organs issued a position statement

with guidance that the leucodepletion of blood components 'provides a significant degree of CMV risk reduction'. This risk reduction is considered adequate protection against transmission of CMV to the majority of patients including haemopoietic stem cell transplant patients. The patient groups that they recommend still require stipulation of CMV-seronegative components are intrauterine transfusions, neonates and elective transfusion during pregnancy (SaBTO 2011).

Hepatitis B virus (HBV)

Screening for hepatitis B is by nucleic acid testing (HBV NAT) (Joint UKBTS/NIBSC Professional Advisory Committee 2013). There are now more than 326,000 people in the UK with chronic hepatitis B and, allowing for factors such as under-reporting, the figure may be even higher (Hepatitis B Foundation UK 2013).

Hepatitis C virus (HCV)

Screening for hepatitis C is by nucleic acid testing (HCV NAT) (Joint UKBTS/NIBSC Professional Advisory Committee 2013). Hepatitis C is transmitted primarily via contact with blood or blood products (Friedman 2001).

Human immunodeficiency virus (HIV-1 and HIV-2)

The human immunodeficiency virus is a retrovirus that infects and kills helper T cells, also known as CD4-positive lymphocytes. The virus can be transmitted via most blood products including red cells, platelets, FFP, and factor VIII and IX concentrates. These viruses are not known to be transmitted in albumin, immunoglobulins or antithrombin III products (Barbara and Contreras 2009). The retrovirus invades cells and slowly destroys the immune system, rendering the individual susceptible to opportunistic infections. Since 1983, when it was recognized that the virus could be transmitted via transfusion, actions have been developed to safeguard blood supplies from transmitting the virus that causes acquired immune deficiency syndrome (AIDS). These include the careful screening of donors and the testing of donated blood.

Other infective agents

Parasites

Plasmodium falciparum is the most dangerous of the human malarial parasites (Barbara and Contreras 2009). Prevention is maintained by questioning donors about foreign travel, in particular those who have visited areas where the disease is prevalent (Bishop 2008).

Prion diseases

Known as transmissible spongiform encephalopathies (TSEs), these are a rare group of conditions which cause progressive neurodegeneration in humans and some animal species (Box 7.5). Prion diseases are believed to be caused by the presence of an abnormal form of a cellular protein (Aguzzi and Collinge 1997, Barbara and Contreras 2009, Vamvakas 1999). These abnormal

Box 7.5 Prion diseases

Prion diseases in animal species

- Scrapie, a disease of sheep.
- Bovine spongiform encephalopathy (BSE).
- Feline spongiform encephalopathy (FSE).
- Chronic wasting disease of deer, mule and elk.

Prion diseases in humans

- Sporadic: classic Creutzfeldt-Jakob disease (CJD).
- Inherited: CJD, Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia (FFI).
- Acquired: kuru, vCJD.

proteins have an altered cellular shape, and become infectious and multiply by converting normal cellular protein to the irregular form. This irregular form is resistant to digestion and breakdown and, once accumulation occurs, can result in the formation of plaque in brain tissue. Transmission is thought to be by direct contact with infected brain or lymphoreticular tissue (Aguzzi and Collinge 1997, Barbara and Contreras 2009, Vamvakas 1999).

There is evidence to suggest that in TSEs, of which vCJD is one, leucocytes, particularly lymphocytes, are the key cells in transportation of the putative infectious agent to the brain (Aguzzi and Collinge 1997, Bradley 1999). There were a total of 163 deaths in cases of definite or probable vCJD in the UK up to 31 December 2007. A further three probable cases were alive on 31 December 2007. Analysis of the incidence of vCJD onsets and deaths from January 1994 to December 2007 indicates that a peak has passed. While this is an encouraging finding, the incidence of vCJD may increase again, particularly if different genetic subgroups with longer incubation periods exist (National CJD Surveillance Unit 2008).

In many developed countries, blood undergoes universal leucodepletion for a number of reasons: to reduce the risk of transmission of vCJD, to remove leucocyte-associated viruses such as CMV and to reduce other complications of transfusions related to white cell content (Contreras and Navarrete 2009).

Sepsis

Sepsis occurs when bacteria enter the blood or blood component that is to be infused. Bacteria can enter at any point from the time of collection, during storage through to administration to the patient. Organisms implicated in transfusion-related sepsis include Gram-negative *Pseudomonas*, *Yersinia* and *Flavobacterium* (Provan et al. 2009). Septic reactions usually present with a fever, tachycardia and/or hypotension, and can lead rapidly to systemic inflammatory response syndrome (SIRS) (Porth 2005). This is a serious life-threatening condition, sometimes referred to as septic shock, and requires urgent medical attention.

Transfusion-related acute lung injury (TRALI)

Transfusion-related acute lung injury is most frequently associated with plasma-rich products such as platelets and FFP (Federico 2009). TRALI is usually caused by antileucocyte antibodies reacting against donor leucocytes. In nearly 90% of cases, either HLA or neutrophil-specific antibodies were detected in the donors and most of the donors were multiparous women. The corresponding antigen in the recipient was also found to be important (Chapman et al. 2009). The antigen/antibody reaction can result in 'leucoagglutination'. Leucoagglutinins can in turn become trapped in the pulmonary microvasculature, causing severe respiratory distress without evidence of circulatory overload or cardiac failure (Contreras and Navarrete 2009).

Transfusion-related acute lung injury is defined as dyspnoea with hypoxia and bilateral pulmonary infiltrates during or within 6 hours of transfusion, not due to circulatory overload or other likely causes (Chapman 2009). As the antibodies were mostly found in multiparous women and, as a result of SHOT reports demonstrating that in the majority of cases the donor was female, the National Blood Service developed a strategy to use only the plasma from male donors for FFP and male plasma in pooled platelets (Chapman et al. 2009).

Transfusion-related acute lung injury is usually treated the same as any adult respiratory distress syndrome (ARDS) and therefore patients who develop TRALI may require ventilatory support (SNBTS 2004) and should be treated as an emergency. Diuretics should not be administered as patients are generally hypotensive and hypovolaemic. Although the symptoms resemble ARDS, TRALI is self-limiting and with most patients improving over a 4-day period, without long-term consequences (Federico 2009). As TRALI is donor related, it is essential that cases are reported to the blood transfusion services so that donors can be contacted, investigated for antibodies to HLA

and if necessary removed from the donor panel (McClelland, 2007, Norfolk 2013).

Transfusion-related immunomodulation

The infusion of foreign antigen during a packed red blood cell (PRBC) transfusion induces a non-specific immunosuppression, which is known as transfusion-associated immunomodulation. Allogeneic plasma components, white blood cells, fibrin and accumulators from the storage process have all been implicated (Englesbe et al. 2005).

Urticaria

This uncommon reaction is caused by the recipient reacting to protein in the donor plasma (Davies and Williamson 1998). Urticaria is characterized by localized oedematous plaques, hives and itching and is usually mediated by histamines (Porth 2005). Therefore urticarial reactions usually respond well to antihistamines which should be administered once the patient has been assessed and antihistamine therapy has been prescribed (SNBTS 2004). The infusion can then be recommenced; however, if symptoms return, the infusion should be discontinued.

Transfusion reactions

In November 1996 the Serious Hazards of Transfusion (SHOT) scheme was launched. This voluntary and anonymized reporting scheme collects data from participating hospitals across the UK and Ireland. The purpose of SHOT is to collect data on the serious morbidity related to the transfusion of blood and blood products. These data have since been utilized to inform education programmes, policy development and guideline development, ultimately improving hospital transfusion practice (SNBTS 2004).

Although the Blood Safety and Quality Regulations 2005 have now made the reporting of such events via SABRE mandatory, the SHOT scheme remains active and important and has presented yearly retrospective reports of data collected since its inception. These data demonstrate improved performance in recognizing reporting of transfusion-related incidents and continue to generate key recommendations to improve all transfusion practice (SNBTS 2004). Despite significant improvement in the reduction of risk from transfusion-transmitted infection, human error which results in an IBC – the transfusion of a blood product that is not suitable for or not intended for the recipient – remains the greatest risk to patients (SNBTS 2004). Figures from the 2013 SHOT report confirm 247 cases in this category (Bolton-Maggs et al. 2014).

The prompt management of any adverse transfusion reaction can reduce associated morbidity and can be life saving. Therefore staff caring for patients receiving transfused products must be fully familiar with the immediate management of any suspected reaction. However, specialist advice should always be sought for the diagnosis and ongoing management of transfusion reactions, such as haemolytic, anaphylactic and septic reactions (McClelland 2007, SNBTS 2004).

Minor transfusion reactions

It should always be remembered that the symptoms of a 'minor' transfusion reaction may be the prelude to a major, life-threatening reaction. It is essential that staff take any transfusion reaction seriously. Symptomatic patients should have their vital signs monitored closely and they should be clearly observable. Patients with persistent or deteriorating symptoms should always be managed as a major reaction and urgent medical and specialist support should be sought (McClelland 2007, SNBTS 2004).

Allergic and anaphylactic reactions are more common and more severe with transfusion of FFP and platelets than with red blood cells (Domen and Hoeltge 2003).

Symptoms of minor reactions include a temperature rise of up to 1.5°C, rash without systemic disturbance and moderate tachycardia without hypotension (SNBTS 2004). Such symptoms may be caused by an immunological reaction to components of the

blood product. Whilst it may be possible to manage such symptoms and continue with the transfusion, the following action should always be taken (Contreras and Navarrete 2009).

- Stop the transfusion and inform the responsible medical team.
- Confirm the patient's identity and recheck their details against the product compatibility label.
- Antihistamines should be considered for skin rashes or urticarial itch.
- Antipyretic agents can be considered for mild fever.

322

It may be possible to continue with the transfusion at a reduced rate once the patient's symptoms are controlled; however, it may be necessary to increase the frequency of observations until the transfusion is completed. Some patients who have regular transfusions may experience recurrent febrile reactions and may benefit from an antipyretic premedication. *Note:* aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) are contraindicated in patients with a thrombocytopenia or coagulopathy (BNF 2014).

Major transfusion reactions

Major transfusion reactions include anaphylaxis, haemolysis and sepsis and may present as a fever of $>38.5^{\circ}\text{C}$, tachycardia \pm hypotension. In such circumstances a severe reaction should always be considered and the transfusion should be stopped until a specialist assessment has been conducted (Box 7.6).

Care should be taken when returning the blood product to the laboratory, to ensure that the product does not leak and that no needles remain attached.

Any further products being held locally for the patient should also be returned to the hospital transfusion laboratory for assessment. The events surrounding the reaction should be clearly documented and reported in the following ways.

- Record the adverse event in the patient's clinical record.
- Complete a detailed incident form as per local policy.
- Follow local, regional and national criteria for reporting via SABRE and SHOT.

Acute haemolytic reactions

These are usually directly related to ABO incompatibilities due to an IBCT where antigen/antibody reactions occur when the recipient's antibodies react with surface antigens on the donor red cells.

Box 7.6 Initial management of a suspected transfusion reaction

- Stop the transfusion and seek urgent medical help.
- Initiate appropriate emergency procedures, for example call resuscitation team.
- Depending on venous access, withdraw the contents of the lumen being used and disconnect the blood product.
- Keep venous access patent.
- Confirm the patient's identity and recheck their details against the product compatibility label.
- Keep the patient and relative informed of all progress and reassure as indicated.
- Initiate close and frequent observations of temperature, pulse, blood pressure, fluid balance.
- Inform the transfusion laboratory and seek the urgent advice of the haematologist for further management.
- Return the transfused product to the laboratory with new blood samples (10 mL clotted and 5 mL ethylenediamine tetra-acetic acid (EDTA)) from the patient's opposite arm (SNBTS 2004) with a completed transfusion reaction notification form (if available) or note the patient's details, the nature and timing of the reaction and details of the component transfused.

This reaction causes a cascade of events within the recipient which can present with chills/rigors, facial flushing, pain/oozing at the cannula site, burning along the vein, chest pain, lumbar or flank pain, or shock (Gillespie and Hillyer 2001, McClelland 2007). Patients may express a feeling of anxiety or doom, which may be associated with cytokine activity. Haemolytic shock can occur after only a few millilitres of blood have been infused. Treatment is often vigorous to reverse hypotension, aid adequate renal perfusion and renal flow to reduce potential damage to renal tubules, and appropriate therapy for DIC reactions (Provan et al. 2009). It is important to remember that most acute haemolytic reactions are preventable as they are usually caused by human error when taking or labelling pre-transfusion samples, collecting blood components and/or failing to perform a correct identity check of blood pack and patient at the bedside (McClelland 2007, Norfolk 2013) (Figure 7.12).

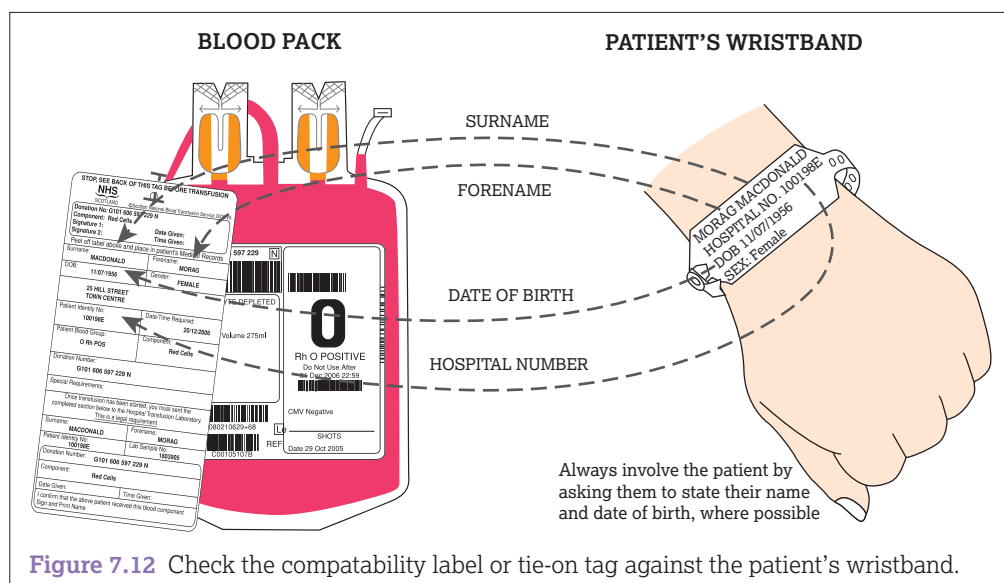

Figure 7.12 Check the compatibility label or tie-on tag against the patient's wristband.

Acute anaphylactic reactions

These are rare and usually occur after only a few millilitres of blood or plasma have been infused (Weinstein and Plumer 2007) and present with bronchial spasm, respiratory distress, abdominal cramps, shock and potential loss of consciousness.

Circulatory overload (transfusion-associated circulatory overload)

Circulatory overload can occur when blood or any of its components are infused rapidly or administered to a patient with an increased plasma volume, causing hypervolaemia. Patients at risk are those with renal or cardiac deficiencies, the young and elderly (Weinstein and Plumer 2007). Patients with signs of cardiac failure should receive their transfusion slowly with diuretic support (McClelland 2007). The need for concomitant drugs such as diuretics should always be assessed before commencing treatment (SNBTS 2004).

Febrile non-haemolytic reactions

These reactions are due to an immunological response to the transfusion of cellular components such as donor leucocytes. Specific patient groups are at risk of greater sensitization to leucocytes, for example, critically ill patients, those receiving anticancer therapies or patients requiring multiple transfusion therapy (Williamson et al. 1999). Such reactions present with a mild fever (up to 2°C from the baseline), rash without systemic disturbance and moderate tachycardia without hypotension (Norfolk 2013, SNBTS 2004).

Hypothermia

Infusing large quantities of cold blood rapidly can cause hypothermia. Patients likely to experience this reaction are those who have suffered massive blood loss due to trauma, haemorrhage, clotting disorders or thrombocytopenia (McClelland 2007). Such reactions present with alteration in vital signs and development of pallor and chills.

Delayed effects

These reactions may occur days, months or even years after transfusion.

Delayed haemolytic reactions

These reactions are caused when immune antibodies react to a foreign antigen. Reactions are classified as primary or secondary. A *primary* reaction is often mild, occurring days or weeks after initial transfusion, and may be indicated by no clinical alteration in haemoglobin following transfusion therapy (Cook 1997a). *Secondary* reactions occur with re-exposure to the same antigen, and on rare occasions may be associated with ABO incompatibilities (Cook 1997a). The patient may present with a fever, mild jaundice and unexplained decrease in haemoglobin value and may require antiglobulin testing (Norfolk 2013).

Hyperkalaemia

Hyperkalaemia is a rare complication associated with trauma and the subsequent infusion of large quantities of blood. Potassium is known to leak out of red cells during storage, thereby increasing circulatory levels in recipients receiving blood products (Cook 1997b). The process is exacerbated if products are kept too long at room temperature or gamma irradiated (Davies and Williamson 1998). From starting the infusion to completion, the infusion should take a maximum of 4 hours (McClelland 2007). The patient may present with irritability, anxiety, abdominal cramps, diarrhoea and weakness in the extremities (Cook 1997b). The patient's medical team should be contacted to assess the patient.

Iron overload

Patients who are dependent on frequent transfusion, such as those with thalassaemic, sickle cell and other transfusion-dependent disorders, can become overloaded with iron (McClelland 2007). A unit of red blood cells contains 250 mg iron, which the body is unable to excrete, and as a result patients receiving large volumes of blood are at risk of iron overload (Davies and Williamson 1998). This can result in poor growth, pigment changes, hepatic cirrhosis, hypoparathyroidism, diabetes, arrhythmia, cardiac failure and death. Chelation therapy through the use of desferrioxamine, which induces iron excretion, minimizes the accumulation of iron (BNF 2014).

- 8.17** Abdominal paracentesis 399
- 8.18** Personal care after death 416

Overview

The aim of this chapter is to present the many varied procedures that contribute towards the comfort of patients at all times. This ranges from the very specific procedures involved in pain management to those that promote comfort from a wider perspective, such as personal hygiene and end-of-life care.

In ensuring patient comfort, it is necessary to consider aspects of any procedure from the pre-planning stage to the return of the patient to their pre-procedure position.

Comfort will mean different things to different patients. It may involve being in a relaxed state of tolerable pain, disappointment or perhaps satisfaction or physical well-being provided by another person. For the nurse, aspects of care to be considered include discussions prior to undertaking the procedure, gaining consent, ensuring pain control and maintaining privacy and dignity, offering mouthcare as well as paying attention to the patient's immediate environment.

For some patients, for instance those with dementia or learning disabilities, addressing the issue of patient comfort may rely on other skills such as observation, non-verbal communication or working closely with family and carers to help identify and meet the patient's needs.

Personal hygiene

Definition

Maintaining levels of good personal hygiene is essential for all patients during their stay in hospital (Massa 2010). Hygiene is the science of health and its maintenance. Personal hygiene is the self-care by which people attend to such functions as

bathing, toileting, general body hygiene and grooming. Hygiene is a highly personal matter determined by individual values and practices. It involves care of the skin, hair, nails, teeth, oral and nasal cavities, eyes, ears, and perianal- and perineal-genital areas (Berman et al. 2010).

Anatomy and physiology

Skin

Being the largest organ of the body, maintaining the skin's integrity is essential to the prevention of infection and the promotion of both physical and psychological health. The skin has several functions.

- Regulation of temperature.
- Physical and immunological protection.
- Excretion and preservation of water balance.
- Sensory perception.
- Communication of feelings.
- Identity, self-perception and body image (Burr and Penzer 2005).

The skin is made up of three layers: epidermis, dermis and deep subcutaneous layer (Figure 8.1).

Epidermis

The epidermis is the outer coating of the skin and contains no blood vessels or nerve endings. The cells on the surface are gradually shed and replaced by new cells which have developed from the deeper layers; this process takes approximately 28 days. The epidermis has hairs, sweat glands and the ducts of sebaceous glands passing through it. It provides an efficient natural barrier (Burr and Penzer 2005).

Figure 8.1 Skin and subcutaneous layer. *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Dermis

The dermis is the thicker layer which contains blood and lymph vessels, nerve fibres, sweat and sebaceous glands. It is made up of white fibrous tissue and yellow elastic fibres which give the skin its toughness and elasticity. It provides the epidermis with structural and nutritional support (Holloway and Jones 2005).

Subcutaneous layer

The subcutaneous layer contains the deep fat cells (areolar and adipose tissue) and provides heat regulation for the body. It is also the support structure for the outer layers of the skin (Tortora and Derrickson 2011). Maintaining skin integrity, through good personal hygiene, will allow this complex system to provide an efficient natural barrier to the external environment.

It is important to remember that the skin is a changing organ, affected by internal and external factors, temperature, air humidity and age (Burr and Penzer 2005). It has great ability to adapt to changes in the environment and stimuli but will be affected by ill health and immobility (McLoughlin 2005). Its integrity, continuity and cleanliness are essential to maintaining its physiological functions.

The ageing process can adversely affect the skin structure. Skin tissue becomes thin and less elastic and resistant to trauma and shearing forces. The blood supply is reduced as cells are replaced more slowly, which adversely affects healing. Transmission of stimuli from sensory receptors slows and can lead to damage. The production of natural oils declines and can lead to dry skin which increases the risk of infection and tissue breakdown (Penzer and Finch 2001). Hence extra care should be taken when washing and drying elderly patients; nursing interventions can protect and restore the skin's natural barrier (Bryant and Rolstad 2001).

Evidence-based approaches

Personal cleanliness is a fundamental value in society. Often, when patients become unwell they depend on nurses to assist them with meeting their personal hygiene needs. When this occurs, it is important that the nurse observes and assesses the patient's needs on an individual basis.

Some patients may have a long-term need for personal care support, such as those with dementia or a severe learning disability; their family and carers will know them best and are best placed to advise you on how best to provide such personal care.

Hygiene is a personal issue and everyone will have their own individual requirements and standards of cleanliness. The nurse should not impose his or her own standards of cleanliness on the patient or even assume that theirs will match those of the patient. Within the assessment, the patient's religious and cultural beliefs should be taken into account and incorporated into care. When the patient has any degree of cognitive impairment, the approach taken to providing any personal care must consider how the patient is likely to experience that care. For example, a patient who has dementia may not know who you are or what you are doing and so may need to be orientated and talked through the process to prevent them from becoming distressed. Personal hygiene is individual to that person and is also based on family influences, peer groups, economic and social factors (Berman et al. 2010).

In Western culture, privacy is of the utmost importance and considered to be a basic human right. In addition, in some religions like Islam, modesty is crucial and can be challenging to manage in the hospital setting (Hollins 2009). Patients may feel a great deal of embarrassment having to depend on another person to help them with an extremely private act. It is therefore surprising that so little reference is made to this in the literature. However, in the clinical situation the best person to discuss this with is the patient, exploring with them how they want their hygiene

needs met and identifying any specific requests they may have related to their culture or religion (Pegram et al. 2007).

Florence Nightingale (1859) first noted the importance of good personal hygiene and the essential role nurses have in maintaining this, to prevent infection and increase well-being. During the delivery of personal hygiene care, the nurse is able to demonstrate a wide range of skills such as assessment, communication, observation and caring for the patient. Within the activity, opportunities may arise for the patient to discuss issues, concerns or fears that they may have regarding admission, treatment, discharge planning or prognosis (Burns and Day 2012). This can be the most significant social interaction of the day for the patient, as the nurse develops a deeper understanding of the patient's personality and needs, providing a personal bond between the nurse and patient (Massa 2010). This relationship offers the nurse an opportunity to encourage the patient to reclaim autonomy and independence within this care need through participation, which can increase patients' feelings of self-worth and dignity.

Delegating personal hygiene to a junior member of the team or a healthcare assistant may mean that vital information about the patients may be missed. It is important that nurses recognize their personal accountability for the care that is provided, but also for delegating care to an appropriate person (RCN 2010). It is crucial that health professionals share their knowledge and any changes identified during procedures; verbal handover and documentation are good tools for this. The world of nursing is ever changing, and there is a risk that activities such as attending to the personal hygiene of patients may become devalued or just another routine (Castledine 2005, Voegeli 2008). The literature supports the enhanced quality of care for patients, when hygiene needs are attended to by qualified/experienced practitioners. Personal hygiene is considered part of the essence of care that nurses should never treat as ritualistic.

Principles of care

Skin care is particularly important to prevent the colonization of Gram-positive and -negative micro-organisms on the skin, which lead to healthcare-associated infection (Parker 2004). By implementing simple personal hygiene measures, the risk of infection can be reduced.

An initial assessment of the skin using observational skills is essential to ascertain the skin's general condition, colour, texture, smell and temperature (Penzer and Finch 2001). Factors that may influence the appearance of the skin are as follows.

- *Nutritional and hydration state:* imbalances will cause loss of elasticity and drying of the skin. Oedema will cause stretching and thinning of the skin (Potter and Griffin Perry 2003).
- *Incontinence:* the presence of urine and/or faeces on the skin increases the normal pH of 4.0–5.5 and makes the skin wet, which increases the risk of tissue breakdown and infection (Ersner et al. 2005).
- *Age, health and mobility status:* for example, the presence of pressure ulcers (Smoker 1999, Stockton and Flynn 2009).
- *Treatment therapies:* for example, radiotherapy (skin may become moist and cracked), chemotherapy (some cytotoxic agents such as methotrexate can cause erythematous rashes), and continuous infusions of 5-fluorouracil (5-FU) can cause a condition called palmar-plantar erythrodysesthesia syndrome, which presents with cracking and epidermal sloughing of the palms and soles (Lokich and Moore 1984). A low platelet count can lead to an increased risk of bruising and a decrease in the white blood cells can influence the rate of healing. Steroids may cause the skin to become papery and fragile.
- *Any concurrent conditions:* for example, eczema, psoriasis, diabetes or stress, can affect the ability of skin to maintain its integrity (Holloway and Jones 2005).

Box 8.1 lists the specific considerations for skin care.

Box 8.1 Specific considerations for skin care

- **Frail and papery skin** should prompt the nurse to take extra care in the bathing process. Patients need to be involved in writing their care plans, ensuring that correct and/or preferred lotions are used; this will maintain the integrity of the skin and prevent the skin from being compromised.
- **Areas of red skin.** If redness is noted, wound prevention measures need to be implemented to prevent sores and ulcers from developing. These include good pressure-relieving positioning and repositioning and the use of barrier products in the form of creams, ointments and films (Joseph and Clifton 2013).
- **Open wounds.** When open wounds are present, such as pressure ulcers, abrasions or cuts, preventive measures such as pressure-relieving mattresses should be used to prevent further breakdown (Philips and Buttery 2009) and dressings such as hydrocolloids used where appropriate to promote wound healing (Bouza et al. 2005).
- **Intravenous devices and drains.** Frequently, patients have intravenous devices and wound drains inserted as part of their therapy and these should be handled with care to prevent the introduction of infection or the 'pulling' of the tubes.

Methods of perineal/perianal care

Meticulous care with the perineal/perianal areas is vital, especially for those people who may be prone to infection. Problems can arise from treatment modalities; radiotherapy, for example, can cause fistulas, diarrhoea, constipation and urinary tract infections. Vigilance with cleanliness can prevent some of these problems or reduce their severity. Whenever possible, patients should be encouraged and assisted to perform this care themselves (Downey and Lloyd 2008). If a nurse is performing the care of this area, it is important that informed consent is sought, where possible, and privacy maintained as the patient may be embarrassed or humiliated. Nurse and patient should discuss this procedure together, ensuring that the patient gives agreement to care (NMC 2013).

Ideally, perineal hygiene should be attended to after the general bath or, at the very least, the water and wipes should be changed and cleaned once utilized due to the large colonies of bacteria that tend to live in or around this area (Gooch 1989, Gould 1994). It is generally acknowledged that soap and lotions administered incorrectly to the perineum/perianal area can cause irritation and infection (Ersser et al. 2005, Holloway and Jones 2005).

Methods of hair care

The way a person feels is often related to their appearance, and hair condition and style are usually pertinent to this. Hair care can be complex and so it should be planned and carried out according to the patient's personal preferences.

Washing the hair of a bed-bound patient can be challenging, but there are several ways to manage this as follows.

- Using a special bed tray water aid.
- Using an inflatable shampoo basin.
- Using a dry or no rinse shampoo.
- Using a no rinse shampoo cap (Schiff 2001).

The patient's condition must always be assessed before performing this task as it would not be appropriate for patients with head and neck or spinal injuries. Shampooing frequency depends on the patient's well-being and their hair condition. Referral to a hairdresser may be appropriate.

Grooming the hair provides an ideal opportunity to observe for dandruff, psoriasis, flaky skin and head lice. Head lice are extremely infectious so it is imperative to treat the hair with a

medicated shampoo as soon as possible. Hospital policy/protocol should be followed regarding the disposal of infected linen. Towel drying of hair should occur and hairdryers can be used with the consent of the patient (NMC 2013). However, use of a hairdryer may not be appropriate if the patient has had recent alopecia (loss of hair). Hairdryers should be checked for safety in accordance with local policy. Care of the beard and moustache is also important. Excess food can often become lodged here so regular grooming is essential for hygiene and comfort purposes. Beard trimmers can be used as appropriate.

Methods for care of the nails and feet

The feet and nails require special care in order to avoid pain and infection. Poor toe nail condition can affect mobility and compromise independence which can increase length of hospital stay (Dingwall 2010). Finger and toe nails should be kept short and neat; nail clippers are recommended for the trimming of nails and emery boards for filing to prevent jagged edges (Malkin and Berridge 2009). Patients with visual impairment or dexterity problems and those with learning disabilities may require assistance with the trimming and filing of nails. Note that in many healthcare settings, toe nail trimming requires a chiropodist or is contraindicated for patients with diabetes, toe infections or peripheral vascular disease, unless performed by a podiatrist (Malkin and Berridge 2009).

Special attention should be paid to cleaning the feet and in between the toes to avoid any fungal infection (Geraghty 2005). Fungal infections of the skin can be subdivided into two distinct categories: dermatophytes (moulds) and *Candida* (yeasts). A fungal infection occurs where moulds or yeasts begin to live on the keratin of the host individual. This can include the keratin of the nail plate, leading to onychomycosis (fungal nail infection). The term 'athlete's foot', caused by poor foot hygiene associated with excess sweating, infrequent changes of shoes and ineffective washing, is a common misnomer for a fungal foot infection. However, it is a precursor to infection as it provides the ideal environment for dermatophytes and yeasts. In general, fungal infections present as red, itchy, dry and flaky areas of skin and, depending on location, there may also be associated maceration and fissuring. Onychomycosis presents as thickened, discoloured nails which are also crumbly, elevated from the nail bed and malodorous (Roberts and Holdich 2012). Powders and creams are available that help with the treatment of infections and odour management, for example miconazole nitrate 2% for fungal infections (BNF 2014).

Diabetic footcare

Chronic diseases such as diabetes and the long-term use of steroids can result in problems such as pressure ulcers, breakdown of skin integrity and delays in healing.

A patient's whole body is affected by diabetes but in particular, this chronic disease can cause foot complications. Damage to the nerves and blood supply to the feet causes lack of sensation and ischaemia. These problems can lead to diabetic foot ulceration which, if left untreated, can result in amputation or even death (Holt 2013).

The Diabetes UK (2012) campaign 'Putting Feet First' highlights the increasing number of amputations caused by diabetes and calls for better awareness and improved standards of care for people with the disease. The importance of recognizing and acting on a diabetic foot ulcer cannot be overestimated. For nurses, it is not a case of having to know everything, but rather knowing who to call and when that can make the difference (Moakes 2012).

Guidelines published by the National Institute for Health and Clinical Excellence (NICE 2004) require that all people with diabetes should have an annual foot examination. As a minimum, this should include:

- testing of foot sensation using a 10 g monofilament or vibration test. Without the patient looking, pressure from a monofilament

or vibration fork is applied to at least five different areas on the sole of the foot. Decreased sensation at any of the sites tested could be an indication of neuropathy

- palpation of foot pulses
- inspection of any foot deformity and footwear.

Based on the findings of the foot examination, the person would then be classified as low risk, increased risk, high risk or ulcerated foot (Table 8.1). By having this information, patients can be given the appropriate care and screening to avoid any acute diabetic foot episodes (Holt 2013).

When a patient with diabetes has a foot with complications such as sensory neuropathy and poor blood supply, it can be easily damaged. Even a small graze or bruise can cause a foot ulcer to develop. Some causes of foot ulceration are:

- animal scratches
- corn/verruca treatment containing salicylic acid
- footwear
- foreign body in shoe
- hot water bottle used in bed
- ill-fitting hosiery, for example, sock seams
- elastic on stockings
- resting feet on or near a heater or radiator
- scald from bath water (Moakes 2012).

The formation of a foot ulcer is multifactorial. The underlying features of diabetes predispose the person to ulceration. Any altered sensation in the foot may impair recognition of injury to the skin, particularly in individuals who are unable to cut their toe nails adequately, and a mycotic nail may damage the skin of an adjacent toe or the nail bed of the affected toe leading to subungual ulceration. Older people with diabetes may suffer from age-related changes to vision which makes nail care more difficult; bending

down to carry out self-checks of the foot may be hampered by reduced mobility, being overweight and loss of dexterity (Roberts and Holdich 2012). Some risk factors for diabetic foot ulcers are as follows.

- Build-up of callus.
- Foot deformity.
- Peripheral arterial disease.
- Peripheral neuropathy.
- Previous amputation.
- Previous ulceration.
- Problems with vision and/or mobility (Drury and Gatling 2005).

Daily foot care checks should be undertaken either by the person with diabetes or a relative/carer and are as follows.

- Check top of foot, bottom of foot, tips of toes, between toes and back of heels.
- Be aware of fragile skin, especially in those who are very old, and of pressure areas if the person is spending a lot of time in one position, for example, in bed or seated.
- Check for pain, but remember absence of pain in those with neuropathy does not mean that all is well.
- Check for foreign bodies in shoes, slippers or sandals.
- Apply emollient all over feet but not in between toes because this may predispose to fungal infection as this is already a moist and warm area.
- Refer for specialist help if needed (Moakes 2012).

When the patient is in a healthcare setting, these checks can be undertaken by a competent healthcare professional. By performing these checks and by touching the feet when applying emollient, problems are much more likely to be detected and treated promptly.

Methods for care of the ears and nose

Lack of attention to cleaning the ears and nose can lead to impairment of the senses. Usually these small organs require minimal care but observation for a build-up of wax in the ears and deposits in the nose is essential to maintain patency. The outer ear can be cleaned with cotton wool or gauze and warm water (Alexander et al. 2007).

Patients undergoing enteral feeding and/or oxygen therapy should have regular nasal care to avoid excessive drying, excoriation of the delicate air passages and skin breakdown. Gentle cleaning of the nasal mucosa with cotton wool/gauze and water is recommended. Coating the area with a thin water-based lubricant to prevent discomfort can be beneficial, but petroleum jelly is not recommended as a nasal skin barrier when oxygen therapy is in progress as it is highly flammable. These interventions will remove debris and maintain a moist environment (Geraghty 2005).

Patients who have piercing to the ears or nose will require cleaning of the holes to avoid the risk of infection. Gently cleaning around the pierced area with cotton wool/gauze and warm water and then towel drying is recommended. Observe for inflammation or oozing; if this occurs, inform the patient and doctor and seek permission from the patient to remove the device.

Pre-procedural considerations

Non-pharmacological support

Soap

Persistent use of some soaps can alter the pH of the skin and remove the natural oils, leading to drying and cracking (Bryant and Rolstad 2001, Smoker 1999), creating an ideal environment for bacteria to multiply (Holloway and Jones 2005). According to Ersser et al. (2005), patients with dry skin have a 2.5-fold greater likelihood of skin breakdown. Care should be taken with skinfolds

Table 8.1 Level of risk for developing foot ulcers

Risk level	Nursing action
Low risk Normal circulation, pulses palpable, normal sensation (feeling in the feet)	Plan care with patient Education and advice in maintaining foot health Assess foot health as part of daily care
Increased risk Evidence of neuropathy, poor or absent pulses	Refer to footcare team or podiatrist Evaluate footwear Offer advice on footcare Assess foot health as part of daily care
High risk Evidence of neuropathy, absent pulses, skin changes, history of previous ulcers	Refer to footcare team or podiatrist Evaluate footwear Assess foot health as part of daily care Perform footcare as part of daily care
Foot ulcerated	Refer to specialist as an emergency and follow planned care accordingly Evaluate and reassess the ulcer on a daily basis

Source: Adapted from NICE (2008).

and crevices, paying particular attention to thorough drying of the areas and observing for any breaks in the skin. It is recommended that the skin is patted and not rubbed, to reduce damage caused by friction (Ersser et al. 2005).

Emollient therapy

Current evidence recommends a move away from traditional washing using soap and water, and recent research demonstrates that surfactants found in soap are irritant to the skin (Voegeli 2008). Penzer and Finch (2001) and Burr and Penzer (2005) recommend the use of emollient therapy for washing and moisturizing to seal the skin. In a literature review of hygiene practices, the use of soap and water remained common practice but several studies suggest that skin cleansers, for example emollient creams, followed by moisturizing may be less likely to disrupt the skin barrier and have a therapeutic benefit (Ersser et al. 2005). These products allow the patient to have a more active role in their own care, as the products can be left within reach and the patient can initiate the activity without the need to access running water (Collins and Hampton 2003).

Washbowls

Conventional plastic washbowls can harbour bacteria and fungi if they are not cleaned and dried effectively. Research indicates that reusable washbowls, washcloths and water can all pose a serious risk of cross-infection (Johnson et al. 2009, Marchaim et al. 2011). Johnson et al. (2009) also highlight that inadequate storage of reusable washbowls can contribute to the presence of microbial biofilms and place patients at risk of cross-infection. A 2007 study at Salford Royal Hospital showed that when a disposable washbowl was introduced alongside other measures, it helped to reduce the number of cases of *C. difficile* infection by 56% over a 5-month period (Power et al. 2010). Many organizations now utilize single-use maceratable pulp washbowls.

Prepackaged cloths

Bacteria exist in hospital water supplies and hospital staff can transmit bacteria both into and via water. In addition, reusable washcloths can spread harmful bacteria when they are transferred to the basin and returned to the patient. Due to the risk of transmission of *Pseudomonas aeruginosa*, the DH (2013b) suggests that organizations should consider utilizing single-use wipes when patients are being cared for in augmented specialized care areas, such as:

- those who are severely immunosuppressed because of disease or treatment
- those cared for in units where organ support is necessary, e.g. critical care
- those who have extensive breaches in their dermal integrity and require contact with water as part of their continuing care, e.g. burns units.

Prepackaged cloths impregnated with cleanser and moisturizers are a cost-effective and evidence-based alternative to soap and water (Larson et al. 2004, Sheppard and Brenner 2000). These wipes are designed for single use straight from the packet and the cleansers and emollients delivered via the wipe are formulated to nourish and hydrate the skin without the need for rinsing and drying after use. To enhance patient comfort, the wipes can be warmed before use. Warming must take place in a dedicated heating unit. A specially designed warming cabinet is available which stores multiple packets at the correct temperature to ensure they are ready for use straight from the warmer (Massa 2010).

Cultural and religious factors

The nurse must respect and consider the patient's cultural and religious factors, while maintaining privacy and dignity at all

Box 8.2 Religion-specific considerations related to personal hygiene

- Those following *Islam* must perform ablution (*wudhu*, to use the Islamic term) before the daily prayer, which is the formal washing of the face, hands and forearms, and so on. One of the criteria for cleanliness is washing after the use of the lavatory. Any traces of urine or faeces must be eliminated by washing with running water, at least. If a bedpan or commode is used, fresh water must be provided for cleansing. The use of toilet tissues for cleaning is not sufficient. With such emphasis on washing and personal hygiene, adhering to the practical teaching of Islam on washing would enhance personal hygiene for the individual and therefore reduce the chance of disease and sickness individually and subsequently for the whole society.
- *Hindus* also place importance on washing before prayer; they believe the left hand should dominate in this process and therefore do not eat with the left hand as it is deemed unclean.
- *Sikhs* place great importance on not shaving or cutting hair, choosing to comb their hair twice a day and washing it regularly. Male Sikhs wear their hair underneath a turban as a sign of respect for God.

times; for example, some people prefer to sit under running water rather than sitting in a bath (Hollins 2009). Some religions do not allow hair washing or brushing, while others may require the hair to be covered by a turban. Similarly, in some countries facial hair is significant and should never be removed without the patient's/relatives' consent. Always establish any preferences before beginning care (Hollins 2009) (Box 8.2).

Clothing

Effort should be made to encourage and empower patients to dress in their own clothing during the day, where possible, and in their own nightwear to sleep. This increases independence and well-being, encourages normality and promotes dignity. If the patient is too unwell or does not have their own clothing, hospital provision should be made available to protect their modesty (Wilson 2006).

Bedbathing

A bedbath is not the most effective way of washing patients, and wherever possible they should be encouraged and supported to shower or bathe. However, a bedbath can be performed if it is the only way to meet the patient's hygiene needs (Dingwall 2010).

Before commencing this procedure, read the patient's care plan, manual handling documentation and risk assessment to gain knowledge of safe practice. Prior to each part of the procedure, explain and obtain verbal agreement from the patient (NMC 2013). It is important that the nurse engages in appropriate conversation with the patient. If two nurses are present during bedbathing, the patient should not be excluded. Complex language and terminology should be adapted to meet the needs of the patient and ensure that he or she understands the procedure (Downey and Lloyd 2008). Planned care is negotiated with the patient and is based on assessment of their individual needs. Planned care should be documented and changed according to the patient's needs on a daily basis. Prior to commencing each step, the patient should be offered the opportunity to participate if able to, to encourage dignity, independence and autonomy.

Privacy and dignity must be maintained throughout, doors and curtains kept closed and only opened when absolutely necessary, with the patient's permission.

Procedure guideline 8.1 Bedbathing a patient

Essential equipment

- Disposable apron
- Non-sterile gloves
- Clean bedlinen
- Bath towels
- Laundry skip, applying local guidelines for soiled and/or infected linen
- Flannels, preferably disposable wipes
- Toiletries, as preferred by patient
- Comb/brush
- Equipment for oral hygiene
- Clean clothes
- Disposable or non-disposable washbowl

Optional equipment

- Antiembolic stockings
- Razor
- Scissors/nail clippers
- Emery boards
- Manual handling equipment
- Urinal, bedpan or commode

Pre-procedure

Action	Rationale
1 Assess and plan care with the patient. Note personal preferences, addressing religious and cultural beliefs. Explain each step of the procedure and gain consent.	To plan care and encourage participation and independence (Hollins 2009, C ; NMC 2013, E,C ; Pegram et al. 2007, E).
2 Offer the patient analgesia as appropriate. During the procedure observe for any non-verbal cues such as grimacing or frowning which may suggest that the patient is experiencing pain or discomfort.	To maintain patient comfort throughout the procedure (Downey and Lloyd 2008, E).
3 Clear the area of any obstacles, ensuring that the environment is warm. Draw the curtains around the bed or close doors to ensure privacy and dignity. Use available signage as appropriate.	To maintain comfort and a safe environment and promote privacy and dignity (NMC 2015, C).
4 Offer the patient the opportunity to use a urinal, bedpan or commode.	To reduce any disruption to procedure and prevent any discomfort (NMC 2015, C).
5 Collect all the equipment listed at the beginning of the procedure by the bedside.	To minimize time away from patient during procedure. E
6 Clean the washbowl with hot soapy water before use if a non-disposable bowl is being used. Fill the bowl with warm water as close to the patient's bedside as possible. Check the temperature of the water with the patient and adjust it as necessary.	To minimize cross-infection (Fraise and Bradley 2009, E ; Parker 2004, C). To promote patient comfort. E
7 Check that the bed brakes are on and adjust the bed to an appropriate height for you to carry out care comfortably.	To prevent the bed moving unexpectedly and to avoid injuring your back (Pegram et al. 2007, E).
8 Wash your hands and put on disposable gloves and apron in accordance with local guidelines.	To minimize risk of cross-infection (Fraise and Bradley 2009, E ; Parker 2004, C).

Throughout the procedure

9 The linen skip should be positioned and kept near to the bed throughout the procedure.	To reduce the potential dispersal of micro-organisms, dust and skin cells from the linen into the environment (Pegram et al. 2007, C).
10 The water used to wash the patient may be changed at any stage during the procedure. For example, if the patient feels the temperature is too hot or cold. Very soapy or dirty water must be changed before proceeding with the wash and water should be changed after washing the genitalia and surrounding area.	To promote patient comfort. E To minimize risk of cross-infection (Downey and Lloyd 2008, E).
11 Care needs to be taken not to wet drains/dressings and IV devices.	To reduce the risk of infection and prevent any drains or IV catheters from becoming dislodged (Downey and Lloyd 2008, E).

Procedure

12 Check for hearing aids, spectacles and wrist watches and with permission remove these from the patient, putting them in a safe place.	To ensure that the patient's face is washed thoroughly. E
13 Place a towel across the patient's chest.	To protect from splashes and to prepare for drying. E

(continued)

Procedure guideline 8.1 Bedbathing a patient (continued)

Action	Rationale
14 Ask the patient whether they use soap on their face. The face, neck and ears should be washed, rinsed and dried.	To promote cleanliness and to ensure that the patient's preferences are acknowledged. E
15 Hearing aids and spectacles should be cleaned and returned to the patient.	To ensure that the prosthesis is in good working order and free from debris and contaminants (Downey and Lloyd 2008, E).
16 Assist the patient with the removal of their upper clothing. The patient should be covered with a bath towel or sheet before folding back the bedclothes. Areas of the body that are not being washed should remain covered.	To maintain the patient's modesty and sustain body temperature (Downey and Lloyd 2008, E).
17 Wash, rinse and pat dry the top half of the patient's body, starting with the side furthest away from you. During washing, pressure points such as elbows can be checked for redness or skin changes.	The rationale for washing the side furthest away first is that any spills will not dampen parts of the body that would have already been washed and dried if carried out the other way round (Pegram et al. 2007, E). To prevent and treat pressure ulcers, ensuring appropriate referrals are made (NMC 2015, C).
18 If pyjama trousers are worn, these should be removed, while keeping the patient covered. If worn, antiembolic stockings should also be carefully removed.	To prevent venous emboli and to prevent and treat pressure ulcers, ensuring appropriate referrals are made (NMC 2015, C).
19 Wash the patient's legs, rinse and pat them dry, starting with the leg furthest away from you. Check pressure points on the heels for any change to skin integrity.	To prevent and treat pressure ulcers, ensuring appropriate referrals are made (NMC 2015, C).
20 Change the water in the bowl and your disposable gloves. Tell the patient that the next step is to wash around the genitalia; ask the patient if they wish to wash this area themselves or gain verbal consent from the patient to do it for them. Using a separate flannel or wipe, wash around the area and then dry it. Remove your gloves, dispose as per hospital policy. When washing this area, remember that female patients are washed from the front to back. The foreskin needs to be drawn back gently when washing the penis of uncircumcised male patients. If the patient has an indwelling catheter, put on clean gloves and wash the tubing, moving the disposable cloth down the tube away from the genital area, then dry the tubing. Remove your gloves and dispose of them as per hospital policy.	To reduce risk of infection and to maintain a safe environment (Pegram et al. 2007, C ; NMC 2015, C). Disposable flannels/wipes are preferable as this reduces the risk of infection (DH 2013b, C).
21 Ensure the patient is covered and has a call bell within easy reach. Change the water and put on clean gloves.	To maintain cleanliness, preserving dignity and privacy (NMC 2015, C).
22 Request assistance as necessary to roll the patient on to their side. Cover the areas of the patient that are not being washed. Wash their back. Pressure points of the sacrum, shoulder blades and spine can be assessed at this time. Using disposable flannel or wipe, wash sacral area, then rinse and dry the area. Gloves should be removed and hands decontaminated. Keep the patient on their side while changing the lower bed sheet. Return patient onto their back, ensuring that they remain covered. Apply toiletries as required. Assist the patient to don appropriate clothing.	To prevent and treat pressure ulcers, ensuring appropriate referrals are made (NMC 2015, C). Disposable flannels/wipes are preferable as this reduces the risk of infection (DH 2013b, C). To minimize risk of cross-infection (Fraise and Bradley 2009, E ; Parker 2004, C).
23 Inspect the patient's finger and toe nails; if necessary clean under the nails using a nail file. Cut or clip finger nails to the top level of the finger, shaping edges with an emery board if necessary. Check feet for any areas of skin dryness, inflammation or calluses. The need for possible podiatry referral should be assessed. Refit antiembolic stocking as necessary, measuring according to local policy. See Chapter 13: Perioperative care, Procedure guideline 13.1: Step-by-step guide to measuring and applying antiembolic stockings.	To enhance positive body image and patient comfort and reduce risk of infection (NMC 2015, C).
24 Provide appropriate equipment, and assist patient to brush their teeth and/or rinse their mouth.	To maintain good oral hygiene and prevent infection (Fraise and Bradley 2009, E ; Parker 2004, C).

25 Style patient's hair as desired.	To enhance patient comfort, and to promote positive body image (NMC 2015, C).
26 Assist male patients with facial shaving, apply chosen shaving foam/soap. Ensure skin is taut; begin shaving from cheeks down to neck in short strokes. Rinse razor as required. Change water and rinse face with clean water (or use electric shaver).	To enhance patient comfort, and to promote positive body image (NMC 2015, C).
27 Remake top bedclothes.	
28 Help patient to sit or lie in desired position.	To enhance patient comfort and reduce risk of pressure area breakdown (NMC 2015, C).
29 Remove equipment from the patient's bedside; replace the patient's possessions in their appropriate place. Place the locker, bedside table and call bell within the reach of the patient.	To maintain a safe environment and promote patient independence (NMC 2015, C).
30 Remove your apron and gloves, disposing of them according to local regulations.	To prevent cross-infection (Loveday et al. 2014, C).
Post-procedure	
31 Document any changes in planned care.	To provide recorded documentation of care and aid communication to the multiprofessional team (NMC 2010, C).

Procedure guideline 8.2 Washing a patient's hair in bed

Essential equipment

- Disposable apron
- Non-sterile gloves
- Comb and brush
- Plastic sheet or pad
- Two large towels
- Shampoo tray
- Receptacle for the shampoo water, e.g. bucket
- Basin and jug
- Shampoo and conditioner
- Hair dryer if required
- Washcloth or pad

Pre-procedure

Action	Rationale
1 Assess and plan care with the patient. Note personal preferences, Explain each step of the procedure and gain their consent.	To plan care and encourage participation and independence (Hollins 2009, C ; NMC 2013, E).
2 Determine the type of shampoo to be used.	Arrange for any prescribed care, e.g. medicated shampoo, to be administered (Berman et al. 2010, E).
3 Assess the patient's ability to lie flat throughout the procedure.	To ensure patient stability, comfort and safety. E
4 Collect all the equipment listed at the beginning of the procedure by the bedside.	To minimize time away from patient during procedure. E
5 Clear the area of any obstacles, ensuring that the environment is warm. Draw the curtains around the bed or close doors to ensure privacy and dignity. Use available signage as appropriate.	To maintain comfort and a safe environment and promote privacy and dignity (NMC 2015, C).
6 Wash your hands and put on disposable gloves and apron in accordance with local guidelines.	To minimize risk of cross-infection (Fraise and Bradley 2009, E ; Parker 2004, C).

Procedure

7 Remove the pillows from under the patient's head, lower or remove the bed head.	Allows access to the patient and gives the nurse more control during the procedure, thus reducing the risk of water entering the patient's eyes/ears (Dingwall 2010, E).
8 Place the plastic sheet under the patient's head and tuck a bath towel around their shoulders, bringing it towards their chest.	This will keep the bed and patient dry. This may prevent unnecessary disruption to the patient by having to change bedlinen and clothes. E

(continued)

Procedure guideline 8.2 Washing a patient's hair in bed (*continued*)

Action	Rationale
9 Gently lift the patient's head and slide in the shampoo tray with the U opening under the neck. Place a towel underneath the patient's neck for support.	The shampoo tray allows water drainage into a receptacle and prevents spills onto the floor. Padding supports the muscles of the neck and prevents undue strain and discomfort (Berman et al. 2010; Dingwall 2010, E).
10 Fold the top bedding down to the waist and cover the upper part of the patient with a towel.	To maintain patient dignity and prevent them from becoming cold (Berman et al. 2010; Dingwall 2010, E).
11 Place the receptacle for the shampoo water on the floor with an absorbent sheet underneath. Put the spout of the shampoo basin over the receptacle.	The receptacle must be lower than the bed to collect used water. Not using an absorbent sheet increases the risk of spills and slips (Dingwall 2010, E).
12 Protect the patient's eyes and ears. Place a washcloth over the patient's eyes. Place cotton balls in the patient's ears if indicated.	The washcloth protects the eyes from soapy water. These keep water from collecting in the ear canals (Berman et al. 2010; Dingwall 2010, E).
13 Ensure the patient is covered and has a call bell within easy reach. Fill the basin with warm water. Check the temperature of the water with the patient and adjust it as necessary.	To preserve dignity and privacy (NMC 2015, C) and patient safety. To promote patient comfort. E
14 Fill a jug with water from the basin, carefully wet the patient's hair and make sure the water drains into the receptacle.	To ensure there is minimal spillage of water. E
15 Apply a small amount of shampoo to the hair and scalp and gently massage with your fingertips.	Massaging stimulates the blood circulation in the scalp. The pads of the fingers are used so that finger nails will not scratch the scalp (Berman et al. 2010, E).
16 Using fresh water from the basin, rinse the hair thoroughly. Start at the top of the head and let the water work its way down to the bottom of the head.	To ensure all the shampoo is removed (Berman et al. 2010, E).
17 Apply conditioner if desired and rinse using warm water until the water runs clear.	Soapy residue causes the appearance of soap scum in the hair and the scalp will become irritated and dry (Dingwall 2010, E).
18 Squeeze excess water from the hair into the shampoo tray before removal. Gently rub hair dry with a towel. Dry the patient's face.	To facilitate optimal drying of the hair. E To ensure patient comfort. E
19 Remove any equipment and return the patient back to a comfortable position.	To ensure patient comfort (Berman et al. 2010; Dingwall 2010, E).
20 Replace any wet linen and ensure that the patient is appropriately clothed.	To ensure patient comfort and warmth. E
21 Style the patient's hair. Use a hair dryer on a cool/warm setting if the patient wishes and if it has had all its safety checks.	To prevent drying of the scalp. Prevents the discomfort of prolonged heat on the scalp (Berman et al. 2010; Dingwall 2010, E).
22 Clear away equipment from the patient's bedside. Place the call bell within the reach of the patient.	To maintain a safe environment and promote patient independence (NMC 2015, C).
23 Remove your apron and gloves, disposing of them according to local regulations.	To prevent cross-infection (Loveday et al. 2014, C).
Post-procedure	
24 Document any changes in planned care.	To provide recorded documentation of care and aid communication to the multiprofessional team (NMC 2010, C).

Eye care**Definition**

Eye care is the process of assessing, cleaning and/or irrigating the eye, including the instillation of prescribed ocular preparations where applicable; patient education is also included (Stollery et al. 2005, Watkinson and Seewoodhary 2007).

Anatomy and physiology

The eye consists of three main parts: the orbit, the globe (eyeball) and the extrinsic structures.

The orbit

The orbit or socket is formed by seven bones of the skull and is lined with fat; it supports and protects the globe and its accessory

Figure 8.2 Horizontal section through the eyeball at the level of the optic nerve. Optic axis and axis of eyeball are included.

structures (blood vessels and nerves) and provides attachments for the ocular muscles (Stollery et al. 2005).

The globe

The globe is approximately 2.5 cm in diameter and can be divided into three layers (Figure 8.2).

- The *outer layer or fibrous tunic* is composed of the transparent cornea and the white sclera. The primary function of the outer layer, in particular the sclera, is protective and it gives shape to the eyeball. The cornea functions as a refracting and protective membrane through which light rays pass on their route to the retina (Watkinson and Seewoodhary 2007).
- The *middle layer or vascular tunic* is composed of the choroid, ciliary body and iris; the globe's vascular supply is provided by the choroid.
- The *inner layer or nervous tunic* is composed of the retina, which contains the light-sensitive cells called the rods and cones. It is responsible for converting light rays into electrical signals that are transmitted to the brain via the optic nerve. This area contains the macula lutea, also known as the yellow spot. The central fovea, the area of highest visual acuity, is also located here, as is the blind spot, the area of no visual field (Watkinson and Seewoodhary 2007).

The globe – internally

The globe is divided into two chambers by the lens (Figure 8.3): the anterior cavity, in front of the lens, and the vitreous chamber, behind the lens. The anterior cavity is divided into the anterior chamber and the posterior chamber by the iris. It contains a clear, watery fluid called the aqueous humour. The vitreous chamber is filled with a jelly-like substance called the vitreous body or vitreous humour. The vitreous humour is a clear gelatinous substance which fills the vitreous chamber, which, unlike the aqueous humour, is produced during fetal development and is never replaced (Tortora and Derrickson 2011). Together, these two fluid-filled cavities help maintain the shape of the eyeball and the intraocular pressure (Tortora and Derrickson 2011).

The aqueous humour is continuously secreted by the ciliary process (a part of the ciliary body) located behind the iris. This fluid then permeates the posterior chamber, passing between the

Figure 8.3 The anterior cavity in front of the lens is incompletely divided into anterior chamber (anterior to iris) and posterior chamber (behind iris), which are continuous through the pupil. Aqueous humour, which fills the cavity, is formed by ciliary processes and reabsorbed into the venous blood by the canal of Schlemm.

lens and the iris, and flows through the pupil into the anterior chamber. From the anterior chamber, the aqueous humour drains into the scleral venous sinus (canal of Schlemm) and is absorbed back into the bloodstream (see Figure 8.3).

The aqueous humour is the principal source of nutrients and waste removal for the lens and cornea, as these structures have no direct blood supply. If the outflow of aqueous humour is blocked, excessive intraocular pressure may develop, leading to the disease process known as glaucoma. This excessive pressure can cause degeneration of the retina, which may result in blindness (Lee 2006).

Extrinsic structures

Extrinsic structures of the eye protect the globe from external injury (Stollery et al. 2005).

- *Eyelashes*: protect the eye from debris.
- *Eyebrows*: prevent moisture, in particular sweat, from flowing into the eye.
- *Eyelids*: the eyelid is made up of complex muscles for eye movement, glands for tear and oil production that serve as a cleansing mechanism against dirt and foreign objects, and sensitive nerves for defence (Watkinson and Seewoodhary 2007).
- *Lacrimal (tear) apparatus*: tears are produced in the lacrimal glands located at the upper, outer edge of the eye. They are excreted onto the upper surface of the globe and wash over the ocular surface by the action of blinking. The function of tears is to clean, moisten and lubricate the ocular surface and eyelids. Tears also provide antiseptics as they contain an enzyme called lysozyme that is able to rupture the cell membranes of some bacteria, leading to their lysis and death (Forrester 2002). The tears collect in the nasal canthus (inner, medial aspect of the eye) from where they drain into the upper and lower lacrimal puncti which drain into the lacrimal sac. From here, the tears pass into the nasolacrimal duct and empty into the nasal cavity (Figure 8.4) (Tortora and Derrickson 2011).

Optic nerve

The optic nerve, which is responsible for vision (cranial nerve II), exits the eye to the side of the macula lutea at an area called the optic disc (see Figure 8.2). This area is sometimes referred to as the anatomical blind spot. The optic nerve passes from the orbit through the optic foramen and into the brain. The two

separate optic nerves meet at the optic chiasma and some optic nerve fibres cross over here to the opposite side of the brain. The nerves then continue along the optic tracts and terminate in the thalamus. From there, projections extend to the visual areas in the occipital lobe of the cerebral cortex (Tortora and Derrickson 2011) (Figure 8.5).

An additional blind spot or area of depressed vision, called a scotoma, may be indicative of a brain tumour. In pituitary gland tumours, for example, it is common to develop bilateral defects in the field of vision due to invasion of the optic chiasma (Goodman and Wickham 2005).

The ageing process

The eye changes with age. This process can start in the third decade of life, with most anatomical and physiological changes becoming more prevalent the older a person becomes (Nigam and Knight 2008) (Box 8.3, Box 8.4).

Related theory

Sight provides us with important sensory input to enable self-care and pleasurable activities such as reading. Early detection of changes in the eye is important to enable effective treatment and prevent long-term problems and even blindness, (Holman et al. 2005, p.37).

Reduced vision or blindness can make the hospital environment very unwelcoming. When caring for patients with eye problems, it is essential to promote a safe, secure environment, where the person is supported and encouraged to communicate their needs effectively.

Evidence-based approaches

Rationale

Indications

Eye care may be necessary under the following circumstances.

- After eye surgery to prevent post-operative complications.
- In the care of the unconscious patient to maintain eye integrity.
- To relieve pain and discomfort.
- To prevent or treat infection.

Box 8.3 Effects of ageing on the eye

Anatomical changes

- The retro-orbital fat atrophies.
- Eyelid tissues become weak.
- The levator muscle weakens, causing the eyelid to droop which can occlude the upper visual field.

Physiological changes

- *Presbyopia*: the distance from which print can be read increases.
- Reduced flexibility of the lens means it can no longer change shape to focus on close objects quickly.
- *Cataracts*: the lens becomes dense and yellow, affecting colour perceptions; it can become so dense that the lens proteins precipitate, creating a halo effect around bright lights.
- Night vision reduces.
- Diminished central vision caused by cells within the retina dying.
- Dry eyes from reduced tear production.

Source: Adapted from Holman et al. (2005), Nigam and Knight (2008).

Box 8.4 Eye conditions common in the older population

- *Glaucoma*: the optic nerve is damaged by increased pressure in the eye, resulting in reduced visual field and pain.
- *Cataract*: see Box 8.3.
- *Diabetic retinopathy*: blood vessels connected to the retina are damaged by the disease and sight becomes blurred and patchy, and can be totally lost.
- *Age-related macular degeneration*: a chronic disorder of the macula cells in the centre of the retina, a highly sensitive area responsible for detailed central vision. As this degenerates, central vision declines which can lead to blindness.

Source: Adapted from Holman et al. (2005), Watkinson and Seewoodhary (2007).

- To prevent or treat injury to the eye, for example to remove sharp objects.
- For eye tests such as refraction.
- For screening to detect disease such as glaucoma.
- To treat existing problems such as conjunctivitis.
- To detect drug-induced toxicity at an early stage.
- To maintain contact lenses and care for false eye prostheses.
- To optimize the eye's visual function, especially with age-related degeneration (Boyd-Monk 2005, Cunningham and Gould 1998, Stollery et al. 2005, Watkinson and Seewoodhary 2007).

These indications may present singularly or in combination.

Eye care includes patient education about the eye and surrounding structures as well as health promotion and safety advice to promote quality of life (Watkinson and Seewoodhary 2007).

Principles of care

Eye care is performed to maintain healthy eyes that are moist and infection free. The eye is an important organ and inadequate techniques may lead to the transmission of infection from one eye to the other or the development of irreversible damage to the eye which could lead to loss of sight (Cunningham and Gould 1998). If an infection is present in one eye, this should be cleaned and/or treated last to prevent transmission of infection to the uninfected eye (Holman et al. 2005).

A clean technique should be used for eye care procedures and an aseptic technique, if deemed necessary, for vulnerable exposed eyes or to reduce the risk of infection (Alexander et al. 2007).

The eye area must be treated gently and unnecessary pressure must be avoided, especially to the globe (Alexander et al. 2007). Low-linting swabs are generally used as lint from other types of swab can become detached and scratch the cornea (Woodrow 2006). The fluids most commonly used for eye care procedures are sterile 0.9% sodium chloride or sterile water for irrigation; however, sterile 0.9% sodium chloride can irritate and sting the sensitive eye area so where possible it is recommended that sterile water is used (Woodrow 2006).

If able, and after appropriate instruction, patients should be encouraged to carry out eye care procedures themselves. However, in the case of post-operative, physically limited or unconscious patients, it is often the nurse who is responsible for eye care.

Consideration should always be given to patients' sight aids, such as glasses and contact lenses (Holman et al. 2005). Assistance may be required to clean these aids and advice regarding the most appropriate method should be sought, preferably from the patient.

For all procedures which involve removal or insertion of contact lenses or prosthetic eyes, the patient should be encouraged to do this themselves as they will have developed their own particular methods. However, the nurse must observe as the patient may still need education to improve their technique. Advice regarding the ideal method of removal and insertion should be sought from the local ophthalmology service or the nursing team in the ophthalmology unit.

Methods of eye assessment

Before beginning any eye care procedure, the eye and surrounding structures should be examined and assessed and then re-examined and reassessed after the intervention. Begin by examining the eye closed, looking carefully at the eyelids, noting any bruising, spasms, inflammation, discharge or crusting (Holman et al. 2005). Look for signs that the eyelids are closed properly, as an inability to close completely could indicate the presence of a cyst or lump that would require further investigation and reporting to the patient's doctor.

Ask the patient to open their eyes and, using a pen torch, look for abnormalities in the conjunctiva such as inflammation, redness or the presence of a discharge; the eye should be clear of clouding and redness (Alexander et al. 2007). Ask the patient whether they are experiencing any pain or photophobia. Any abnormalities need to be reported to the patient's doctor immediately, as eye complications can develop quickly. Any changes should also be documented (Alexander et al. 2007, Holman et al. 2005, NMC 2010).

Methods of eye swabbing

Eye swabbing is performed to clear the outer eye structures of foreign bodies, including discharges, which could be infected matter. The swab should be moistened with sterile water for irrigation and lightly wiped over the eyelid from the nose outward. This process should be repeated with clean gauze until the area is clean of discharge or encrustation.

Methods of eye irrigation

Eye irrigation is usually performed to remove foreign bodies or caustic substances from the eye, for example domestic cleaning agents or medications, particularly cytotoxic material; it should be performed as soon as possible to minimize damage (Stollery et al. 2005). The procedure is also used for pre-operative preparation or to remove infected material.

Using the least volume of sterile water for irrigation necessary will reduce the likelihood of deeper corneal damage which can be a side-effect of the corrosive chemicals due to water's hypotonic nature (Kuckelkorn et al. 2002). The volume required will vary depending on the degree of contamination; copious amounts are needed for corrosive chemicals and smaller volumes for removal of eye secretions. The solution may be directed to the area affected by using an intravenous fluid giving set to ensure a controllable, directable flow of fluid (Marsden 2007, Rodrigues 2009). To avoid physical damage, the tubing should be held approximately 2.5 cm from the eye (Stollery et al. 2005) and directed to the inner canthus. Other irrigation devices include the Morgan lens, an irrigating contact lens that is attached to a giving set to enable hands-free irrigation. Eye wash and eye irrigation stations are commercially available and mix tap water with air for a very soft spray of water (Marsden 2007).

Care of contact lenses

Contact lenses are thin, curved discs made of hard or soft plastic or a combination of both. Hard contact lenses are made of a rigid plastic that does not absorb water or saline solutions and can be worn for a maximum of 12–14 hours continuously. Soft contact lenses are more pliable, retain more water and so can be worn for up to 30 days and cleaned once weekly. Ill-fitting lenses may reduce the tear film between lens and cornea, which may result in oxygen deprivation of the cornea, leading to corneal oedema and blurred vision. Further damage to the corneal epithelial cells may lead to corneal abrasion and pain. Gas-permeable lenses are a combination of both hard and soft plastic; these permit oxygen to reach the cornea, providing greater comfort, and can be left in for several days (Olver and Cassidy 2005).

Most people look after their own contact lenses. Cleaning and storage solutions depend on the type of lenses used; manufacturers provide specific instructions for the care of their products.

They should be stored in a container with slots for right (R) and left (L) eye, so they can be worn in the correct eye. Seriously ill patients should have their lenses removed and stored correctly until they can reinsert them. Contact lenses are stored in a sterile solution when they are not in the eye; this helps to lubricate the lens and enable it to glide over the cornea, reducing the risk of injury.

Artificial eyes

These are made of glass or plastic; some are permanently implanted. Most people who have artificial eyes care for them themselves. If the patient is unable to do this, it is recommended that the eye is removed once daily for cleaning; the patient will be able to advise how they would like this done (Alexander et al. 2007). However, if they are unable to do so, advice should be sought from the local ophthalmology service or the nursing team in the ophthalmology unit.

Pre-procedural considerations

Light source

A good light source such as a minor procedure light or bright lamp is necessary to enable careful assessment of the eyes and to avoid damage to the delicate structures.

Position of light source

The light source should be positioned above and behind the nurse. It should never be allowed to shine directly into the patient's eyes, as this will be extremely uncomfortable for the patient (Shaw 2006).

Position of patient

The patient should be sitting or lying with their head tilted backwards and chin pointing upwards. This allows for easy access to the eyes and is usually a good position for patient comfort and compliance (Stollery et al. 2005).

Procedure guideline 8.3 Eye swabbing

Essential equipment

- Sterile dressing pack
- Sterile low-linting or lint-free swabs
- Sterile water for irrigation
- Light source

Optional equipment

- Sterile/non-sterile powder-free gloves

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. Ask the patient to explain how their eyes feel, if they are able to.
- 2 Assist the patient into the correct position:
 - Head well supported and tilted back
 - Preferably the patient should be in bed or lying on a couch.
- 3 Ensure an adequate light source, taking care not to dazzle the patient.
- 4 Wash hands and put on personal protective equipment.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To have a baseline understanding of current problems or changes the patient is experiencing (NMC 2015, **C**).

The patient needs to be discouraged from flinching or making unexpected movements and so should be in the most comfortable, pain-free position possible at the start of the procedure (Shaw 2006, **R5**).

To enable access to and assessment of the eyes. **E**

To enable patient comfort. **E**

To enable maximum observation of the eyes without causing the patient harm or discomfort (Shaw 2006, **R5**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 5 Always treat the uninfected or uninflamed eye first.
- 6 Always bathe lids with the eyes closed first.
- 7 Ask the patient to look up and, using a slightly moistened swab, gently swab the lower lid from the inner canthus outwards. Use an aseptic technique for the damaged or postoperative eye.
- 8 Ensure that the edge of the swab is not above the lid margin.
- 9 Using a new swab each time, repeat the procedure until all the discharge has been removed.

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

To reduce the risk of damaging the cornea and to remove any crusted discharge. **E**

If the swab is too wet, the solution will run down the patient's cheek. This increases the risk of cross-infection and causes the patient discomfort. Swabbing from the nasal corner outwards avoids the risk of swabbing discharge into the lacrimal punctum or even across the bridge of the nose into the other eye. Aseptic technique reduces the risk of cross-infection (Fraise and Bradley 2009, **E**).

To avoid touching the sensitive cornea. **E**

To reduce risk of cross-infection (Fraise and Bradley 2009, **E**).

10 Gently swab the upper lid by slightly everting the lid margin and asking the patient to look down. Swab from the nasal corner outwards and use a new swab each time until all discharge has been removed.	To effectively remove any foreign material from the eye. E To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
11 Once both eyelids have been cleaned and dried, make the patient comfortable.	To ensure patient comfort. E
12 Remove and dispose of equipment.	To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, E).
13 Wash hands.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
Post-procedure	
14 Discuss with the patient any changes post procedure; report any adverse effects to the patient's doctor. Record the procedure in the appropriate documents.	To monitor effectiveness of procedure, trends and fluctuations (NMC 2010, C).

Procedure guideline 8.4 Eye irrigation

Essential equipment

- Sterile dressing pack
- Sterile water for irrigation (in an emergency, tap water may be used)
- Receiver (kidney dish or plastic receptacle)
- Towel
- Plastic cape
- Intravenous fluid giving set and drip stand
- Warm water in a bowl to warm irrigating fluid to tepid temperature
- Low-linting or lint-free swabs
- Light source

Optional equipment

- Anaesthetic drops
- Sterile/non-sterile powder-free gloves

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. Ask the patient to explain how their eyes feel, if they are able to.
- 2 Wash hands and put on personal protective equipment.
- 3 If possible, remove any contact lens (see Procedure guideline 8.7: Contact lens removal: hard lenses and Procedure guideline 8.8: Contact lens removal: soft lenses).
- 4 Instil anaesthetic drops if required.
- 5 The patient should sit upright with head supported and tilted to the affected side.
- 6 Drape the patient's shoulders with a towel or if available a waterproof cape. Ask the patient to hold the receiver (kidney dish or plastic receptacle) against the cheek below the eye being irrigated.
- 7 Prepare the irrigation fluid to the appropriate temperature by placing in bowl of water until warmed.
Hang the irrigation fluid on the drip stand, connect the fluid to the intravenous giving set and prime the line.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To have a baseline understanding of current problems or changes the patient is experiencing (Rodrigues 2009, **E**).
- To reduce risk of cross-infection (Fraise and Bradley 2009, **E**).
- To ensure no reservoir of chemical remains in the eye (Marsden 2006, **E**).
- To relieve pain and aid irrigation (Duffy 2008, **E**).
- To avoid the solution running either over the nose into the other eye, to avoid cross-infection, or out of the affected eye and down the side of the cheek (Fraise and Bradley 2009, **E**).
To reduce risk of cross-infection (Fraise and Bradley 2009, **E**).
To prevent washing the discharge down the lacrimal duct or across the cheek (Marsden 2007, **E**).
- To protect the patient from getting wet and to collect irrigation fluid as it runs away from the eye (Rodrigues 2009, **E**).
- Tepid fluid will be more comfortable for the patient. The solution should be poured across the inner aspect of the nurse's wrist to test the temperature (Duffy 2008, **E**).
To ensure that the irrigation fluid is ready for the procedure (Marsden 2007, **E**).

(continued)

Procedure guideline guideline 8.4 Eye irrigation (*continued*)

Procedure

Action	Rationale
8 If there is any discharge, proceed as for eye swabbing (see Procedure guideline 8.3: Eye swabbing).	To remove any infected material. E
9 Hold the patient's eyelids apart, using your first and second fingers, against the orbital ridge. Do not press on the eyeball.	The patient will be unable to hold the eye open once irrigation commences (Marsden 2007, E). To avoid causing the patient discomfort or pain (Alexander et al. 2007, C).
10 Warn the patient that the flow of solution is going to start and pour a little onto the cheek first.	To allow time to adjust to the feeling of water flow (Duffy 2008, E).
11 Direct the flow of the fluid from the nasal corner outwards (Action figure 11). Keep the fluid flow constant by adjusting the giving set roller clamp.	To wash away from the lacrimal punctum and prevent contaminating other eye. E To ensure constant flow (Rodrigues 2009, E).
12 Ask the patient to look up, down and to either side while irrigating.	To ensure that the whole area, including fornices, is irrigated (Stollery et al. 2005, E).
13 Evert upper and lower lids whilst irrigating.	To ensure complete removal of any foreign body. E
14 Keep the flow of irrigation fluid constant.	To ensure swift removal of any foreign body (Marsden 2006, R5).
15 When the eye has been thoroughly irrigated, ask the patient to close the eyes and use a new swab to dry the lids.	For patient comfort (Rodrigues 2009, E).
16 Take the receiver from the patient and dry the cheek.	To prevent spillage of receiver contents and promote patient comfort (Duffy 2008, E).
17 Make the patient comfortable.	

Post-procedure

18 Remove and dispose of equipment.	To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, E).
19 Wash hands with bactericidal soap and water.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
20 Document the intervention in the patient's notes.	To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010, C).
21 Discuss with the patient any changes post procedure; report any adverse effects to the patient's doctor.	To monitor effectiveness of procedure, trends and fluctuations (NMC 2010, C).

Action Figure 11 Irrigation of the eye from inner to outer canthus.

Procedure guideline 8.5 Artificial eye care: insertion*Essential equipment*

- Sterile dressing pack
- Sterile water for irrigation
- Low-linting or lint-free swabs

Optional equipment

- Sterile/non-sterile powder-free gloves
- Extractor

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands and put on personal protective equipment.

Rationale

To ensure that the patient understands the procedure and gives their consent (NMC 2013, **C**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Wearing non-sterile gloves and with the dominant hand, gently lift up the upper eyelid and pull down the lower eyelid. With the other hand, hold the prosthesis between the thumb and index finger and gently insert it.

To minimize patient discomfort and ensure correct insertion. **E**

Post-procedure

- 4 Remove gloves and dispose of equipment.
- 5 Wash hands with bactericidal soap and water.
- 6 Document the intervention in the patient's notes.

To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, **E**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010, **C**).

Procedure guideline 8.6 Artificial eye care: removal*Essential equipment*

- Sterile dressing pack
- Sterile water for irrigation
- Low-linting or lint-free swabs

Optional equipment

- Sterile/non-sterile powder-free gloves
- Extractor

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands and put on personal protective equipment.

Rationale

To ensure that the patient understands the procedure and gives their consent (NMC 2013, **C**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Wearing non-sterile gloves and with the dominant hand, gently pull the eyelid downwards and exert slight pressure below the eyelid to overcome the suction, enabling the prosthesis to be removed. An extractor may be necessary to gently lever the eye out.
- 4 Rinse and drain the eye socket with sterile water for irrigation.
- 5 Clean the eye with sterile water for irrigation.

To minimize patient discomfort and trauma to the area (Alexander et al. 2007, **C, E**).

To remove any loose debris and to minimize damage caused by touch. **E**

To prevent the build-up of debris and to reduce the risk of infection (Fraise and Bradley 2009, **E**).

Post-procedure

- 6 Remove gloves and dispose of equipment.
- 7 Wash hands with bactericidal soap and water.
- 8 Document the intervention in the patient's notes.

To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, **E**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010, **C**).

Procedure guideline 8.7 Contact lens removal: hard lenses

Essential equipment <ul style="list-style-type: none">• Sterile dressing pack• Contact lens solution• Low-linting or lint-free swabs• Apron	Optional equipment <ul style="list-style-type: none">• Sterile/non-sterile powder-free gloves
---	--

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their consent (NMC 2013, C).
2 Wash hands and put on apron.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).

Procedure

3 Wearing non-sterile gloves and using thumb and forefinger, separate the eyelids. Keeping the eyelid stationary, place the index finger on the lens. Gently move the lens to one side of the cornea and pull away (Action figure 3).	To minimize corneal trauma (Stollery et al. 2005, R5).
4 Store lenses in the appropriate solution as recommended by the manufacturer and ensure lenses are placed in the correct left and right storage pots.	To prevent deterioration and contamination (Stollery et al. 2005, R5).
5 Refer to manufacturer’s instructions for further storage information, particularly if patient will not be using the lenses for a lengthy period of time.	To prevent deterioration of lens and growth of organisms. E

Post-procedure

6 Remove and dispose of equipment.	To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, E).
7 Wash hands with bactericidal soap and water.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
8 Document the intervention in the patient’s notes.	To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010, C).

Procedure guideline 8.8 Contact lens removal: soft lenses**Essential equipment**

- Sterile dressing pack
- Contact lens solution
- Low-linting or lint-free swabs

Optional equipment

- Sterile/non-sterile powder-free gloves

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands and put on personal protective equipment.

Rationale

To ensure that the patient understands the procedure and gives their consent (NMC 2013, **C**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Wearing non-sterile gloves, gently pinch the lens between the thumb and index finger (**Action figure 3**).
- 4 Store lenses in the appropriate solution as recommended by the manufacturer and ensure lenses are placed in the correct left and right storage pots.
- 5 Refer to manufacturer's instructions for further storage information, particularly if patient will not be using the lenses for a lengthy period of time.
- 6 Make the patient comfortable.

To encourage the lens to fold together, allowing air to enter underneath the lens for easy removal. **E**

To prevent deterioration and contamination (Stollery et al. 2005, **E**).

To prevent deterioration and growth of organisms. **E**

Post-procedure

- 7 Remove and dispose of equipment.
- 8 Wash hands with bactericidal soap and water.
- 9 Document the intervention in the patient's notes.

To keep area clean and reduce risk of cross-infection (Fraise and Bradley 2009, **E**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010, **C**).

Ear care

Definition

Ear care encompasses the assessment and cleaning of the ears, including the instillation of prescribed ear drops. The monitoring and maintenance of hearing are also included.

Anatomy and physiology

The ears capture sounds for hearing and maintain balance for equilibrium (Nigam and Knight 2008). The ear has three parts: external, middle and inner (Figure 8.6).

350

External ear

The external ear is a protective funnel made up of the cartilaginous pinna and external acoustic canal and the eardrum (see Figure 8.6). The external acoustic canal is lined with small hairs and next to it lie the ceruminous glands which produce cerumen or ear wax. The amalgamation of cerumen and hairs prevents foreign objects from entering the ear.

The pinna collects sound waves and delivers them via the external acoustic canal to the tympanic membrane or eardrum which vibrates in harmony (Nigam and Knight 2008, Richardson 2007). The eardrum separates the external and middle ear; it has a slight cone shape and the pointed end sits within the inner ear to assist the funnelling of sounds.

Middle ear

The middle ear is an air-filled chamber. It contains the three smallest bones in the body, the malleus, incus and stapes, collectively known as the auditory ossicles. To one side, it has a thin bony partition that holds two small membrane-covered apertures which are the oval and round windows (Tortora and Derrickson 2011). The auditory ossicles receive vibrations from the tympanic membrane. Vibrations are passed on to the oval window and through to the cochlea in the inner ear; within this process the sound waves are magnified (Alexander et al. 2007, Richardson 2007).

At the bottom of the chamber lies the eustachian tube which connects to the nasopharynx and regulates the pressure in the ear. It is usually closed but yawning or swallowing briefly opens it, allowing air to enter or leave until the pressure in the middle ear equalizes to that of external air pressure (Richardson 2007). When the pressures are equalized, the tympanic membrane vibrates freely as the sound waves hit it. However, if the pressures are not balanced, the individual may experience pain, hearing impairment, tinnitus and vertigo (Tortora and Derrickson 2011).

Figure 8.6 Internal structure of the ear. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

Inner ear

The inner ear is very small and includes the organ of Corti, which is situated inside the snail-shaped cochlea, the three semi-circular canals and vestibular apparatus (see Figure 8.6).

The organ of Corti is the organ for hearing. It is fluid-filled and has a membranous layer that connects to the end of the auditory nerve; the membrane is covered in tiny cells with hair-like projections (Alexander et al. 2007). Sound waves travel through the fluid and are distributed to the hair cells. At this point the sound waves change to impulses which pass along the auditory nerve to the brainstem and cortex, where they are interpreted as sound.

The semi-circular canals and vestibular apparatus maintain balance. These canals are highly sensitive; they contain fluid and hair cells that recognize when the head moves and send signals to the brain to maintain equilibrium. The brain interprets these messages along with visual input from the eyes (Nigam and Knight 2008). Adjustments to the muscles and joints are made in response to the information received (Tortora and Derrickson 2011).

If the inner ear structures are damaged, the patient may develop permanent vertigo or hearing loss (Pullen 2006).

Ear wax impaction

Ear wax (cerumen) is a waxy secretion of glands within the auditory canal, combined with skin scales and hair. As the cerumen dries, it usually falls out of the ear canal but in some circumstances the wax can become impacted (Harkin and Kelleher 2011).

Ear wax impaction is the biggest cause of ear problems; thousands of people in the UK have ear wax removed every week (Harkin and Kelleher 2011) (Box 8.5).

The symptoms of ear wax impaction are:

- dull hearing
- tinnitus
- disturbed balance
- earache
- itchiness in the ear
- reflex cough
- dizziness
- vertigo (Alexander et al. 2007).

Related theory

Communication and balance can be affected by poor ear hygiene; for example, using cotton buds to clean the ears can result in ear wax impaction which can dull hearing. Hearing loss can develop over time and become less noticeable to the individual and those close to them, as they find alternative ways to cope. Hearing impairment can cause frustration, stress, social isolation, paranoia and depression (Harkin and Kelleher 2011).

It is imperative that nurses notice and investigate when patients don't respond when spoken to or report feeling frustrated when communicating with others (Harkin 2005). There is a high overall incidence of hearing difficulties in people with learning disabilities. These are due to a variety of factors including genetic tendencies to deafness, fragile X syndrome, structural

Box 8.5 Individuals prone to ear wax impaction

- Older people.
- Those with learning disabilities – the reason for this is not known.
- Narrow ear canals.
- Hearing aid users.
- Those who use cotton buds to clean the ear as this causes the wax to be pushed further down the canal and can cause injury to the surface of the canal.

Source: Adapted from Aung and Mulley (2002), Harkin (2008), Kraszewski (2008).

abnormalities within the organ and neural complications which can further complicate communication difficulties for this population (Dingwall 2010).

Nurses need to be aware of how ear problems occur so they are able to explore these with patients and identify problems early and provide appropriate patient education. All findings should be documented and handed over to the patient's doctor for further investigation (Box 8.6) such as hearing assessment.

Evidence-based approaches

After bathing or showering, the outer ear should be dried with tissue or alcohol-free wipes; nothing should be put into the ear to dry it (Harkin 2008). The ear canal is self-cleaning through jaw movement and epithelial migration action which moves wax and debris up to the outer ear skin (Harkin 2008).

Principles of care

Ear hygiene needs to be carried out carefully to avoid causing damage to the ear. Public awareness of this is low and leads to attempts to remove wax with instruments such as cotton swabs

and hairpins (Dingwall 2010). As well as traumatizing the skin, these actions often contribute to increased wax production and impaction (see Box 8.5) and can also impair the self-cleansing mechanism of the organ. Fundamentals of ear hygiene include the following.

- Never insert any implements such as cotton buds into the ear.
- To dry/clean the outside of the ear, use a dry tissue or alcohol-free baby wipe around and behind the ear after the patient has showered/bathed.
- Use a soft disposable damp cloth to gently wipe around the cartilaginous area of the ear.

If there are any signs of inflammation or the patient is complaining of any discomfort:

- keep the ears dry, avoiding any entry of water: shampoo and soaps may be irritating to the skin
- when washing hair, use cotton wool coated in petroleum jelly or ear plugs placed at the entrance to both ear canals.

Assessment

A good light source such as a bull's eye lamp and head mirror or an operating lamp positioned above and behind the nurse is necessary prior to commencing ear care procedures to enable careful assessment of the ears and to avoid damage to the delicate structures (Alexander et al. 2007). The patient and nurse should be sitting at the same height to examine the outer ear and pinna (Harkin 2008). Any alteration to the appearance of the ear must be reported to the doctor.

Before proceeding with any form of invasive ear care, it is important to undertake careful examination of the ear, taking note of any discharge, redness or swelling, and the amount and texture of any ear wax present, as this will give an indication of the general health of the ear. A small amount of wax should be expected in the ear canal. Its absence may be a sign of a dry skin condition, infection or excessive cleaning that has interfered with the normal wax production (Harkin 2008).

The nurse should discuss with the patient their current level of hearing and after the procedure they should ask the patient if there are any changes so as to monitor the effectiveness of the intervention. Consideration should always be given to a patient's hearing aids and assistance given to clean these. Advice regarding the most appropriate method should be sought, preferably from the patient. Irrigation of the inner ear is sometimes necessary to remove foreign bodies or to clear excessive build-up of ear wax (cerumen) (Harkin 2008).

Poor ear care can cause:

- otitis media
- trauma to the external meatus
- tinnitus
- deafness
- perforation of the tympanic membrane.

Special care should be taken to avoid damage to the aural cavity and eardrum.

Methods of ear wax softener use

Due to the invasive nature of ear irrigation, it is advised that the patient first tries using wax softeners such as olive oil, which may avoid the need for irrigation (Jacobs 2008, Kraszewski 2008). A typical treatment regime for ear wax softening is the instillation of 2–3 drops of olive oil into the ear daily for a 5-day period (Aung and Mulley 2002).

Methods of ear irrigation

Ear irrigation is an invasive procedure that requires good understanding of the anatomy and physiology of the ear and competence with the procedure (Kraszewski 2008).

Box 8.6 Hearing tests for adults

Pure tone audiometry

Pure tone audiometry (PTA) tests the hearing of both ears. During PTA, a machine called an audiometer is used to produce sounds at various volumes and frequencies (pitches).

Speech perception

The speech perception test, also sometimes known as a speech discrimination test or speech audiometry, involves testing ability to hear words without using any visual information. The words may be played through headphones or a speaker, or spoken by the tester.

Tympanometry

The eardrum should allow as much sound as possible to pass into the middle ear. If sound is reflected back from the eardrum, hearing will be impaired.

During tympanometry, a small tube is placed at the entrance of the ear and air gently blown down it into the ear. The test can be used to confirm whether the ear is blocked, most commonly by fluid.

Whispered voice test

The whispered voice test is a very simple hearing test. It involves the tester blocking one of the participant's ears and testing their hearing by whispering words at varying volumes.

Tuning fork test

A tuning fork produces sound waves at a fixed pitch when it is gently tapped and can be used to test different aspects of hearing.

The tester will tap the tuning fork on their elbow or knee to make it vibrate, before holding it at different places around the participant's head.

Bone conduction test

A bone conduction test is often carried out as part of a routine pure tone audiometry (PTA) test in adults.

Bone conduction involves placing a vibrating probe against the mastoid bone behind the ear. It tests how well sounds transmitted through the bone are heard.

Bone conduction is a more sophisticated version of the tuning fork test, and when used together with PTA, it can help determine whether hearing loss comes from the outer and middle ear, the inner ear, or both (NHS Choices 2013).

Box 8.7 Contraindications to ear irrigation

- Perforated eardrums.
- Middle ear infection in the previous 6 weeks.
- Mucus discharge.
- *In situ* grommet.
- Cleft palate.
- Acute otitis externa with pain and tenderness to the pinna.
- History of ear surgery (Jacobs 2008).

352

An electric oral jet irrigator fitted with a special ear irrigator tip is recommended for ear irrigation as the water pressure can be controlled more precisely, along with the direction of the water (Aung and Mulley 2002). The water temperature should be 37°; if too hot or cold, it can cause dizziness or vertigo (Aung and Mulley 2002). The traditional method of irrigation uses a metal water-filled, hand-held syringe but due to the high risk of infection and trauma to the ear, this is no longer recommended practice (Harkin 2008).

Following irrigation, the patient's symptoms should resolve. If the symptoms continue, further treatment may be required and in some cases referral to Ear Nose and Throat (ENT) may be appropriate. Irrigation is not the only method of removing excess ear-wax. Those patients who have contraindications to ear irrigation (Box 8.7) still require wax removal, and this can be by instrumentation or microsuction. This must only be carried out by a nurse trained to carry out this procedure. This procedure is not readily accessible in primary care so patients are usually referred to local ENT clinics.

Mouth care

Definition

Mouth care is the care given to the oral mucosa, lips, teeth and gums in order to promote health and prevent or treat disease. It

involves assessment, correct care and patient education to promote independence (Hahn and Jones 2000).

Anatomy and physiology

Structure of the oral cavity

The mouth consists of the vestibule and the oral cavity (Figure 8.7). The vestibule is the space between the lips and cheeks on the outside and the teeth and gingivae (gums) on the inside. The palate forms the roof of the oral cavity with the base of the tongue forming the floor of the mouth. It is bordered by the alveolar arches, teeth and gums at either side (Cooley 2002). The lips and cheeks are formed of skeletal muscle; the inner part of the cheeks is known as the buccal mucosa and consists of columnar epithelium. The lips are involved in speech and facial expression and keep food within the oral cavity. The cheeks control the location of food as the teeth break it down.

Teeth

Teeth are formed of the crown (the visible part) and the root. The crown is covered in enamel, a hard, dense material which cannot repair itself once damaged. Below the enamel cap, the tooth is formed of a bone-like material called dentine. This extends into the root and surrounds the pulp cavity, which contains nerve fibres, blood vessels and connective tissue. When the pulp cavity extends into the root, it is known as the root canal. Teeth are embedded in alveoli (sockets) in the maxilla and mandible and are held in place by periodontal ligaments and a substance known as cementum. Teeth are important in breaking down and grinding food and are also involved in producing sounds in speech (Marieb 2001).

Tongue

The tongue is a muscular structure extending from its tip (apex) to the posterior attachment in the oropharynx. It houses taste buds and is involved in taste, forming food into a bolus and pushing it to the back of the mouth for swallowing. It is also involved in the articulation of sounds in speech.

Figure 8.7 Structures of the mouth (the oral cavity). *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Palate

The palate consists of the hard palate anteriorly and the soft palate which is a muscular structure leading to the palatoglossal arches and the uvula. The hard and soft palates are involved in mastication, swallowing and production of speech (Lockhart and Resick 2006).

Saliva

Saliva is produced by the parotid glands (in front of the ears), which produce saliva rich in amylase, the submandibular glands (in the lower part of the floor of the mouth), which produce mucinous saliva, the sublingual glands (in the floor of the mouth between the side of the tongue and the teeth), producing viscous saliva, and many minor salivary glands throughout the oral cavity (Hahn and Jones 2000). One litre of saliva can be produced daily, consisting of mainly water with electrolytes, amylase, proteins such as mucin, lysozyme and IgA and metabolic wastes (Lockhart and Resick 2006). Saliva is slightly acidic and can act as a buffer. It is also important in mastication, taste and speech. It acts as a defence against infection by physically washing debris off teeth and saliva proteins also have an antibacterial action (Hahn and Jones 2000).

Related theory

Oral health can be defined as 'a state of being free from chronic mouth and facial pain, oral and throat cancer, oral sores, birth defects such as a cleft lip and palate, periodontal (gum) disease, tooth decay and tooth loss and other diseases and disorders that affect the oral cavity' (WHO 2012). Good oral hygiene is essential as poor oral health can affect a patient's ability to eat or taste food, affect verbal and non-verbal communication, limit self-confidence and desire to interact with others and cause pain and infection, in some cases leading to life-threatening illness (Malkin 2009). Evidence has shown that the knowledge and attitudes of caregivers are integral to the delivery of effective oral care. The barriers to providing effective oral care include the view of oral health as a low priority, psychological distress about working inside another person's mouth and the lack of time (Bissett and Preshaw 2011).

Dental decay

Dental decay begins with the formation of a biofilm known as plaque which is made up of sugar, bacteria and other debris on the teeth. Tooth enamel can be damaged due to bacterial action, resulting in a drop in pH around the tooth. Once there is damage to the enamel then the inner dentine can also decay (Cooley 2002). Areas of decay in teeth are known as caries. Plaque can be physically removed by brushing and flossing teeth. If it is not regularly removed, it can harden to form calculus (tartar) which requires dental treatment for removal. Calculus can also disrupt the seal between the gingiva and the tooth, resulting in red, swollen and bleeding gums (gingivitis). This inflammation can progress to the formation of deep pockets of infection, damaging the teeth and underlying bone (periodontitis) (Marieb 2001). Smoking is known to be a risk factor for periodontitis and other factors such as xerostomia can also increase the risk of such problems.

Xerostomia

Xerostomia is the subjective sensation of a dry mouth, which does not always correlate to a reduction in saliva production (Maher 2004). It can be associated with thickened saliva or discomfort which may be burning in nature, leading to difficulty eating or speaking (Davies 2005b). Thirty percent of 65-year-olds have xerostomia and salivary gland hypofunction (Bissett and Preshaw 2011).

Where possible, the cause should be treated; sips of water normally only relieve the problem briefly. Artificial saliva may be helpful and mucin-based salivary substitutes are the most effective, available in gel and spray forms. Production of saliva may be stimulated by use of sugar-free chewing gum but acidic sweets

should be avoided as they may cause discomfort and increase the risk of dental caries (Davies 2000). Salivary stimulants such as pilocarpine can also be useful. Studies have also demonstrated that acupuncture can be helpful (Davies 2005b).

Patients with xerostomia must pay careful attention to oral hygiene as they are at increased risk of oral complications such as caries and periodontitis due to loss of the protective effect of saliva (Maher 2004).

Evidence-based approaches

Principles of care

The aims of oral care are to:

- keep the oral mucosa and lips clean, soft, moist and intact
- keep natural teeth free from plaque and debris
- maintain denture hygiene and prevent disease related to dentures
- prevent oral infection
- prevent oral discomfort
- maintain the mouth in a state of normal function (Jones 1998).

Box 8.8 lists the recommendations for maintaining oral health.

Within a variety of care settings, patients can find themselves at risk of poor oral health. Patients in particular need of assistance or extra care include those with the following problems.

- Patients who are nil by mouth (including unconscious or ventilated patients).
- Patients who mouth breathe (including those on oxygen therapy or with a nasogastric tube).
- Cancer patients receiving radiotherapy to the head and neck or chemotherapy which can directly affect the oral cavity or result in reduced immunity to infection.
- Patients having oral surgery or who have traumatic injury to the head and neck.
- Older patients.
- Patients with diabetes.
- Patients unable to maintain their own oral hygiene due to physical disability or psychological disorders which could affect motivation.
- Patients with clotting disorders.
- Patients who have dry mouth or gum overgrowth as side-effects of medication (Carpenito-Moyet 2012).

Every patient should have a thorough assessment of the oral cavity. This should begin with a detailed nursing history of the

Box 8.8 Factors that maintain good oral health

- Eating a healthy diet, particularly limiting sugary foods and drinks to reduce the build-up of plaque (this includes sugar-containing medicines).
- Stop smoking; it is known to increase the risk of gum disease and oral cancers.
- Limit alcohol consumption: high intake is a known risk factor for oral cancers.
- Have regular dental check-ups.
- Brush teeth for 2 minutes at least twice daily with a fluoride toothpaste and use floss or an interdental brush to clean areas that are hard to reach.
- Look for signs of oral disease; consult a dentist if anything unusual is seen.
- Take care in activities such as contact sports where facial injuries can occur.

Source: DH (2005). © Crown copyright. Reproduced under the Open Government Licence v2.0.

patient's usual oral hygiene practices. This will help the nurse determine the patient's needs and preferences when planning oral care, and will also establish the level of nursing care required. Examples of those who may need assistance include those with dexterity problems where hand co-ordination may be impaired, those with cognitive impairment, those whose illness may cause them to feel fatigued and those whose illness imposes restrictions on activities (Kozier et al. 2008).

Good assessment is vital before a care plan can be formulated. Assessment should include visual inspection and obtaining a history from the patient. Many factors should be considered when carrying out a full oral assessment (Box 8.9).

354

Assessment of the oral cavity should include assessment of the lips, tongue, gums and tissues, saliva, natural teeth or dentures, oral cleanliness, and the presence of any dental pain (Chalmers et al. 2005). This is especially important if the patient has cognitive impairment or a learning disability that may prevent them from self-reporting any oral or dental symptoms.

Inspection should be undertaken in good light, gloves should be worn, a pen torch should be available, and any dentures or plates should be removed. It is helpful to have a set order in which areas are examined so nothing is missed. The following areas should be inspected.

- *The lips:* are they dry, cracked or bleeding?
- *The upper and lower labial sulci (inner part of the lip towards the vestibule):* the lip should be retracted with a gloved finger or tongue depressor.
- *The buccal mucosa on the right and left sides:* is it intact, soft, moist, coated, ulcerated or inflamed?
- *The dorsal surface of the tongue (ask the patient to stick out the tongue):* is it dry, coated or ulcerated?
- *The ventral surface of the tongue (ask the patient to lift the tongue up and move it from side to side):* can the patient move it normally?
- *The floor of the mouth should also be inspected:* is the normal saliva pool present, is the saliva watery?
- *The hard and soft palate:* are they intact, ulcerated or red?
- *The gums:* are they inflamed or bleeding?
- *The teeth:* are they present, cared for, loose or stained, is debris present? (Davies 2005a, Hahn and Jones 2000)

Patients with dentures

Patients with dentures should be encouraged or assisted to remove and clean the denture at least daily. The denture should be cleaned over a towel or a water-filled sink to reduce the risk of damage if it is dropped. It should be brushed with a large toothbrush, denture brush or personal nailbrush and a specialized denture paste or cleaner. Toothpaste should never be used as it

is too abrasive for dentures. The dentures should be rinsed with water before being replaced in the mouth. Denture wearers are at risk of fungal infections developing under the denture and spreading to the hard palate and should be advised to remove and soak the denture ideally overnight or at least for 1 hour. The denture should be soaked in water or a disinfectant commercial denture soak preparation if you suspect the patient has an oral infection (Frazer et al. 2009). If the denture has metal parts or if infection is present, chlorhexidine 0.2% can be used to disinfect the denture (Sweeney 2005). The denture should be rinsed well before reinsertion. It should be marked with the wearer's name and the storage container should also be marked and should be either disposable or able to be sterilized (Chalmers and Pearson 2005). Denture wearers should also clean any remaining teeth, gums and tongue with a soft toothbrush and fluoride toothpaste. They should also have regular dental check-ups as ill-fitting dentures can cause ulcers or irritation (Clay 2000, Duffin 2008).

Patients needing assistance

A variety of patient groups may need assistance. Patients with mental illness or learning disabilities may need encouragement or assistance to maintain their oral hygiene (Doyle and Dalton 2008, Griffiths et al. 2000). Patients with conditions affecting mobility, sight or dexterity may find it difficult to carry out oral hygiene without assistance. Practical aids such as using a mirror and sitting down rather than standing can aid independence. Use of a foam handle aid to make the toothbrush easier to hold (Figure 8.8) or a pump action toothpaste can also help (Holman et al. 2005).

Older patients may be at risk of oral problems due to a natural decline in salivary gland function, wear and tear of teeth,

Figure 8.8 Foam handle to assist with holding a toothbrush.

Box 8.9 Factors to consider when carrying out an oral assessment

- Usual oral hygiene practice and frequency.
- Regularity of dental visits.
- Oral discomfort or pain.
- Dry mouth.
- Difficulty chewing.
- Difficulty swallowing.
- Difficulty speaking.
- Halitosis (malodorous breath).
- Drooling.
- Presence of dentures and normal care routine.
- Current or past dental problems.
- Other risk factors, for example diabetes, steroid treatment, smoking, alcohol intake, altered nutritional status.

Source: Adapted from Davies (2005a), Malkin (2009).

and taking medication with side-effects which can cause oral problems such as dry mouth, taste changes or increased risk of infection (Chalmers and Pearson 2005, Clay 2000, Fitzpatrick 2000). Regular assessment and assistance with maintaining oral hygiene are recommended (NHSQIS 2004). For the patient who needs assistance, it is recommended that the carer stands behind or to the side of the patient and supports the lower jaw (Sweeney 2005).

Unconscious patients

Unconscious patients require particular interventions to maintain oral hygiene and comfort. For patients who are close to death, there is a lack of evidence relating to oral care and the focus should be on patient comfort. Any interventions causing distress should be stopped; mouthcare can be offered 1–2 hourly but in practice it should be dependent on the need of the individual (Sweeney 2005). Gentle cleaning with a soft toothbrush or foam stick is recommended and a lubricant should be applied to the lips (Dahlin 2004).

In critically ill patients who are unconscious and requiring mechanical ventilation, management is different (Box 8.10). It is well known that aspiration of oropharyngeal flora can cause bacterial pneumonia (Li et al. 2000). Ventilator-associated pneumonia (VAP) is a serious complication which can occur in up to a quarter of ventilated patients and has a mortality of up to 50% (Berry et al. 2007). In critically ill patients the mouth can become colonized within 48 hours of admission to hospital with bacteria that tend to be more virulent than those normally found in the mouth (Grap et al. 2003). The oropharynx can become colonized, as can an artificial airway. This can allow pathogens to travel to the respiratory tract, resulting in pneumonia (Cutler and Davis 2005). It is well recognized that good oral care is essential in critically ill patients to reduce the incidence of VAP.

Other contributing factors to poor oral health in this group of patients include dry mouth related to use of oxygen, mouth breathing and the patient being nil by mouth. The presence of tubes or securing tapes can make it difficult to view and clean the oral cavity. Further research is needed in this area as there is a lack of trial-based evidence to support practice (Munro and Grap 2004).

Legal and professional issues

Nurses should provide a high standard of care to patients, based on the best evidence available, ensuring they have the necessary skills (NMC 2015). Numerous studies have found that nurses feel they lack knowledge and training about providing oral care (Southern 2007). Although a number of training tools are available, the provision of adequate training before and after registration requires further attention (Doyle and Dalton 2008, NHSQIS 2004). As is the case for all procedures, a full explanation must be given to the patient and verbal consent obtained (NMC 2013). If patients refuse oral care, nurses should try and explore their reasons for refusal. If you suspect a patient lacks capacity to understand the outcome of refusing oral care then you should follow the guidance in the most current version of the Mental Capacity Act.

Box 8.10 Recommendations for oral care in critically ill patients

- Daily assessment.
- Oral care 2–4 hourly.
- Brushing with a small-headed soft toothbrush and fluoride toothpaste.
- Cleaning the mouth with foam sticks and chlorhexidine mouthwash or gel for patients for whom a toothbrush would be unsuitable, for example bleeding, severe ulcers.
- Use of suction to prevent aspiration.

Source: Adapted from Abidia (2007), Stiefel et al. (2000).

Pre-procedural considerations

Equipment

Toothbrush

The toothbrush is recognized as being the most effective means of removing plaque and debris from the teeth and gums. A small-headed, medium-textured brush is most effective at reaching all areas of the mouth. Powered toothbrushes have been shown to be as effective as manual toothbrushes and may be easier for patients with limited dexterity to use (Robinson et al. 2005). Aids such as foam handles can also be obtained from the occupational therapist to make a manual toothbrush easier to hold (see Figure 8.8). The toothbrush should be allowed to air dry to reduce bacterial contamination and changed every 3 months or sooner if worn (Hahn and Jones 2000). For patients with a sore mouth, a soft or baby toothbrush can be used.

Foam sticks

The foam stick is one of the most common pieces of equipment used in hospital to provide oral care although it is well known that less plaque is removed than with a toothbrush, particularly from less obvious areas of the teeth (Pearson and Hutton 2002). The foam stick should only be used on patients who cannot tolerate use of a toothbrush, such as those with painful or bleeding mouths. Care should be taken that the foam head is securely attached to avoid risk of accidental aspiration (Malkin 2009).

Interdental cleaning

The use of dental floss or other equipment is recommended to clean areas between the teeth which may be difficult to reach with a toothbrush (Huskinson and Lloyd 2009). There is currently limited evidence of the efficacy of flossing although it is generally believed to be beneficial (Berchier et al. 2008). A variety of equipment is available such as dental floss, dental tape, wood sticks or interdental brushes (Figure 8.9). For patients who have limited dexterity, this may be difficult or impossible to carry out. Similarly, in patients with painful mouths or bleeding gums, this type of equipment could cause further discomfort or bleeding and should be avoided.

Oral irrigation devices such as the WaterPik® can also be used for interdental cleaning. Oral irrigation involves a jet of water being used to remove debris and plaque and can be useful for people who find it difficult to use dental floss or tape such as those with braces. A systematic review of oral irrigation has shown a positive tendency but no overall benefit in reducing plaque over use of a toothbrush alone (Husseini et al. 2008).

Figure 8.9 Examples of interdental cleaning products. (a) Disposable flosser. (b) Interdental brush. (c) Dental floss.

Assessment and recording tools

The mouth should be assessed as part of the initial nursing assessment and should be reassessed regularly thereafter (DH 2001, NHSQIS 2004). Frequency of assessment is often based on clinical judgement rather than evidence. For patients at high risk of changes to the condition of the mouth, such as those receiving high-dose chemotherapy, assessment should be carried out daily (Quinn et al. 2008). For elderly patients receiving long-term care, it has been recommended that reassessment takes place on a regular basis. Recommendations for the frequency of assessment vary – monthly (NHSQIS 2004) or quarterly (Sarin et al. 2008) – but all recommend assessment on admission to the care facility and then at regular intervals throughout the year.

The use of an oral assessment tool is recommended to ensure consistency between assessors and to monitor changes. A number of tools have been devised for different patient groups. Tools such as the WHO scale (WHO 1979) or the Oral Assessment Guide (OAG) (Eilers et al. 1988) are commonly used in assessing patients receiving anticancer treatments. Numerous other tools exist to assess oral mucositis, although some lack evidence of validity and reliability. Use of a validated tool is recommended (Huskinson and Lloyd 2009). Several tools have also been designed to meet the needs of elderly patients and those with dementia (Kayser-Jones et al. 1995, Roberts 2001). An example of a tool that can be used with patients in residential care is the Oral Health Assessment Tool (OHAT; Chalmers et al. 2005).

The ideal assessment tool should measure:

- functional changes, for example ability to talk or eat
- physical changes, for example presence of ulcerated areas
- subjective changes, for example pain or dryness.

The ideal tool has not yet been developed and it may be necessary to use a combination of tools to make a thorough assessment. Patient education to encourage self-assessment is also recommended (Quinn et al. 2008).

Pharmacological support

The choice of an oral care agent will be dependent on the aim of care. The agent may be used to remove debris and plaque, prevent superimposed infection, alleviate pain, provide comfort, stop bleeding, provide lubrication or treat specific problems (Dickinson and Porter 2006). A wide variety of agents is available and choice should be determined by the individual needs of the patient and the particular clinical situation together with a detailed nursing assessment. There is ongoing debate on the efficacy of agents presently available and there is insufficient evidence to clearly state the best agents to use in the clinical setting.

Toothpaste

Toothpaste is a paste or gel used with a toothbrush (mechanical or powered) to clean and maintain the health of teeth and gums. It is an abrasive substance that aids in the removal of food from the teeth and dental plaque. Most of the cleaning is achieved from the mechanical action of the toothbrush and not by the toothpaste. Most toothpastes have active ingredients to help prevent tooth and gum disease. Toothpastes are composed of 20–42% water with a variety of other components such as abrasives (remove plaque and stains from the tooth surface), fluoride (prevents cavities) and detergents (surfactants used mainly as a foaming agent). Different types are listed in the Dental Prescribing Formulary.

A pea-sized amount of fluoride toothpaste should be used; fluoride is known to have anticaries activity and can reduce dentine sensitivity. If toothpaste is too abrasive for a patient whose mouth is painful, water alone can be used (Sweeney 2005).

Commercial mouthwash

Over-the-counter mouthwashes are not generally recommended. Many have a high alcohol content which can cause stinging, particularly for patients with sensitive mouths (Milligan et al. 2001).

Bland rinses

Several agents have been used to rinse the mouth, moisten the mucosa and loosen and remove debris. Normal saline has been recommended by a number of authors as part of a patient's oral care. This relatively cheap and generally well-tolerated solution can alleviate discomfort although it is not effective at removing heavy amounts of debris (Milligan et al. 2001). Patients with mucositis can benefit from frequent rinsing of the mouth with warm normal saline to remove debris without causing irritation (Meehan 2005). The use of water has also been suggested to rinse the mouth after meals to remove debris (Sweeney 2005). Its use in critical care has been discouraged due to risk of infection in vulnerable patients, but sterile water may be an alternative (Berry et al. 2007). Sodium bicarbonate has been used in some centres although there is some evidence that patients find it unpleasant to taste and that it can alter pH in the mouth, predisposing to bacterial growth (Wood 2004).

Chlorhexidine gluconate

Chlorhexidine gluconate is an effective antibacterial and anti-plaque agent. For the patient who is unable to use a toothbrush, it can provide a chemical method of stopping plaque build-up. As chlorhexidine is released from tissues for up to 12 hours, it only needs to be used twice daily. Chlorhexidine does not remove plaque which is already present so brushing of teeth should continue as far as possible (Sweeney 2005). Foam sticks can be used with chlorhexidine rather than plain water for an antibacterial effect (Huskinson and Lloyd 2009). It is also available as a gel formulation which may be useful for those requiring a non-foaming alternative to toothpaste (patients at risk of aspiration or with swallowing difficulties).

Contraindicated agents

A number of agents widely used in the past for mouth care have been found to have detrimental effects and are no longer recommended. Glycerine and lemon swabs have been used for dry mouth but the acid content can damage tooth enamel and the overall effect is to increase oral dryness (Hahn and Jones 2000). Hydrogen peroxide is also not recommended as it can cause mucosal abnormalities (Berry et al. 2007).

Specific patient pharmacological preparations

Fluoride

Fluoride helps to prevent and arrest tooth decay, especially radiation caries, demineralization and decalcification. High-dose fluoride toothpaste may be recommended for patients with xerostomia (NHSQIS 2004).

Artificial saliva

Saliva substitutes which are mucin based are more effective than those which are carboxymethylcellulose based for relieving dry mouth (xerostomia) (Davies 2005b). Recommendations are to spray several times around the mouth and then to use the tongue to spread the artificial saliva around. It should be used prior to meals and at any other time when the mouth feels dry (Davies 2000).

Coating agents

A coating agent can be used to coat the surface of the mouth, forming a thin protective film over painful oral lesions or

mucositis. Oral lesions or mucositis can be caused by medication, disease, oral surgery, stress, traumatic ulcers caused by dental braces and dentures, radiotherapy and chemotherapy. Examples include Gelclair, Mugard and Episil. These products should be rinsed around the mouth to form a protective layer over the sore areas, and generally applied 1 hour before eating. Several agents have been used to coat the oral mucosa and they are thought to have a protective effect although there is limited evidence to support their use. Sucralfate has not been shown to be effective in preventing or treating chemotherapy- or radiotherapy-associated oral mucositis (Clarkson et al. 2007, Worthington et al. 2007).

Antifungal agents

Colonization of the mouth with yeast occurs in one-third of the population. In patients receiving steroids or antibiotics, the

balance of oral flora can be altered and oral candidiasis (oral thrush) can occur. Predisposing factors also include xerostomia and the presence of dentures. These infections can be treated with either topical or systemic antifungal medications. In debilitated or immunocompromised patients, candidiasis can become a systemic disease.

Antifungal agents are a group of drugs specifically used for the treatment of fungal infections. Oropharyngeal candidiasis can be treated with either topical antifungal agents (e.g. nystatin, clotrimazole, amphotericin B oral suspension) or systemic oral azoles (fluconazole, itraconazole or posaconazole). Length of treatment will depend on the pharmacological agent chosen and should follow recommendations in the *British National Formulary* (most current publication) and local prescribing guidelines.

Topical treatment is normally effective using an antifungal oral suspension or lozenges (Finlay and Davies 2005).

Procedure guideline 8.9 Mouth care

Essential equipment

- Small torch
- Plastic cups
- Mouthwash or cleaning solutions
- Appropriate equipment for cleaning
- Clean receiver or bowl
- Paper tissues/gauze
- Wooden spatula
- Small-headed, soft toothbrush
- Toothpaste
- Non-sterile disposable gloves
- Dental floss

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. When possible, encourage patients to carry out their own oral care.
- 2 Wash hands with soap and water and dry with paper towel or use alcohol handrub. Put on disposable gloves.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To enable patients to gain confidence in managing their own symptoms (DH 2005a, **C**).

To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Prepare solutions required.

Solutions must always be prepared immediately before use to maximize their efficacy and minimize the risk of microbial contamination (Fraise and Bradley 2009, **E**).
- 4 Carry out oral assessment using an oral assessment tool.

Provides baseline to enable monitoring of mucosal changes and evaluate response to treatment and care (Eilers et al. 1988, **R5**; Sonis et al. 2004, **R5**).
- 5 (a) Inspect the patient's mouth, including teeth, with the aid of a torch, spatula and gauze, paying special attention to the lips, buccal mucosa, lateral and ventral surfaces of the tongue, floor of the mouth and the soft palate (**Action figure 5**).

The mouth is examined for changes in condition with respect to moisture, cleanliness, infected or bleeding areas, ulcers, and so on. These areas are known to be more susceptible to cytotoxic damage (Sonis et al. 2004, **R5**).

To assess nutritional deficits, salivary changes and pain secondary to oral changes (Sonis et al. 2004, **R5**).
- 6 Using a soft, small toothbrush and toothpaste (or foam stick if the gingiva is damaged or susceptible to bleeding), brush the patient's natural teeth, gums and tongue.

To remove adherent materials from the teeth, tongue and gum surfaces (Hitz Lindenmüller and Lambrecht 2011, **E**). Brushing stimulates gingival tissues to maintain tone and prevent circulatory stasis (Clay 2000, **E**; Pearson and Hutton 2002, **R1b**). Foam stick reduces possibility of trauma (Cooley 2002, **E**).

(continued)

Procedure guideline 8.9 Mouth care (continued)

Action	Rationale
7 Hold the brush against the teeth with the bristles at a 45° angle. The tips of the outer bristles should rest against and penetrate under the gingival sulcus. Then move the bristles back and forth using horizontal or circular strokes and a vibrating motion (bass sulcular technique), from the sulcus to the crowns of the teeth. A gentle scrubbing action is recommended, using small movements with gentle pressure for 2 minutes (Sweeney 2005). The brush should be placed at a 45° angle against the teeth and overlaying the gum edge to allow cleaning of the gingival margin (Jones 1998). Repeat until all teeth surfaces have been cleaned. Clean the biting surfaces of the teeth by moving the toothbrush back and forth over them in short strokes and brush tongue to remove any debris.	Brushing loosens and removes debris trapped on and between the teeth and gums (DH 2005a, C). This reduces the growth medium for pathogenic organisms and minimizes the risk of plaque formation and dental caries (Clay 2000, E ; Pearson and Hutton 2002, R1b).
8 Give a beaker of water to the patient. Encourage patient to rinse the mouth vigorously then spit the contents into a receiver. Paper tissues should be to hand to dry any spillage of water or dribbling.	Rinsing removes loosened debris and toothpaste and makes the mouth taste fresher (Sonis et al. 2004, R5).
9 If the patient is unable to rinse and spit, use a rinsed toothbrush to clean the teeth and moistened foam sticks to wipe the gums and oral mucosa. Foam sticks should be used with a rotating action so that most of the surface is used.	To remove debris as effectively as possible (Sonis et al. 2004, R5).
10 Floss teeth (unless contraindicated, such as clotting abnormality, thrombocytopenia) once in 24 hours using lightly waxed floss. (a) To floss the upper teeth, use your thumb and index finger to stretch the floss and wrap one end of floss around the third finger of each hand. Move the floss up and down between the teeth from the tops of the crowns to the gum and along the gum lines wherever possible (Action figure 10). (b) To floss the lower teeth, use the index fingers to stretch the floss.	Flossing helps to remove debris between teeth. Flossing when patient has abnormal clotting or low platelets may lead to bleeding and predispose the oral mucosa to infection (Clay 2000, E ; Beck 2004, E).

Post-procedure

11 Discard remaining mouthwash solutions.	To prevent infection (Fraise and Bradley 2009, E).
12 Clean the toothbrush and allow it to air dry.	To prevent the risk of contamination (Jones 1998, E).
13 Remove gloves. Wash hands with soap and water and dry with paper towel or use alcohol handrub.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
14 Ensure the patient is comfortable.	

Action Figure 5 Oral assessment using a torch, spatula and gauze.

Action Figure 10 Interdental cleaning using dental floss.

Procedure guideline 8.10 Mouth care for the patient with dentures

Essential equipment

- Small torch
- Plastic cups
- Mouthwash or cleaning solutions
- Appropriate equipment for cleaning dentures
- Clean receiver or bowl
- Small-headed, soft toothbrush or denture brush
- Denture paste
- Non-sterile disposable gloves
- Denture pot

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. When possible, encourage patients to carry out their own oral care.
- 2 Wash hands with soap and water and dry with paper towel or use alcohol handrub. Put on disposable gloves.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To enable patients to gain confidence in managing their own symptoms (DH 2005a, **C**).
To reduce the risk of cross-infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Prepare solutions required.
- 4 If the patient cannot remove their own dentures, remove the lower denture first.
 - (a) *Lower denture*: grasp it in the middle and lift it, rotating it gently to remove from the mouth, and place in denture pot.
 - (b) *Upper denture*: remove the upper denture by grasping firmly in the middle and tilting the denture forward while putting pressure on the front teeth to break the seal with the palate. Rotate the denture from side to side to remove it from the mouth and place it in the denture pot.
- 5 Carry out oral assessment using an oral assessment tool.

Solutions must always be prepared immediately before use to maximize their efficacy and minimize the risk of microbial contamination (Fraise and Bradley 2009, **E**).

The lower denture should be removed first to avoid the risk of aspiration (Sweeney 2005, **R5**).

Removal of dentures is necessary for cleaning of underlying tissues (Sweeney 2005, **R5**).

Provides baseline to enable monitoring of mucosal changes and evaluate response to treatment and care (Eilers et al. 1988, **R5**; Sonis et al. 2004, **R5**).
- 6 (a) Inspect the patient's mouth with the aid of a torch, spatula and gauze, paying special attention to the lips, buccal mucosa, lateral and ventral surfaces of the tongue, floor of the mouth and the soft palate (see Procedure guideline 8.9: Mouth care, **Action figure 5**).
(b) Ask the patient if they have any of the following: taste changes, change in saliva production and composition, oral discomfort or difficulty swallowing.

The mouth is examined for changes in condition with respect to moisture, cleanliness, infected or bleeding areas, ulcers, and so on. These areas are known to be more susceptible to cytotoxic damage (Sonis et al. 2004, **R5**).

To assess nutritional deficits, salivary changes and pain secondary to oral changes (Sonis et al. 2004, **R5**).

(continued)

Procedure guideline 8.10 Mouth care for the patient with dentures (*continued*)

Action	Rationale
7 Give a beaker of water to the patient. Encourage patient to rinse the mouth vigorously then spit the contents into a receiver. Paper tissues should be to hand to dry any spillage of water or dribbling.	Rinsing removes loosened debris and makes the mouth taste fresher (Sonis et al. 2004, R5).
8 Clean the patient's dentures on all surfaces with a denture brush or toothbrush and soap and water or denture cleaner. Check the dentures for cracks, sharp edges and missing teeth. Rinse them well and return them to the patient.	Cleaning dentures removes accumulated food debris which could be broken down by salivary enzymes to products which irritate and cause inflammation of the adjacent mucosal tissue (Sweeney 2005, R5).
9 Dentures should be removed for at least 1 hour but ideally overnight and placed in a suitable cleaning solution.	Dentures can easily become colonized by bacteria. Soaking can disinfect the denture, discouraging bacterial growth (Clay 2000, E ; Sweeney 2005, R2b).

Post-procedure

10 Discard remaining mouthwash solutions.	To prevent infection (Fraise and Bradley 2009, E).
11 Clean the toothbrush or denture brush and allow it to air dry.	To prevent the risk of contamination (Jones 1998, E).
12 Remove gloves. Wash hands with soap and water and dry with paper towel or use alcohol handrub.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).
13 Ensure the patient is comfortable.	

Problem-solving table 8.1 Prevention and resolution (Procedure guidelines 8.9 and 8.10)

Problem	Cause	Prevention	Action
Dry mouth (xerostomia).	Oxygen therapy, mouth breathing, nil by mouth.	Humidified oxygen.	Swabbing the mouth with moistened foam stick or encouraging the patient to rinse the mouth with water and spit it out.
Dry mouth (xerostomia).	Salivary gland hypofunction due to disease, drugs or side-effects of radiotherapy or chemotherapy.	Not always possible to prevent.	Good oral hygiene to prevent complications, use of salivary stimulants, for example chewing gum, pilocarpine or saliva substitutes.
Patient unable to tolerate toothbrush.	Pain, for example post surgery. Mucositis.	Consider anaesthetic mouth spray or mouthwash before mouth care. Give regular and/or prn analgesia.	Use foam sticks and chlorhexidine 0.2% to clean the patient's teeth, gums and mucosa; 0.9% sodium chloride rinse can be used if the patient cannot tolerate any form of oral care.
Toothbrush inappropriate or ineffective.	Infected stomatis. Accumulation of dried mucus, new lesions, blood or debris.	As above.	As above and take a swab of any infected areas for culture before giving mouth care.

Pain**Definition**

Pain is a complex phenomenon, that has physiological, psychological and social factors that influence the individual patient experience. It is subjective so the patient's perspective is important to understand. It has both a physical and an affective (emotional) component. To reflect this, the International Association for the Study of Pain (IASP 1994) published the following definition of pain: 'An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described

in terms of such damage'. As pain is subjective, another favoured definition for use in clinical practice, proposed originally by McCaffrey (1968) and cited in McCaffrey (2000, p.2), is: 'Pain is whatever the experiencing person says it is, existing whenever the experiencing person says it does'.

Anatomy and physiology

Pain mechanisms (anatomy and physiology) are usually described in terms of nociceptive pain or neuropathic pain. As with acute and chronic pain, it may be common for pain to be both nociceptive and neuropathic in origin rather than purely one or the other.

Figure 8.10 Processing of sensory input and motor output by the spinal cord. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

Nociceptive pain

Nociceptive pain is the 'normal' pain pathway that occurs in response to tissue injury or damage (Figure 8.10). It consists of four components: transduction, transmission, perception and modulation. Nociceptors are free nerve endings found at the end of pain neurones. They occur in skin and subcutaneous tissue, muscle, visceral organs, tendons, fascia, joint capsules and arterial walls (Godfrey 2005). Nociceptors respond to noxious thermal stimuli (heat and cold) and mechanical stimuli (stretching, compression, infiltration) and to the chemical mediators released as part of the inflammatory response to tissue injury. These chemical mediators include prostaglandins, bradykinin, substance P, serotonin and adenosine. As a result of this stimulation process, an action potential is generated in the nerve (*transduction*).

The pain signal is then transmitted along the peripheral nervous system (A delta and C fibres) to the central nervous system, arriving at the dorsal horn of the spinal cord. Neurotransmitters are released to allow the pain signal to be transmitted from the endings of the peripheral nerves to the nociceptors in the dorsal horn. The message is then transmitted to the brain where perception of the pain occurs (*transmission*). *Perception* is the end-result of the neuronal activity of pain transmission. The perception of pain includes behavioural, psychological and emotional components as well as physiological processes.

Modulation occurs when the transmission of pain impulses in the spinal cord is changed or inhibited. Modulatory influences on pain perception are complex, involving a gating system which is linked to a descending modulatory pathway. Modulation can occur as a result of a natural release of inhibitory neurotransmitter chemicals that inhibit transmission of pain impulses and therefore produce analgesia. Other interventions, including distraction, relaxation, sense of well-being, heat/cold therapy, massage and TENS, can also help to modulate pain perception. Analgesic medications work by inhibiting some of the chemicals involved in pain transduction and transmission and thus modulating pain perception (Figure 8.11). Pain signals can also be increased by certain factors such as anxiety, fear and low mood/depression.

Figure 8.11 The pain pathway showing key sites for particular analgesic interventions.

Neuropathic pain

Neuropathic pain is not pain that originates as part of 'normal' pain pathways. It has been described as pain related to abnormal processing within the nervous system (Mann 2008). Nerve injury or dysfunction can be caused by a range of conditions such as infection, trauma, metabolic disorder, chemotherapy, surgery, radiation, neurotoxins, nerve compression, joint degeneration, tumour infiltration and malnutrition (Mann 2008).

The mechanisms by which neuropathic pain is generated and maintained are not fully understood but the following theories are currently thought to contribute.

- Damage or abnormalities in the nerves change the way that nerves communicate with each other.
- Pain receptors require less stimulation to initiate pain signals both in peripheral nerves and the central nervous system, where it is often referred to as central sensitization.
- Pain transmission is altered from its normal sequence.
- There may be an increase in the release of chemical neurotransmitters.
- There can be increased and chaotic firing of nerves.
- Damaged nerves spontaneously generate impulses in the absence of any stimulation.
- The descending inhibitory systems may also be reduced or lost.

The nervous system changes its structure and function in response to the input it receives, i.e. it is plastic. Plasticity is evident at all levels from the nociceptor to the brain (cortex). These mechanisms result in increased activity or transmission of pain signals despite less input from the peripheral nervous system. Pain can be spontaneous, may be triggered by non-painful stimuli such as touch (allodynia), may be an exaggerated pain response (hyperalgesia) and patients may also experience non-painful sensations such as pins and needles and tingling (paraesthesias).

Related theory

Many factors influence the expression of pain and may be associated with the patient, the nurse or the clinical environment (organizational aspects) (Carr and Mann 2000). Pain can have many dimensions including physical, psychological, spiritual and sociocultural.

Pain can be categorized into three main types.

- Acute pain – less than 3 months' (12 weeks) duration.
- Persistent or chronic pain – more than 3 months' (12 weeks) duration.
- Cancer pain associated with a malignancy.

There are several ways to categorize the types of pain that occur, for example nociceptive (somatic or visceral) or neuropathic. It

is increasingly recognized that acute and chronic pain may represent a continuum rather than being distinct separate entities (Macintyre et al. 2010) and may combine different pain mechanisms and vary in duration.

Acute pain

The IASP has defined acute pain as: 'Pain of recent onset and probable limited duration. It usually has an identifiable temporal and causal relationship to injury or disease' (Ready and Edwards 1992, p.1). Acute pain is produced by a wide range of physiological processes, and includes inflammatory, neuropathic, sympathetically maintained, visceral and cancer pain (Walker et al. 2006). Acute pain serves a purpose by alerting the individual to a problem and acting as a warning of tissue damage or potential tissue damage. If left untreated, it may result in severe consequences; for example, not seeking help for acute abdominal pain may result in an emergency such as appendicitis progressing to peritonitis. Acute pain is short-term pain of less than 12 weeks' duration (British Pain Society 2008). It occurs in response to any type of injury to the body and resolves when the injury heals.

Common causes of acute pain include:

- surgery (e.g. upper or lower abdominal surgery, colorectal surgery, gynaecological surgery, appendicectomy, orthopaedic surgery)
- acute trauma (e.g. work-related injuries, road traffic accidents, sports injuries, head injury, spinal and neck injuries, burns/scalds)
- acute musculoskeletal pain (e.g. acute low back pain, acute joint pain)
- procedural pain or incident pain (e.g. related to a painful procedure such as venepuncture, insertion of catheter or drain or pain as a consequence of a movement or an event, e.g. defecation after anal surgery, ischaemic leg pain associated with intermittent claudication on walking)
- acute visceral pain (e.g. ischaemic heart disease, pancreatitis, cholecystitis, ulcerative colitis, Crohn's disease, cystitis) (Mann and Carr 2006).

Chronic pain

Chronic pain is usually prolonged and defined as pain that exists for more than 3 months, lasting beyond the usual course of the acute disease or expected time of healing (IASP 1996). It is often associated with major changes in personality, lifestyle and functional ability (Orenius et al. 2013). Chronic pain occurs as a result of non-malignant chronic conditions such as neuropathic, musculoskeletal and chronic post-operative pain syndromes or as a result of cancer. Types of chronic pain include the following.

- *Chronic benign pain*: pain that persists for more than 6 months but does not necessarily change over time, for example low back pain.
- *Recurrent acute pain*: acute pain that is associated with chronic conditions, episodes which occur regularly over a period longer than 6 months and potentially over a lifetime, for example migraine and trigeminal neuralgia.
- *Chronic progressive pain*: pain that persists for more than 6 months, originates from a constant cause and is likely to increase in severity, for example degenerative disorders such as osteoporosis (Mackintosh and Elson 2008).

Common causes of chronic pain can be:

- musculoskeletal pain, e.g. degenerative low back pain, osteoarthritis, polymyalgia
- post-traumatic pain, e.g. nerve plexus injury, vertebral crush fractures
- post-surgical pain, e.g. after breast surgery, thoracotomy, vasectomy, hernia repair, amputation

- central pain, e.g. spinal cord damage, central post-stroke pain, multiple sclerosis
- peripheral nerve pain, e.g. peripheral neuropathy, complex regional pain syndrome
- facial pain, e.g. trigeminal neuralgia, temporomandibular joint pain, atypical facial pain
- headaches, e.g. tension headache, migraine, cluster headaches, medication overuse headache
- infection, e.g. post-herpetic neuralgia (PHN), HIV-related pains
- vascular pain, e.g. peripheral vascular disease, Raynaud's, refractory angina
- visceral pain, e.g. pancreatitis, sickle cell pain, interstitial cystitis, endometriosis
- life-limiting conditions, e.g. cancer, end-stage heart failure (Simpson 2008).

Patients with chronic pain often describe variations in the intensity of the pain, either throughout the day or day by day depending on their activities (Nicholas et al. 2003). Within the medical literature, several terms are used to describe the variations in pain including pain flare, episodic pain, exacerbation of pain, transient/transitory pain and breakthrough pain.

Cancer pain management

Pain is a common symptom in patients with cancer (Chapman 2012). Causes of cancer pain can be multifactorial and often are related to the effects of cancer treatment such as surgery, radiotherapy or chemotherapy. In some instances, pain can be caused by the cancer itself such as patients with bone metastases or where the cancer has caused injury to nerves. Cancer pain has been reported as being present in a third of patients undergoing active anticancer treatment with a curative intent. It has also been suggested that patients who have treatment to both cure and for palliation experience pain in 59% of cases, with 64% of patients experiencing pain in advanced disease (van den Beuken-van-Everdingen et al. 2007). Cancer can be both acute and chronic and requires careful assessment and attention to detail, including a detailed history of previously tried medications and responses to these pharmacological interventions. Assessment, treatment plan and review are key in the management of cancer pain.

Evidence-based approaches

The ethos of this section will be based on acute and chronic pain management.

Rationale for effective acute pain control

There are several reasons why acute pain needs to be well controlled, not least that patients have a right to expect adequate treatment of pain and that all members of the healthcare team have an ethical obligation to provide it (Audit Commission 1997). It is now known that undertreatment of acute pain coupled with the physiological response to surgery or injury, known as the stress response, can have a number of adverse consequences (Macintyre and Schug 2007).

Pain can have long-lasting effects on the central nervous system, leaving an 'imprint' if pain is poorly controlled, which may mean that future episodes of pain are difficult to control (Carr 2007). Uncontrolled pain can lead to increased anxiety, fear, sleeplessness and muscle tension which further exacerbate pain. It can delay the recovery process by hindering mobilization and deep breathing, which increases the risk of a patient developing a deep vein thrombosis, chest infection or pressure ulcer. Pain can also lead to significant delays in gastric emptying and a reduction in intestinal motility (Macintyre and Schug 2007). With severe pain, activity of the sympathetic nervous system and the neuroendocrine 'stress response' causes platelet activation, changes in regional blood flow and stress on the heart. These can lead to impaired wound healing and myocardial ischaemia (Macintyre and Schug 2007). There is evidence to suggest that in the long

term, poorly controlled acute pain may lead to the development of chronic pain. Perkins and Kehlet (2000) established that moderate-to-severe acute post-operative pain was a predictor for developing chronic pain after breast surgery, thoracic surgery and hernia repair.

Methods of pain assessment

Pain assessment is a key step in the process of managing pain and pain should be assessed before any intervention takes place. The aim of assessment is to identify all the factors, physical and non-physical, that affect the patient's perception of pain. A comprehensive clinical assessment is essential to gain a thorough understanding of the patient's pain, select an appropriate analgesic therapy, evaluate the effectiveness of interventions and modify therapy according to the patient's response.

Acute pain assessment

The key components of acute pain assessment are the pain history, measurement of the pain and the response to any intervention (Macintyre and Schug 2007). A pain history in addition to a physical examination can provide important information that will help in understanding the cause of the pain. A pain history should be repeated when there is any sign of an alteration in the nature and intensity of the pain.

Assessment of pre-existing pain

Patients who have been taking regular opioid analgesics for a pre-existing chronic pain problem may require higher doses of analgesia to manage an acute pain episode (Lewis and Williams 2005, Macintyre 2001, Mehta and Langford 2006). It is therefore important to take a history of pre-existing pain and analgesic use so that appropriate analgesic measures can be planned in advance of surgery. This is particularly important for opioid-tolerant patients irrespective of whether opioid tolerance is due to analgesic therapy or recreational opioid drug use (Box 8.11).

Assessment of location and intensity of pain

Location

Many complex surgical procedures involve more than one incision site and the nature and extent of pain at each site may vary. A careful assessment of the location and type of pain is required, because each pain problem may respond to different pain management techniques. Pain location may also help to determine why pain is exacerbated by certain movements or positions (Anderson and Cleeland 2003).

Intensity

As part of the assessment process, it is important to assess the intensity of pain. Only then can the effects of any intervention be

evaluated and care modified as appropriate. The simplest techniques for pain measurement involve the use of a verbal rating scale, numerical rating scale or visual analogue scale. Patients are asked to match pain intensity to the scale. Three principles apply to the use of these scales.

- The patient must be involved in scoring their own pain intensity. It provides the patient with an opportunity to express their pain intensity and also what it means to them and the effect it has on their lives. This is important because healthcare professionals frequently underestimate the intensity of a patient's pain and effectiveness of pain relief (Drayer et al. 1999, Idvall et al. 2002, Loveman and Gale 2000).
- Pain intensity assessment should incorporate different components of pain. This should include assessment of static (rest) pain and dynamic pain (on sitting, coughing or moving the affected part). For example, in a post-operative patient this is important to prevent complications of delayed recovery such as chest infections and emboli (deep vein thrombosis, pulmonary embolism) and to determine if analgesia is adequate for return of normal function (Hobbs and Hodgkinson 2003, Macintyre and Schug 2007).
- It is important to remember that a complete picture of a patient's pain cannot be derived solely from the use of a pain scale (Lawler 1997). Ongoing communication with the patient is required to uncover and manage any psychosocial factors that may be affecting the patient's pain experience.

Chronic pain assessment

There are many pain assessment tools that have been developed specifically for patients with chronic pain (Mann and Carr 2006). Pain assessment tools should be used to support the diagnosis and to determine the effectiveness of any treatment for the pain. The assessment tool should be easy to use and understand by patients and healthcare professionals (Cox 2010). Assessment tools for chronic pain need to be able to define the pain as well as assess the impact the pain is having on the patient's mood and lifestyle. Unidimensional tools can be suitable for the assessment of acute pain but, in chronic pain, more holistic tools are required to facilitate a better understanding of the nature of the pain. The concept of total pain reminds practitioners that pain is a deeply personal experience and that one of the greatest challenges is for nurses to be able to facilitate the expression for each individual of that particular pain (Krishnasamy 2008). Pain assessment needs to acknowledge these facts and particular attention must be paid to factors that will modulate pain sensitivity (Table 8.2).

Assessment in vulnerable and older adults

Pain assessment in vulnerable adults, for example those with cognitive impairment or dementia, and older adults may require

Box 8.11 Key points for managing acute pain in opioid-dependent patients

- Good communication: patients at risk should be identified at preassessment and effective communication maintained between preassessment staff, recovery staff and anaesthetist/pain service.
- Formalization of peri- and post-operative pain management plan.
- Use of adjuvant drugs and regional analgesia peri- and post-operatively to spare opioid use.
- Physical dependence requires baseline pre-operative opioids to be maintained to prevent acute withdrawal symptoms.
- Post-operative opioid requirements may vary depending on the effects of surgery.

Table 8.2 Factors affecting pain sensitivity

Sensitivity increased	Sensitivity lowered
Discomfort	Relief of symptoms
Insomnia	Sleep
Fatigue	Rest
Anxiety	Sympathy
Fear	Understanding
Anger	Companionship
Sadness	Diversional activity
Depression	Reduction in anxiety
Boredom	Elevation of mood

careful consideration. Older people form the population most likely to have their pain inadequately assessed and especially so for those patients who are elderly and have dementia (Ni Thuathail and Welford 2011). Barriers to effective pain relief for this group of patients include issues such as lack of recognition by the staff that the patient is in pain, insufficient education about pain in this group, misdiagnosis of pain and the lack of use of appropriate assessment tools (McAuliffe et al. 2008). The same can be said for people with learning disabilities. It is not uncommon for assumptions to be made that people with learning disabilities do not experience pain and for their pain to go unassessed (Beacroft and Dodd 2010). Assessing pain in people with learning disabilities may require the use of non-verbal pain assessment tools and working closely with family and carers who may recognize indicators that the person with a learning disability is in pain.

Culture and effects on pain assessment

Individuals are greatly influenced by each other and by the cultural groups they belong to. Ethnic, religious and socio-economic factors all affect the way we live in society. Pain is greatly influenced by cultural factors (Fink and Gates 2006). Some groups are stoical regarding expressions of pain whilst others are more expressive, behaviours that may have been learned in childhood. The key in nursing is to ensure patients are cared for in a culturally comfortable way. The principles that can be applied in this situation include the following.

- Understand the patient as a unique person.
- Explore that patient's experience of illness and pain.
- Perceive pain management from the patient's perspective.
- Promote shared decision making and adapt care where possible to meet the patient's expectations (Narayan 2010).

Pre-procedural considerations

Assessment and recording tools

Accurate pain assessment is a prerequisite of effective control and is an essential component of nursing care. In the assessment process, the nurse gathers information from the patient that allows an understanding of the patient's experience and its effect on their life. The information obtained guides the nurse in planning and evaluating strategies for care. Pain is rarely static; therefore, its assessment is not a one-time process but is ongoing.

Pain assessment can be difficult to achieve. For example, the tendency suggested by both research and clinical practice is for the patient not to report any pain or to do so inadequately or inaccurately, minimizing the pain experience (McCaffery and Beebe 1989). Nurses are influenced by a number of variables when assessing the amount of pain a patient is suffering (Kitson 1994). Pargson and Hailey (1999) demonstrated that healthcare providers usually over- or underestimate a patient's pain. It has also been suggested that nurses do not possess sufficient knowledge to care for patients in pain (Drayer et al. 1999, McCaffery and Ferrell 1997). A survey of over 3000 nurses (McCaffery and Robinson 2002) demonstrated that nurse education has improved confidence in the pain assessment process but that further education continues to be required in the pharmacology of pain medications and addressing nurses' fears of opioid addiction and respiratory depression, which continue to contribute to the undertreatment of pain.

A variety of pain assessment tools exist to assist nurses to assess pain and plan nursing care. They enable pain to be successfully assessed and monitored (McCaffery and Beebe 1989, Twycross et al. 1996, Walker et al. 1987) and improve communication between staff and patients (Raiman 1986). Higginson (1998, p.150) notes that: 'Taking assessments directly from the patient is the most valid way of collecting information on their quality of life'. Encouraging patients to take an active role in their pain assessment by using pain tools helps to increase their confidence and makes them feel part of the pain management process.

Some degree of caution, however, must be exercised with the use of pain assessment tools. The nurse must be careful to select the tool that is most appropriate for a particular type of pain experience (Box 8.12). For example, it would not be appropriate to use a pain assessment tool designed for use with patients with chronic pain to assess post-operative pain. Furthermore, pain tools should not be used totally indiscriminately. Walker et al. (1987) found that pain tools appeared to have little value in cases of unresolved or intractable pain.

The use of pain assessment tools for acute pain has been shown both to increase the effectiveness of nursing interventions and to improve the management of pain (Harmer and Davies 1998, Scott 1994). Several pain assessment tools are available. Verbal descriptor scales (VDS) are based on numerically ranked words such as 'none', 'mild', 'moderate', 'severe' and 'very severe' for assessing both pain intensity and response to analgesia. Numerical rating scales (NRS) have both written and verbal forms. The written forms are either a vertical or a horizontal line with '0', indicating no pain, located at one end of the line and '10', indicating severe pain, at the other. This type of scale is easily used as a verbal scale of 0–10 if patients are unable to see or focus on a written scale. Although originally published as a line with a scale of 0–10, there are many versions of it (Williamson and Hoggart 2005). Since many of these scales focus on assessing the intensity of pain, it is important that nurses remember to combine their use of these tools with an assessment of the patient's psychosocial needs.

Other pain assessment tools have been developed to capture the multidimensional nature of pain. These specifically measure several features of the pain experience, including the location and intensity of pain, pattern of pain over time, the effect of pain on the patient's daily function and activities, the effect on the patient's mood and the ability to interact and socialize with others. Examples of these include the McGill Pain Questionnaire (MPQ) (Melzack 1975) and the Brief Pain Inventory which has been validated for use in chronic non-cancer pain (Tan et al. 2004). These are more commonly used in chronic pain assessment. Accurate pain assessment and reassessment are crucial to develop an understanding and baseline measure of the pain. The key is to ask appropriate questions which should seek to cover the following areas. The SOCRATES pain assessment framework is a mnemonic commonly used by healthcare professionals.

- S** – *severity*: none, mild, moderate, severe
- O** – *onset*: when and how did it start?
- C** – *characteristic*: is it shooting, burning, aching – ask the patient to describe it
- R** – *radiation*: does it radiate anywhere else?
- A** – *additional factors*: what makes it better?
- T** – *time*: is it there all the time, is there a time of day when it is worse?
- E** – *exacerbating factors*: what makes it worse?
- S** – *site*: where is the pain?

Box 8.12 Most commonly used pain assessment tools

The most commonly used pain assessment tools meet the following criteria.

- *Simplicity*: ease of understanding for all patient groups.
- *Reliability*: reliability of the tool when used in similar patient groups; results are reproducible and consistent.
- *Valid*: the tool measures the patient's perception of pain.
- *Sensitivity*: sensitivity of the tool to the patient's pain.
- *Accuracy*: accurate and precise recording of data.
- *Interpretable*: meaningful pain scores or data are produced.
- *Feasibility/practicality*: the degree of effort involved in using the tool is acceptable; a practical tool is more likely to be used by patients.

In addition to this, questions relating to the following psychosocial elements should also be addressed.

- The effect of pain on mood.
- Are relationships affected by the pain?
- Physical limitations caused by the pain.
- Social effects: has the pain resulted in a loss of work or loss of role?
- Other types of pain affecting the patient.
- Previous treatments for pain and their effects.
- Other co-morbidities.
- Allergies (Mackintosh and Elson 2008).

Neuropathic pain may require a specific assessment tool. Patients may describe spontaneous pain (arising without detectable stimulation) and evoked pain (abnormal responses to stimuli) (Bennett 2001). The Leeds Assessment of Neuropathic Symptoms and Signs (LANSS) pain scale (Bennett 2001) was developed to more accurately assess this type of pain.

In adults with no or mild cognitive impairment, both numerical rating scales (0–10) and verbal descriptor rating scales (no pain, mild, moderate or severe pain) are reliable and valid for patients' self-report of pain intensity. The Mini Mental State Examination

is the tool most commonly used to assess mental health status and is frequently used as a precursor to pain assessment (Ni Thuathail and Welford 2011). Older or vulnerable adults with moderate-to-severe cognitive/communication impairment may be able to use pictorial rating scales such as the Pain Thermometer or the Faces Pain Scale (Royal College of Physicians, British Geriatric Society and British Pain Society 2007). For patients with dementia or who may be unable to vocalize, an observational tool that assesses pain behaviours may need to be considered, such as the Abbey Scale (Abbey et al. 2004, Royal College of Physicians, British Geriatric Society and British Pain Society 2007). Similarly for patients who have a learning disability, who cannot communicate their pain verbally, the use of pictorial or non-verbal assessment tools may be appropriate and questioning those around the patient who know them well can be a great asset in assessing the pain needs of the person with a learning disability.

Fixed times for reviewing the pain have been omitted intentionally to allow for flexibility. It is suggested that, initially, the patient's pain is reviewed by the patient and nurse every 4 hours. When a patient's level of pain has stabilized, recordings may be made less frequently, for example 12-hourly or daily. The chart should be discontinued if a patient's pain becomes totally controlled.

Procedure guideline 8.11 Pain assessment

Essential equipment

- Select an appropriate assessment tool. For example:
 - in acute pain, consider the use of a verbal or numerical rating scale
 - in chronic pain, consider the use of the British Pain Inventory (BPI)
 - in adults with severe cognitive impairment, consider the use of the Abbey Scale

Pre-procedure

Action

- 1 Explain the purpose of using the chart to the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent and co-operation (NMC 2013, **C**; Sherman et al. 2004, **R4**).

Procedure

- 2 Encourage the patient, where appropriate, to identify pain themselves and to describe the character of the pain, if possible.

The body outline (see Figure 8.12) is a tool for the patient to describe their own pain experience (Sherman et al. 2004, **R4**).

- 3 When it is necessary for the nurse to complete the chart, ensure that the patient's own description of their pain is recorded.

To reduce the risk of misinterpretation. **E**

- 4 (a) Record any factors that influence the intensity of the pain, for example activities or interventions that reduce or increase the pain such as distractions or a heat pad.
(b) Record whether or not the patient is pain free at night, at rest or on movement.
(c) Record frequency of pain, what helps to relieve the pain, what makes the pain worse and how the patient feels when they are in pain.
(d) Determine if there are any associated symptoms when the pain is present, i.e. nausea and vomiting.

Ascertaining how and when the patient experiences pain enables the nurse to plan realistic goals. For example, relieving the patient's pain during the night and while they are at rest is usually easier to achieve than relief from pain on movement (Davis and McVicker 2000, **E**).

To gain an understanding of the experience of pain for the patient (Twycross and Wilcock 2001, **R5**).

To ensure all elements of a pain assessment are explored (Macintyre and Schug 2007, **E**).

- 5 Index each site (Figure 8.12) in whatever way seems most appropriate, for example shading or colouring of areas or arrows to indicate shooting pains.

This enables individual pain sites to be located (Sherman et al. 2004, **R4**).

(continued)

Procedure guideline 8.11 Pain assessment (*continued*)

Action

- 6 Give each pain site a numerical value according to the pain intensity or the pain scale and note time recorded where possible.
If cognitive impairment is present then complete an appropriate tool so that the patient does not need to verbalize a pain score.
- 7 Record any analgesia given and note route, dose and response.

Rationale

To indicate the intensity of the pain at each site (Turk and Okifuji 1999, **E**).
To ensure that the patient's pain is assessed as well as possible (Abbey et al. 2004, **E**).
To monitor efficacy of prescribed analgesia (Twycross and Wilcock 2001, **R5**).

Post-procedure

- 8 Record any significant activities that are likely to influence the patient's pain.
- 9 Discuss with the patient an ongoing reassessment plan for pain.

Extra pharmacological or non-pharmacological interventions might be indicated (Disorbio et al. 2006, **E**; Turk and Okifuji 1999, **E**).
To ensure that the patient is informed regarding ongoing pain assessment and understands when to alert the nurse if needing additional help, for example when there is a change in nature of the pain or when the pain is not responding to the planned treatment or activities of daily living are being inhibited which previously could be maintained (Macintyre and Schug 2007, **E**).

Figure 8.12 Body diagram used for pain assessment.

Pain management

Evidence-based approaches

Pain management uses a multidisciplinary team approach that matches therapy to the individual patient. In some instances simple analgesia can be sufficient to control pain. Simple or non-opioid analgesics include paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) used either individually or in combination.

Multimodal analgesia

Multimodal or balanced analgesia involves the use of more than one analgesic compound or method of pain control to achieve

additive (or synergistic) pain relief while minimizing adverse effects (Schug and Chong 2009). This allows for lower doses of individual drugs. It combines different analgesics that act by different mechanisms and at different sites in the nervous system. The aim is to achieve greater analgesia than each of the individual drugs could provide alone.

Opioids, non-opioids (such as paracetamol, NSAIDs, cyclooxygenase-2-selective inhibitors [COX-2]), local anaesthetics and anticonvulsants are all examples of drugs that may be used as part of a multimodal analgesic approach. An example of multimodal analgesia to manage acute post-operative pain would be a continuous epidural infusion of a combined opioid and local anaesthetic solution in combination with paracetamol and an NSAID (if not contraindicated). Another example would be a continuous peripheral nerve block with paracetamol and an NSAID. Both of these approaches combine different analgesic compounds and analgesic approaches (oral route, epidural route and peripheral nerve block).

A multimodal approach may also include non-pharmacological approaches such as relaxation therapy, imagery, transcutaneous electrical nerve stimulation (TENS) and heat therapy.

Management of persistent chronic and cancer pain

The control of pain is directed by the 'analgesic ladder', which was presented by the World Health Organization (WHO) in 1996 as a guide to the management of persistent cancer pain (Figure 8.13). It is also often used to guide the management of chronic persistent pain. It involves a stepwise approach to the use of analgesics, including non-opioids (step 1), opioids for mild-to-moderate pain (step 2) and opioids for moderate-to-severe pain (step 3). Adjuvant drugs are those that contribute to pain relief but are not primarily indicated for pain management. They can be used at all steps of the ladder. Examples include antidepressant and anticonvulsant drugs, corticosteroids, benzodiazepines, antispasmodics and bisphosphonates. The WHO treatment guide recommends the following five points for the correct use of analgesics.

- Administered orally if appropriate.
- Given at regular intervals.
- Prescribed according to assessment of pain intensity evaluated using a pain intensity scale.
- The dose of the analgesic should be adapted to the individual. There is no standard dose to treat certain types of pain.

- Analgesia should be prescribed with ongoing review, monitoring for effectiveness and side-effects (WHO 1996).

Therefore, some patients who present with severe pain will need to start on step 3 of the ladder; it would not be appropriate to progress through each step in this circumstance. Treatment of chronic/cancer pain does not necessarily begin with step 1, progress to step 2 and follow with step 3 (Eisenberg et al. 2005).

It is important to remember that the patient will experience different types of pain due to different aetiological and physiological changes. Each pain needs to be assessed separately, since the pain may need to be managed in a different manner and one analgesic intervention or route will rarely be sufficient. Often the best practice is to combine different types of analgesia in order to achieve maximum pain control (Table 8.3). It is also important to utilize non-pharmacological interventions at all stages of the treatment plan.

Accurate ongoing assessment is imperative for efficient and effective pain control.

Methods of pain management

Using the WHO analgesic ladder

The analgesic ladder was designed as a framework for the management of chronic pain (see Figure 8.13). There are several drugs available to manage chronic pain and the analgesic ladder allows the flexibility to choose from the range according to the patient's requirements and tolerance (Hanks et al. 2004). For acute pain management, the WHO ladder can be used as a guide in reverse, starting at step 3 for immediate post-operative pain and moving down through step 2 and then step 1 as post-operative pain improves.

Step 1: non-opioid drugs

Examples of non-opioid drugs include paracetamol, aspirin and NSAIDs that are effective for mild-to-moderate pain. These drugs are especially effective for musculoskeletal and visceral pain (Twycross and Wilcock 2001).

Table 8.3 The use of adjuvant drugs (co-analgesics)

Type	Use	Examples
Non-steroidal anti-inflammatory drugs	Bone pain	Diclofenac
	Muscular pain	Naproxen
	Inflammation	Ibuprofen
	Visceral pain	
Steroids	Pressure	Dexamethasone
	Bone pain	Prednisolone
	Inflammation	
	Raised intracranial pressure	
Tricyclic antidepressants	Neuropathic pain	Amitriptyline
Anticonvulsants		Sodium valproate
		Carbamazepine
		Gabapentin
		Pregabalin
Antibiotics	Infection	Flucloxacillin
		Trimethoprim
Benzodiazepines	Anxiety	Diazepam
		Clonazepam
Antispasmodics	Spasms	Baclofen
Bisphosphonates	Bone pain	Sodium clodronate
		Disodium pamidronate
		Zoledronic acid

Step 2: opioids for mild-to-moderate pain

Examples of opioids for mild-to-moderate pain include codeine, dihydrocodeine, tramadol and low-dose oxycodone (steps 2 and 3). These drugs are used when adequate pain management is not achieved with non-opioids and are usually used in combination formulations. It is not recommended to administer another analgesic from the same group if the drug being used is not controlling the pain. Uncontrolled pain needs to be assessed and managed with the titration of an opioid by moving up the ladder. The exception to this would be if the patient was experiencing intolerable side-effects on the weak opioid and an alternative drug might be beneficial.

Step 3: opioids for moderate-to-severe pain

Examples of opioids for moderate-to-severe pain include morphine, oxycodone, fentanyl, diamorphine, methadone, buprenorphine, hydromorphone and alfentanil.

Methods of drug delivery

Oral analgesia

Oral opioids are used less frequently in the immediate post-operative period because many patients are nil by mouth or on restricted oral intake for a period of time. Often this route is used if patients require strong analgesics following discontinuation of epidural or intravenous analgesia. Morphine is an ideal oral preparation because it is available as a tablet (Sevredol) or an elixir (Oramorph). Oxycodone can be given as second-line opioid

treatment if patients are allergic/sensitive to or fail to respond to morphine.

Intravenous analgesia

Continuous intravenous infusions of opioids such as morphine, diamorphine and fentanyl are effective for controlling pain in the immediate post-operative period. Their use is often restricted to critical care units where patients can be closely monitored because of the potential risk of respiratory depression (Macintyre and Schug 2007). Compared with patient-controlled analgesia (PCA), continuous infusions of opioids for acute pain management in a general ward setting resulted in a fivefold increase in the incidence of respiratory depression (Schug and Torrie 1993).

Patient-controlled analgesia is an alternative and safer technique for giving intravenous opioids (usually morphine, diamorphine, fentanyl or oxycodone) in the ward environment (Sidebotham et al. 1997). With PCA, patients self-administer intermittent doses of opioids, by using an infusion pump and timing device. When in pain, the patient presses a button connected to the pump and a set dose of opioid is delivered (usually intravenously but it may also be given subcutaneously) to the patient (Macintyre and Schug 2007).

There are a number of advantages to using PCA.

- PCA is more likely to maintain reasonably constant blood concentrations of the opioid within the analgesic corridor. This is the blood level where analgesia is achieved without significant side-effects. The flexibility of PCA helps to overcome the wide interpatient variation in opioid requirements (Macintyre and Schug 2007).
- PCA allows patients to titrate analgesia against daily variations in the pain stimulus (Tye and Gell-Walker 2000). By using a PCA pump, patients can administer analgesia as soon as pain occurs and titrate the dose according to increases and decreases in the pain stimulus. This is particularly helpful for controlling more intense pain during movement.
- PCA prevents delays in patients receiving analgesics (Chumbley et al. 2002).

Whilst PCA may be very effective for controlling pain for a number of patients undergoing surgery (Macintyre and Schug 2007), it is not suitable for the groups listed in Box 8.13.

Epidural analgesia

Epidural analgesia refers to the provision of pain relief by continuous administration of analgesic pharmacological agents (usually low concentrations of local anaesthetics and opioids) into the epidural space via an indwelling catheter (Macintyre et al. 2010). Giving analgesia epidurally is a particularly valuable technique for the prevention of post-operative pain in patients undergoing major thoracic, abdominal and lower limb surgery, and can sometimes be used to manage the pain associated with trauma. Commonly used opioids for epidural analgesia include fentanyl and diamorphine (Wheatley et al. 2001). Combinations of low concentrations of local anaesthetic agents and opioids have been shown to provide consistently superior pain relief compared with either drug alone (Macintyre and Schug 2007).

Box 8.13 Patients for whom patient-controlled analgesia (PCA) is inappropriate

- Those who are unable to activate the PCA device due to problems with dexterity or visual impairment.
- Those who are unable to understand the concept of PCA, particularly the very young or patients who are confused.
- Those who do not wish to take responsibility for their pain control.

Subcutaneous analgesia

Opioids are often given subcutaneously to manage chronic cancer pain. More recently, there has been an increase in the use of subcutaneous opioids for post-operative pain control. Both PCA and nurse-administered opioid injections of morphine, diamorphine or oxycodone via an indwelling subcutaneous cannula have been used successfully to manage postoperative pain (Macintyre and Schug 2007). An advantage of giving analgesia subcutaneously is that it avoids the problems associated with maintaining intravenous access.

Intramuscular analgesia

Until the early 1990s, regular 3–4-hourly intramuscular injections of opioids such as pethidine and morphine were routinely used for the management of post-operative pain. Because alternative techniques such as PCA and epidural analgesia are now available, intramuscular analgesia is used less frequently. Some useful algorithms have been developed to give guidance on titrating intramuscular analgesia (Harmer and Davies 1998, Macintyre and Schug 2007). Absorption via this route may be impaired in conditions of poor perfusion (e.g. in hypovolaemia, shock, hypothermia or immobility). This may lead to inadequate early analgesia (the drug cannot be absorbed properly and reach the systemic circulation and so forms a drug depot) and late absorption of the drug depot (where the drug has remained in the muscular tissue and is absorbed only once perfusion is restored) (Macintyre et al. 2010).

Transdermal analgesia

Transdermal analgesia is a simple method of giving analgesia. It is convenient, and often very acceptable to patients, particularly those who dislike tablets or have many to take. A number of patch formulations have been developed to allow the delivery of drugs across the skin (such as fentanyl, buprenorphine or local anaesthetics). Disadvantages of giving strong opioids such as fentanyl by this route include inflexibility (the patient usually has to be on a stable dose of an opioid and it takes a long time for a dose increase to take effect) and breakthrough doses must be given by another route (oral, buccal or sublingual).

Buccal or sublingual analgesia

Buccal means the analgesia is placed between the upper lip and the lining of the upper gum. A sublingual drug is placed under the tongue. Drugs given by this route pass directly into the systemic circulation and bypass first-pass metabolism. Their speed of onset is often rapid (Stannard and Booth 2004).

Pre-procedural considerations

Pharmacological support

Non-opioid analgesics

Paracetamol and paracetamol combinations

The use of non-opioid analgesics such as paracetamol or paracetamol combined with a weak opioid such as codeine is recommended for managing pain following minor surgical procedures or when the pain following major surgery begins to subside (McQuay et al. 1997). Paracetamol can also be given rectally if the oral route is contraindicated. An intravenous preparation of paracetamol is now available and can provide effective analgesia after surgical procedures (Romsing et al. 2002). It is more effective and of faster onset than the same dose given enterally. The use of the intravenous form should be limited to patients in whom the enteral route cannot be used. With regard to dosing schedules for parenteral administration of paracetamol, the dose should be reduced for those who weigh 50 kg or under. For example, patients who weigh 33–50 kg should not exceed a maximum daily dose of 60 mg/kg, not exceeding 3 g. For patients over 50 kg with an additional risk factor for hepatotoxicity, the maximum daily dose should be 3 g in 24 hours and for those patients over 50 kg

with no risk factor then the maximum daily dose can be up to 4 g (Bristol-Myers Squibb 2012).

Paracetamol taken in the correct dose of not more than 4 g per day is relatively free of side-effects. When used in combination with codeine preparations, the most frequent side-effect is constipation.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) have been shown to provide better pain relief than paracetamol combinations for acute pain (McQuay et al. 1997). These drugs can be used alone or in combination with both opioid and non-opioid analgesics. Two commonly used NSAIDs are diclofenac, which can be administered by the oral, parenteral, enteral or rectal route, and ibuprofen, which is available only as an oral or enteral preparation. The disadvantage of both of these is that often side-effects such as coagulation problems, renal impairment and gastrointestinal disturbances limit their use. Newer COX-2-specific NSAIDs have the advantage that they have similar analgesic and anti-inflammatory effects (Reicin et al. 2001) but have no effect on platelets or the gastric mucosa (Rowbotham 2000). As a result, coagulation problems and gastrointestinal irritation are likely to be significantly reduced. However, recently, several of these drugs have been withdrawn from the market due to long-term cardiovascular side-effects and it will take time for newer products with an improved safety profile to re-establish themselves in practice (Macintyre et al. 2010).

A recent meta-analysis has suggested that there is little evidence to suggest that any of these drugs are safe in cardiovascular terms. Compared with placebo, rofecoxib was associated with the highest risk of myocardial infarction and ibuprofen with the highest risk of stroke followed by diclofenac. Diclofenac and lumiracoxib were associated with the highest risk of cardiovascular death. Naproxen is viewed as being least harmful for cardiovascular safety but this advantage should be weighed against gastrointestinal toxicity (Trelle 2011).

Opioid analgesics

Opioids are the first-line treatment for pain that follows major surgery (Macintyre and Jarvis 1996) and can also be prescribed for cancer and non-cancer-related chronic pain. Opioid doses need to be titrated carefully to achieve pain relief to suit each individual patient while minimizing any unwanted side-effects (McQuay et al. 1997).

A number of opioids are used for controlling pain following surgery. These include morphine, diamorphine, fentanyl and oxycodone. The most common routes of opioid administration are intravenous, epidural, subcutaneous, intramuscular or oral.

Evidence for the concept of opioid rotation when patients have intolerable opioid-related side-effects originates from cancer pain studies (Quigley 2004) but it may be a useful strategy to consider in the management of acute pain as well.

Opioids for mild-to-moderate pain

Tramadol

It has been suggested that despite progress in pain management, chronic non-cancer pain (CNCP) still represents a clinical challenge (Coluzzi and Mattia 2007). The efficacy and safety profile of tramadol make it suitable as a long-term treatment in a variety of CNCP conditions (Coluzzi and Mattia 2007). In recent studies tramadol has also been recognized as being efficacious in the management of chronic cancer pain of moderate severity (Davis et al. 2005).

It is uncertain whether tramadol is more effective than other opioids for mild-to-moderate neuropathic pain; one report suggests a reduction in allodynia (pain from stimuli which are not normally painful) (Sindrup and Jensen 1999, Twycross and Wilcock 2001). Nurses should be aware that circumstantial reports suggest that tramadol lowers seizure threshold, and therefore care needs to be

taken in those patients who have a history of epilepsy, as well as any other medications that may contribute to the lowering of the seizure threshold, for example tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) (Twycross and Wilcock 2001). Few patients with severe pain will achieve a satisfactory level of pain control with tramadol. It is available in immediate and modified-release preparations.

Tramadol has been shown to be an effective analgesic for post-operative pain (McQuay and Moore 1998, Reicin et al. 2001). Although tramadol does have some side-effects, which include nausea and dizziness, it is free of NSAID side-effects and causes less constipation than codeine preparations and opioids (Bamigbade and Langford 1998). The combination of tramadol with paracetamol is more effective than either of the two components administered alone (McQuay and Edwards 2003).

Codeine phosphate

Codeine is metabolized by the hepatic cytochrome CYP2D6 to morphine. Approximately 7% of Caucasians and 1–3% of the Asian population are poor CYP2D6 metabolizers and therefore do not experience effective analgesia with codeine.

Codeine is available in tablet and syrup formulations. Doses of 30–60 mg po qds are generally prescribed to a maximum of 240 mg/24 h. It is also available in combination preparations with a non-opioid. The combination preparations are available in varying strengths of codeine and paracetamol, including co-codamol 8 mg/500 mg, 15 mg/500 mg and 30 mg/500 mg.

Opioids for the management of chronic non-cancer pain

Opioids are being used increasingly to treat persistent pain. They have a well-established role in the management of acute pain and for those with cancer and palliative care needs. There is evidence from research that opioids can be helpful in the short and medium term in providing symptomatic pain relief from other non-cancer pain conditions (British Pain Society 2010). Opioids are prescribed to reduce pain intensity. Rarely is pain completely relieved by opioids alone (British Pain Society 2010). In approximately 80% of cases patients will experience at least one adverse side-effect from opioids. Opioids should be given careful consideration before they are commenced and patients should be informed that the effects of long-term use of opioids is unknown in terms of effects on endocrine and immune function (British Pain Society 2010). When opioid therapy is commenced, a plan to review the patient in terms of opioid effects must be in place. From a palliative care perspective, there is new guidance available from NICE to support safe prescribing of opioids (NICE 2012).

Morphine

A large amount of information and research is available concerning morphine and therefore it tends to be the first-line opioid (of choice). It is available in oral, rectal, parenteral and intraspinal preparations.

All strong opioids require careful titration from an expert practitioner. Where possible, modified-release preparations should be used at regular intervals in the management of persistent pain (British Pain Society 2010). For patients who are requiring in excess of 120–180 mg of morphine or equivalent, advice from a pain specialist should be sought. Patients should be informed of potential side-effects such as constipation, nausea and increased sleepiness, in order to allay any fear. The patient should also be told that nausea and drowsiness are transitory and normally improve within 48 hours, but that constipation can be an ongoing problem and it is recommended that a laxative should be prescribed when the opioid is started. The most effective laxative for this group of patients is a combination of both a softening and a stimulating laxative (Davis et al. 2005).

Patients often have many concerns about commencing strong drugs such as morphine. Fears frequently centre around addiction and abuse (Cherny 2010). Time should be taken to reassure

patients and their families and provide verbal and written information (NICE 2012).

Although morphine is still considered to be the opioid drug of choice for moderate-to-severe pain (Hanks et al. 2004), alternative opioids allow the practitioner to carefully assess the patient on an individual basis and select the most appropriate one to use.

Durogesic (fentanyl)

Fentanyl is a strong opioid, available in a patch, which is recommended in patients who have stable pain requirements. Transdermal patches are available in doses of 12, 25, 50, 75 or 100 micrograms per hour. It is reported to have an improved side-effect profile in comparison to morphine in relation to constipation (Cherny and Catane 2010), although some patients experience nausea and mild drowsiness (BMA/Royal Pharmaceutical Society of Great Britain 2008). Use of the patch has increased because it frees the patient from taking tablets.

Changing of the patch is recommended every 3 days but in some circumstances patients may require a dosing interval of 2 days (Cherny and Catane 2010). The patch should be applied to skin that is free from excess hair and any form of irritation and should not be applied to irradiated areas. It is advisable to change the location on the body to avoid an adverse skin reaction. Occasionally difficulties arise relating to the titration of the patch as each patch is equivalent to a range of morphine (Table 8.4).

Methadone

Methadone is a synthetic opioid developed more than 40 years ago (Riley 2006). It is available in oral, rectal and parenteral preparations. There has been some reluctance amongst professionals to use methadone, which arose from the difficulties experienced in titrating the drug due to its long half-life (15 hours) that caused accumulation to occur, especially in the elderly (Gannon 1997). There are different methods of achieving effective titration (Gannon 1997); for example, one regimen is to calculate one-tenth of the total daily dose of morphine (maximum starting dose must not exceed 30 mg). Administer the methadone to the patient on an as-required basis but not within 3 hours of the last fixed dose. The total dose required over a 24-hour period is calculated after 5–6 days, divided and given as a two or three times daily regimen and this avoids the build-up of methadone within the body (Morley and Makin 1998). Titration is recommended in a hospital setting to ensure accurate administration. This can be difficult for patients because they have to experience pain before they are administered a dose of methadone in the titration period.

Methadone can be a cheap, effective alternative to morphine if titration is supervised by the specialist pain or palliative care team (Gardner-Nix 1996).

It is particularly useful in patients with renal failure. Morphine is excreted via the kidneys and, if renal failure occurs, this may lead to the patient experiencing severe drowsiness as a result of accumulation of morphine metabolites (Gannon 1997). Methadone is

lipid soluble and is metabolized mainly in the liver. About half of the drug and its metabolites are excreted by the intestines and half by the kidneys. Methadone should be used with the advice of a pain specialist

Oxycodone

Oxycodone is available as an immediate or modified-release preparation and titration should occur in the same way as morphine. Oxycodone is a useful alternative to morphine (Riley 2006). It has similar properties and can be administered orally, rectally and parenterally. Oxycodone has similar side-effects and is usually given 4–6 hourly. It has an analgesic potency 1.5–2.0 times higher than morphine. It has similar side-effects to morphine, although oxycodone has been found to cause less nausea (Heiskanen and Kalso 1997) and significantly less itchiness (Mucci-LoRusso et al. 1998).

A study by Riley (2012) identified that on a population level there is no difference between morphine and oxycodone in terms of analgesia efficacy and tolerability.

Targinact

This drug is a combination of modified-release oxycodone and naloxone. The aim of this combination is to prevent the potential negative effects on bowel function. It is suggested that approximately 97% of the naloxone is eliminated by first-pass metabolism in the healthy liver, preventing it from significantly affecting analgesic effects (Vondrackova et al. 2008).

Tapentadol

Tapentadol is a centrally acting opioid analgesic supported by evidence for the management of acute and severe chronic pain (Schwartz et al. 2011, Wild et al. 2010). It is available in oral preparations in immediate- and modified-release forms. The conversion factor for tapentadol from oral morphine is 2.5:1. Therefore 10 mg oral morphine is equivalent to 25 mg of tapentadol. Side-effects associated with tapentadol are similar to other opioids, including dizziness, headaches, somnolence, nausea and constipation.

Diamorphine

Diamorphine is used parenterally in a syringe pump or PCA pump for the control of moderate-to-severe pain when patients are unable to take the oral form of morphine. It is calculated by dividing the total daily dose of oral morphine by three. Breakthrough doses are calculated by dividing the 24-hour dose of diamorphine by six and administering on an as-required basis (Fallon et al. 2010).

Buprenorphine

Buprenorphine is an alternative strong opioid available in patch form. The patch has similar advantages to fentanyl but does not contain a reservoir of the drug. Instead, it is contained in a matrix form with effective levels of the drug being reached within 24 hours. Titration is recommended with an alternative opioid initially and then transfer to the patch when stable requirements have been reached. A lower dose patch (Butrans) is available in strengths of 5, 10 and 20 µg/h that should be worn continuously by the patient for 7 days. The higher dose patch (Transtec) of 35, 52.5 and 70 µg/h is now licensed to be used up to 96 hours or twice weekly for patient convenience. Conversion is based on the chart supplied by the pharmaceutical company which demonstrates equivalent doses. Buprenorphine is also available as a sublingual tablet, which is titrated from 200 to 800 µg 6 hourly. Conversion is based on multiplying the total daily dose of buprenorphine by 100 to give the total daily dose of morphine (i.e. 200 µg buprenorphine/8-hourly = 600 µg buprenorphine/24 hours = 60 mg morphine/24 hours) (Budd 2002).

Transmucosal opioids such as fentanyl citrate (Actiq), Absoral, Effentora and intranasal preparations such as Pecfent are licensed to be used for the treatment of cancer breakthrough pain.

Table 8.4 Recommended conversion rate guide from oral morphine to 72-hour fentanyl patch

Morphine dose in 24 hours (mg)	Fentanyl TTS (µg/h)
30	12
60	25
120	50
180	75
240	100

TTS, transdermal therapeutic system.

There are some circumstances when these agents are used off licence but they should always be used under the guidance of a specialist.

Oral transmucosal fentanyl citrate (Actiq)

Licensed for the management of breakthrough pain in patients who are already on an established maintenance dose of opioid for cancer pain, oral transmucosal fentanyl citrate (OTFC) is a lozenge which is rubbed against the oral mucosa on the side of the cheek which leads to the lozenge being dissolved by the saliva. The advantage of OTFC is its fast onset via the buccal mucosa (5–15 minutes) and its short duration (up to 2 hours). It is available in a range of doses (200–1600 µg) but there is no direct relation between the baseline analgesia and the breakthrough dose. Titration can be difficult and lengthy as the recommended starting dose is 200 µg with titration upwards (Portenoy et al. 1999). It is recommended that the lozenge be removed from the mouth if the pain subsides before it has completely dissolved. The lozenge should not be reused but should be dissolved under running hot water.

Fentanyl buccal tablet (Effentora)

This is a licensed medication for breakthrough pain in adults with cancer who are already receiving a maintenance opioid for chronic cancer. Patients receiving maintenance opioid therapy are those who are taking at least 60 mg of oral morphine daily, at least 25 µg of transdermal fentanyl per hour, at least 30 mg of oxycodone daily, at least 8 mg of oral hydromorphone daily or an equi-analgesic dose of another opioid for a week or longer. This buccal tablet is available in 100, 200, 400, 600 and 800 µg. It is placed on the oral mucosa above the third upper molar which leads to the tablet being dissolved by the saliva. It usually takes 15–25 minutes for the tablet to dissolve. It is recommended that if the tablet has not completely dissolved within 30 minutes then the remainder of the tablet should be swallowed with water as it is thought that the tablet will then only be likely to consist of inactive substances rather than active fentanyl (Darwish et al. 2007).

Abstral is an oral transmucosal delivery formulation of fentanyl citrate, indicated for the management of breakthrough pain in patients using opioid therapy for chronic cancer pain (Rauch et al. 2009). The tablet is administered sublingually and it rapidly disintegrates, ensuring the fentanyl dissolves quickly. Abstral is available in six dosing strengths: 100, 200, 300, 400, 600 and 800 µg fentanyl citrate.

Adjuvant drugs (co-analgesics)

Most chronic pain contains elements of neuropathic pain. Patients with nociceptive pain are likely to gain some benefit from conventional medications such as NSAIDs but these drugs come with a strong side-effect profile. Individuals with neuropathic pain are likely to gain some relief from co-analgesics such as tricyclic antidepressants (e.g. amitriptyline and nortriptyline) and anticonvulsant drugs (e.g. gabapentin and pregabalin) (Mackintosh and Elson 2008).

The WHO analgesic ladder recommends the use of these drugs in combination with non-opioids, opioids for mild-to-moderate pain and opioids for moderate-to-severe pain (see Figure 8.13).

Nitrous oxide (Entonox)

Inhaled nitrous oxide provides analgesia that is short acting and works quickly. It has a special role in managing pain associated with procedures such as wound dressings, drain removal and in acute trauma (see section on 'Entonox administration' below for further details).

Local anaesthetics

In addition to epidural analgesia, local anaesthetics may be used to block individual or groups of peripheral nerves during surgical procedures and to infiltrate surgical wounds at the end of an

operation (Carroll and Bowsher 1993). Occasionally these techniques may be used to extend the duration of post-operative analgesia beyond the finite period that a single injection technique provides (Macintyre et al. 2010). Techniques include regular intermittent bolus doses or continuous infusions of local anaesthetic.

A topical preparation (patch) containing local anaesthetic is also available to manage acute or chronic neuropathic pain in areas of intact skin with hypersensitivity.

Cannabis

Studies are currently examining the potential benefits of using cannabis for the management of chronic conditions, for example multiple sclerosis and cancer. There is some evidence for relief of spasticity and neuropathic pain and for improvement in sleep (Lynch and Campbell 2011). Further studies in pain and on long-term treatment risks and benefits are needed.

Anaesthetic interventions for managing complex cancer-related pain

Sometimes it is difficult to attain and maintain adequate pain control without significant side-effects and it is in situations such as this that anaesthetic interventions may be of benefit.

Effective control can be achieved by epidural or intrathecal (spinal) infusions:

- as single injections for simple nerve blocks, or
- regional nerve blocks which target individual nerves, plexi or ganglia (Hicks and Simpson 2004).

Examples include managing pelvic pain and post-radiation brachial plexopathy.

These interventions can be useful but careful consideration and assessment must take place to ensure that any potential side-effects are discussed with the patient (anaesthetic interventions may severely limit the patient's activities) and that future planning is addressed with the patient and family as an epidural/intrathecal infusion may limit discharge options for the patient who is dying.

Education of patient

Opioids and driving

In the UK patients who are prescribed opioids are permitted to drive. The British Pain Society has suggested under certain circumstances that patients who are taking opioids should not drive. These circumstances include:

- The condition for which they are being treated has physical consequences that might impair their driving ability.
- They feel unfit to drive.
- They have just started opioid treatment.
- The dose of opioid has been recently adjusted upwards or downwards (as withdrawal of opioids can also have an impact on driving).
- They have consumed alcohol or drugs that can produce an additive effect.

The Driving and Vehicle Licensing Agency (DVLA) is the only legal body that can advise a patient about their right to hold a driving licence. Patients starting opioids should be advised to inform the DVLA that they are now taking opioids and prescribers should document that this advice has been given (British Pain Society 2010).

Complications

The use of opioids in renal failure

Renal failure can cause significant and dangerous side-effects due to the accumulation of the drug. A systematic review in patients with cancer pain has concluded that fentanyl, alfentanil and

methadone, with caveats, are the medications likely to cause least harm in patients with renal impairment when used appropriately (King et al. 2011). Basic guidelines for pain management in renal failure include the following.

- Reduce analgesia dose and/or dose frequency (6-hourly instead of 4-hourly).
- Select a more appropriate drug (not renally excreted).
- Avoid modified-release preparations.
- Seek advice from a specialist pain/palliative care team and/or pharmacist (Farrell and Rich 2000).

372 Non-pharmacological methods of managing pain

Optimal pain control is more likely to be achieved by combining non-pharmacological with pharmacological techniques. Despite the lack of research evidence to support the effectiveness of many non-pharmacological techniques, their benefits to patients and families should not be underestimated.

Psychological interventions

A number of simple psychological interventions can improve a patient's pain control by:

- reducing anxiety, stress and muscle tension
- distraction (distraction plays a role in pain management by pushing awareness of pain out of central cognition)
- increasing control and pain-coping mechanisms
- improving general well-being.

Some simple interventions include the following.

Creating trusting therapeutic relationships

By creating trusting relationships with patients, nurses are instrumental in reducing anxiety and helping patients to cope with pain. Nurses may underestimate the benefits and comfort they bring by staying with a patient who is experiencing pain (Mann and Carr 2006). Nurses can help to create a trusting relationship by:

- listening to the patient
- believing the patient's pain experience (Seers 1996)
- acting as a patient advocate
- providing patients with appropriate physical and emotional support.

The use of gentle humour

Pasero and McCaffery (1998) suggest that many patients find gentle humour an effective way of coping with pain. Humour may be particularly helpful prior to a painful procedure as it can have a lasting effect. In the clinical setting, humorous tapes, books and videos can be made available for patient use.

Information/education

Patient information/education can make all the difference between effective and ineffective pain relief. Information/education helps to reduce anxiety (Macintyre and Schug 2007, Taylor 2001) and enables patients to make informed decisions about their care. Patients should be given specific information about why pain control is important, what to expect in terms of pain relief, how they can participate in their management and what to do if pain is not controlled. Some caution is required, however, because not all patients respond positively to the same level of information. Patients with high levels of anxiety may find that detailed information can increase their anxiety and influence their pain control. New NICE guidance on the safe prescribing of opioids suggests that all patients who start on opioids should be offered written information to support them (NICE 2012).

Relaxation

Whilst scientific evidence for the effectiveness of relaxation techniques is limited (Carroll and Seers 1998, Seers and Carroll 1998),

a number of studies have shown benefits for patients experiencing pain (Good et al. 1999, Lang et al. 2000, Sloman et al. 1994). Payne (1995) describes several relaxation techniques ranging from simple breathing techniques to progressive muscle relaxation and more complex techniques. One simple relaxation technique script that has been adapted for use at the Royal Marsden Hospital is outlined in Box 8.14. This technique can be taught to patients and used during painful procedures or at times when the patient feels anxious or stressed. Patients should be encouraged to practise the technique to gain mastery.

Music

The use of music in the healthcare setting can also provide relaxation and distraction from pain (Beck 1991, Good 1996, Heiser et al. 1997). Setting up a library of music (e.g. easy listening, classical) and having personal listening devices available for patient use is a simple way to provide patients with relaxing music. Vaajoki et al. (2012) reported significantly lower pain intensity and pain distress in bedrest on the second post-operative day in a music group compared with a control group after elective abdominal surgery.

Art

Art therapies can assist the patient in moving the focus of attention away from the physical sensation of pain (Bullington et al. 2005, Pavlek 2008). The skills of an art therapist are required to ensure the successful use of this intervention.

Physical interventions

In addition to psychological interventions, a number of physical interventions can be helpful in reducing pain.

Box 8.14 Simple relaxation technique script

Relaxation technique script

Please note that breathing rate during this technique should be normal for the patient in their present condition.

- 1 Loosen any tight clothing and position yourself comfortably, either lying or sitting. Have your arms and legs uncrossed. Ensure your back and head are well supported.
- 2 Allow both your hands to rest on your abdomen, one on top of the other. It may be helpful to place a pillow on your lap for your hands to rest on.
- 3 Gently allow your eyes to close. Breathe normally in and out through your nose if you find this comfortable.
- 4 As you breathe in, be aware of your abdomen rising gently under your hands (do not force this movement).
- 5 As you breathe out, be aware of your abdomen relaxing under your hands.
- 6 Let your shoulders relax and drop down.
- 7 Let your jaw relax.
- 8 Now keep your attention softly focused on the rise and fall of your abdomen as this movement follows each breath.
- 9 Repeat steps 4–8 for between 3 and 5 minutes or longer if appropriate.

During the exercise

As you become aware of any thoughts that arise, let them go and just bring your attention back to the rise and fall of the abdomen. If you are still having difficulty focusing on the technique, try saying the following phrases: 'I am relaxed' or 'I feel calm'.

To finish the exercise

Now slowly become aware of your surroundings, stretch out your fingers and toes, gently open your eyes and come back to the room.

Comfort measures

Simple comfort measures such as positioning pillows and bed-linen (such as supporting a painful limb) (Mann and Carr 2006) can help the patient feel more relaxed and improve patient comfort and pain control. Other comfort measures include ensuring that interruptions and noise are minimized to promote rest and ensuring the ambient temperature is comfortable.

Exercise

Both passive and active physical exercises may benefit patients by increasing range of motion (Feine and Lund 1997), preventing joint stiffness and muscle wasting which may further compound pain problems. Exercise should always be tailored to the patient's tolerance and stamina. A simple exercise regimen which is practised regularly and supervised by a therapist can help patients feel better and more in control as well as having benefits in terms of pain relief. It can increase mobility and flexibility whilst restoring confidence and challenging fear avoidance behaviour (Mann and Carr 2006).

Rest

In addition to exercise, teaching patients to rest comfortably in any position when in pain is a meaningful action and the base from which a person can learn to move more easily (O'Connor and Webb 2002). A person with a terminal illness may experience restriction of movement and neuromuscular pain with increased tension. For these patients, learning to rest and letting go of any tension can be helpful.

Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) (Figure 8.14) is thought to work by sending a weak electrical current through the skin to stimulate the sensory nerve endings. Depending on the stimulation parameters used, TENS is thought to modulate pain impulses by closing the gate to pain transmission within the spinal cord by stimulating the release of natural pain-relieving chemicals in the brain and spinal cord (King 1999).

Evidence for the use of TENS is variable. Johnson and Martinson (2007) reported significant decreases in pain at rest and on movement in a meta-analysis of 38 studies on TENS and peripheral nerve stimulation for chronic musculoskeletal pain. The evidence for TENS for post-operative pain is often negative, but this may be due to how the studies are conducted.

Heat therapies

For decades superficial heat therapy has been used to relieve a variety of muscular and joint pains, including arthritis, back pain

and period pain. There is much anecdotal and some scientific evidence to support the usefulness of heat as an adjunct to other pain treatments (French et al. 2006).

Heat works by:

- stimulating thermoreceptors in the skin and deeper tissues, thereby reducing the sensitivity to pain by closing the gating system in the spinal cord
- reducing muscle spasm
- reducing the viscosity of synovial fluid which alleviates painful stiffness during movement and increases joint range (Carr and Mann 2000).

In the home environment, people use a variety of different methods for applying heat therapies, such as warm baths, hot water bottles, wheat-based heat packs and electrical heating pads. In the hospital setting, caution is required with this equipment as it does not reach health and safety standards (no even and regular temperature distribution) and there have been incidences of serious burns (Barillo et al. 2000). Carr and Mann (2000) note that heat therapy should not be used immediately following tissue damage as it will increase swelling. The Medicines and Healthcare Products Regulatory Agency (MHRA 2005) has documented evidence of burns caused by using heat patches or packs and therefore urges caution in their use and also recommends regular checking of skin throughout therapy.

Cold therapies

Cold therapies can also be used to stimulate nerves and modulate pain (Carr and Mann 2000). Cold may be particularly valuable following an acute bruising injury where it can help to reduce inflammation and limit further damage. Cold can be applied in the form of crushed ice or gel-filled cold packs which should be wrapped in a towel to protect the skin from an ice burn.

Acupuncture

Definition

Acupuncture is a therapeutic technique that involves the insertion of fine needles into the skin and underlying tissues at specific points for therapeutic or preventive purposes (White et al. 2008).

Anatomy and physiology

Acupuncture has been used in China for over 2000 years; the history of Western medical acupuncture started in the 1970s when a medically qualified doctor took a rational, scientific approach to exploring acupuncture and its benefits (White et al. 2008). We still don't know exactly how acupuncture works but due to numerous scientific studies, there is evidence to show that acupuncture works on the nervous system and the muscles.

Five mechanisms have been identified and these can overlap (White et al. 2008).

Local effects

Action potentials in nerve fibres in the skin and muscle are activated by the acupuncture needles. Various substances are released as a result and this causes an increase in local blood flow. This can often be seen as a red mark around the acupuncture needle during treatment. The local effect can also cause an increase in the blood supply in the deeper tissue which can aid wound healing.

Segmental effects

The action potentials activated by the local effects continue to travel up the nerve to the spinal cord and reduce the painful stimuli by reducing activity at the dorsal horn. This is the main mechanism by which acupuncture relieves pain.

Figure 8.14 TENS machine.

Extrasegmental effects

This is a response in which the effect of acupuncture is not restricted to a single area. This is due to the action potentials continuing to the brainstem; this then affects every segment of the spinal cord (White et al. 2008).

Central effects

Acupuncture affects other structures in the brain such as the hypothalamus and limbic system. In these areas acupuncture can have a regulatory effect; this can be used to treat nausea, hormone imbalances, drug addiction. These effects have been shown on MRI scans.

374

Myofascial trigger point effect

People can experience pain due to 'tight bands' or 'pressure/trigger points' in their muscles. Acupuncture is effective in treating this pain; the needles are inserted directly into the painful area and often the patient experiences instant pain relief. It is thought that acupuncture was originally developed for this type of pain.

Evidence-based approaches

Acupuncture is used for a number of different conditions; both non-malignant and malignant pain, nausea (post-operative and chemotherapy induced), fatigue, addiction, infertility. There are a number of Cochrane reports and NICE guidelines indicating the effectiveness of the use of acupuncture in various conditions. There are also numerous randomized controlled trials showing the effectiveness of acupuncture (White et al. 2012).

Indications

- Pain – both acute and chronic (malignant and non-malignant)
- Xerostomia
- Nausea and vomiting (post-operative, secondary to chemotherapy, in pregnancy)
- Intractable fatigue
- Breathlessness
- Anxiety
- Vasomotor symptoms, e.g. hot flushes
- To encourage wound healing
- Addiction, e.g. stop smoking, alcohol dependence
- Infertility, dysmenorrhoea
- Asthma
- Urological conditions, e.g. irritable bladder

Figure 8.15, Figure 8.16 and Figure 8.17 show some common acupuncture points used in practice.

Contraindications

Acupuncture is contraindicated in patients who:

- refuse, e.g. in cases of extreme needle phobia
- have pain originating from an unknown cause
- are unable to give informed consent or co-operate with treatment
- have severe clotting dysfunction or who bruise spontaneously.

Needling should be avoided:

- directly onto a tumour nodule or into an area of ulceration
- in lymphoedematous limbs or limbs prone to lymphoedema
- in the ipsilateral arm in patients who have undergone axillary dissection (risk of development of swelling and lymphoedema after insertion of any needle)
- in areas of spinal instability due to potential risk of cord compression (due to acupuncture's muscle-relaxing properties)
- into a prosthesis (could cause leakage of saline/silicone)
- over intracranial deficits following neurosurgery.

Figure 8.15 A point used for acupuncture.

Caution should be taken with:

- patients who are underweight (not to needle too deeply over the chest wall)
- patients who are confused
- patients who are agitated
- patients with a metal allergy
- patients receiving anticoagulation therapy
- patients who are immunocompromised
- patients with peripheral vascular disease
- patients with blood-borne infections, e.g. HIV
- patients who are pregnant
- patients who are prone to keloid scar formation
- all cancer patients as they may be very sensitive to acupuncture, so close supervision is advised, especially during the first treatment.

Safety aspects of acupuncture for palliation of symptoms have been reviewed. Reported adverse effects of acupuncture have been categorized as follows.

- Delayed or missed diagnosis (i.e. orthodox diagnostic categories).
- Deterioration of disorder under treatment.
- Vegetative reactions (e.g. syncope, vertigo, sweating).
- Bacterial and viral infections (e.g. hepatitis B and C and HIV infection).
- Trauma of tissues and organs.

Figure 8.16 A point used for pain relief.

Legal and professional issues

All acupuncture practitioners must have completed a recognized, validated, formal training course within their scope of professional practice (for example, the Foundation Course in Acupuncture provided by the British Medical Acupuncture Society (BMAS)). Any nurses who practise acupuncture should check with their union to ensure they have appropriate indemnity cover.

Pre-procedural considerations

Equipment

Acupuncture needles consist of a shaft and a handle. The handle is made of either plastic or metal. The needles are single use and disposable and are covered by a safety guide tube.

There are different dimensions of needles available:

- 0.25 or 0.30 mm diameter needles are standard
- 25 or 40 mm length needles are standard.

Figure 8.17 Points used to treat migraines/headaches.

Assessment and recording tools

Record the patient's treatment in the hospital notes/hospital computer system, e.g condition, acupuncture points used, outcome (Figure 8.18).

Patient preparation

Patients should be treated in a comfortable well-supported position on a couch, either lying down or sitting, with the facility to lie down quickly in case they feel faint during or after the procedure. A healthcare professional should remain with the patient throughout their first treatment as their reaction to acupuncture is unknown.

Consent

All patients must sign a consent form to agree to treatment. There is no specific consent form but follow local policy. An example of a consent form to use can be found on the BMAS website (www.medical-acupuncture.co.uk).

Date at first presentation	Ref.	Age	Sex	Diagnosis or presenting complaint (PC)	Duration of PC (months)	No. of Rx	Response

(BMAS 2013)

Procedure guideline 8.12 Acupuncture: preparation and administration

Essential equipment		
<ul style="list-style-type: none">• Hand-washing facilities• Couch and pillows to support the patient• Cotton wool swabs• Sharps bin• Tray to hold needles• Needles• Facilities for record keeping		
Procedure		
Action		Rationale
1 Take a full medical history from the patient.		To ensure acupuncture is not contraindicated and to ascertain which treatment points need to be used.
2 Explain the procedure to the patient and give the patient an information sheet.		
3 Take patient's consent.		Patient needs to agree to treatment.
4 Ask the patient to lie down.		To reduce the risk of the patient fainting (White et al. 2008, E).
5 Wash hands.		To minimize the risk of infection (DH 2007, C).
6 Give treatment.		
7 Count the needles used (use the empty introducers on the tray as a reminder).		To ensure no needles are lost/miscounted (White et al. 2008, E).
8 Leave needles <i>in situ</i> for 20 minutes; remove if the patient cannot tolerate them. Stay with the patient throughout.		To ensure safe treatment.
9 Remove the needles and count them as they are removed.		To ensure no needles are lost/miscounted (White et al. 2008, E).
10 Ensure the patient feels OK; let the patient rest on the couch if they feel dizzy, etc.		To reduce the risk of the patient fainting (White et al. 2008, E).
11 Document needling points used on patient record.		To ensure that the treatment can be replicated/adjusted at the next appointment according to response (White et al. 2008, E).

Post-procedural considerations

If patients are having treatment in an outpatient setting, they can travel home immediately after treatment. If the patient feels dizzy/faint, they should rest and drink fluids until the feeling passes.

Complications

Although rare, there can be some complications when practising acupuncture.

- Fainting can occur in some patients who are tired, nervous or stressed. This occurs in 5–10% of patients. To avoid this, all patients should be treated whilst lying down.
- Pain during insertion of the needles is due to clumsy technique. This can also occur if a patient moves during treatment, and therefore patients should be treated on a stable bed.
- Pneumothorax – this is very rare in practice and caused by a practitioner with poor anatomical knowledge (Park et al. 2010).

Epidural and intrathecal analgesia

Definition

The term ‘spinal analgesia’ refers to both the epidural and intrathecal route (Day 2001, Sloan 2004). The spinal cord rests in a medium of cerebrospinal fluid (CSF), which is contained by the protective membrane of the dura mater. Analgesics applied outside the dura mater are termed epidural analgesia, and medications given into the CSF are termed intrathecal analgesia (Sloan 2004).

Anatomy and physiology

The spinal cord (Figure 8.19, Figure 8.20) is covered by the meninges; the *pia mater* is closely applied to the cord and the

arachnoid mater lies closely with the outer, tough covering of the *dura mater* (Behar et al. 2007). The epidural space lies outside all three membranes, encasing the spinal cord between the spinal dura and ligamentum flavum. The contents of the epidural space include a rich venous plexus, spinal arterioles, lymphatics and extradural fat.

The intrathecal space (also termed the subarachnoid space) lies between the arachnoid mater and pia mater and contains the CSF (Chapman and Day 2001).

There are 31 pairs of spinal nerves of varying size which pass out through the intervertebral foramina between each vertebra (Chapman and Day 2001). There are two main groups of nerve fibres.

- *Myelinated*: myelin is a thin, fatty sheath which protects and insulates the nerve fibres and prevents impulses from being transmitted to adjacent fibres.
- *Unmyelinated*: delicate fibres, more susceptible to hypoxia and toxins than myelinated fibres.

The spinal nerves are composed of a posterior and anterior root, which join to form the nerve.

- *Posterior root*: transmits ascending sensory impulses from the periphery to the spinal cord.
- *Anterior root*: transmits descending motor impulses from the spinal cord to the periphery by means of its corresponding spinal nerve (Chapman and Day 2001, Day 2001, Gelinas and Arbour 2014).

Specific skin surface areas are supplied/innervated by each of the spinal nerves. These skin areas are known as dermatomes (Figure 8.21).

Evidence-based approaches

Epidural analgesia is the administration of analgesics (local anaesthetics and opioids with or without adjuvants such as corticosteroids and clonidine) into the epidural space via an indwelling catheter (Macintyre et al. 2010). This technique enables analgesics to be injected close to the spinal cord and spinal nerves where they exert a powerful analgesic effect. It is one of the most effective techniques available for the management of acute pain (Macintyre and Schug 2007, Wheatley et al. 2001).

Intrathecal (spinal) analgesia is the administration of analgesic drugs directly into the CSF in the intrathecal space (Gelinas and Arbour 2014). The intrathecal space is also referred to as the subarachnoid space. Analgesic drugs given via this route are 10 times as potent as those given into the epidural space so doses given are much smaller.

Spinal blocks are forms of anaesthesia that temporarily interrupt sensation from the chest, abdomen and legs by injection of local anaesthetic medication in the vertebral canal, which contains the

spinal cord, spinal nerves and CSF. They are typically given as a single injection which will last for 2–6 hours depending on the type and volume of local anaesthetic given. If an opioid is given, such as morphine, this can produce analgesia lasting 12 hours (Macintyre et al. 2010).

In chronic pain, this method (intrathecal drug delivery – ITDD) can be utilized for the delivery of continuous infusions of analgesia in the following groups of patients:

- chronic non-cancer pain unresponsive to other analgesics or when analgesia leads to intolerable side-effects
- cancer pain that is uncontrolled with appropriate systemic opioids or when analgesia leads to intolerable side-effects
- spasticity.

Several different types of drug delivery systems are available.

- Percutaneous catheters (tunnelled or not) used with an external pump, which are easy to place and may be appropriate if the patient has limited life expectancy.
- Fully implantable ITDD systems with an injection port to enable top-up of the analgesic medication, and a programmable function to allow for adjustments in dose and rate settings from an external device.

Local anaesthetics, opioids and other drugs such as clonidine can be given via this route.

The use of drugs via either the epidural or the intrathecal route can cause both a loss of sensation (anaesthesia) and a loss of pain (analgesia).

Rationale

There are three main advantages to using epidural or intrathecal analgesia.

- It has the potential to provide effective dynamic pain relief for many patients (D'Arcy 2011).
- The combination of local anaesthetic agents with opioids has a synergistic action that allows the concentration of each drug to be reduced. This limits the unwanted side-effects of each drug (Hurley et al. 2010).

- There is also evidence that the use of epidural analgesia may reduce the stress response to surgery or trauma, thereby reducing morbidity, recovery time and hospital stay (Kehlet 1997).

Indications

- Provision of analgesia during labour.
- As an alternative to general anaesthesia, for example in severe respiratory disease or for patients with malignant hyperthermia.

- Provision of post-operative analgesia. Epidural analgesia has been used since the late 1940s as a method of controlling post-operative pain (Chapman and Day 2001).
- Provision of analgesia for pain resulting from trauma, for example fractured ribs, which may result in respiratory impairment due to pain on breathing.
- Management of chronic intractable pain in patients with chronic or cancer-related pain who experience the following:
 - unacceptable side-effects with systemic opioids
 - unsuccessful treatment with opioids via other routes despite escalating doses
 - severe neuropathic pain due to tumour invasion or compression of nerves (Day 2001, Mercadante 1999, Smitt et al. 1998).
- To relieve muscle spasm and pain resulting from lumbar cord pressure due to disc protrusion or local oedema and inflammation.

For cancer patients who do not obtain pain relief from treatment with opioids administered orally, rectally, by injection or continuous infusion, there is evidence that both epidural and intrathecal analgesia can be effective (Ballantyne and Carwood 2005). Intrathecal analgesia can either be delivered via an external infusion pump or can be part of a fully implantable reservoir system (Dickson 2004).

Contraindications

These may be absolute or relative.

Absolute

- Patients with coagulation defects, which may result in haematoma formation and spinal cord compression, for example iatrogenic (anticoagulated patient) or congenital (haemophiliacs), or thrombocytopenia due to disease or as the result of anticancer treatment (Horlocker and Wedel 1998).
- Local sepsis at the site of proposed epidural or intrathecal injection; the result might be meningitis or epidural abscess formation.
- Proven allergy to the intended drug.
- Unstable spinal fracture.
- Patient refusal to consent to the procedure.

Relative

- Unstable cardiovascular system.
- Spinal deformity.
- Raised intracranial pressure (a risk of herniation if a dural tap occurs).
- Certain neurological conditions, for example multiple sclerosis, where an epidural may result in an exacerbation of the disease (Hall 2000).
- Unavailability of staff trained in the management of epidural or intrathecal analgesia (Macintyre and Schug 2007). Hall (2000) notes that staff managing patients with epidural or intrathecal analgesia should have undertaken a period of formal training to care for patients safely and competently.

Methods of administration

Continuous infusion

Continuous infusions of epidural drugs are the most effective way of providing dynamic pain relief after major surgical procedures (Kehlet and Holte 2001). Continuous infusions of intrathecal analgesic drugs have been shown to be effective in the management of chronic intractable pain (Ballantyne and Carwood 2005).

Continuous infusions can be given by either a syringe pump or a designated infusion pump system. The effectiveness of this method of administering drugs is dependent on a number of factors including the combination of drugs used, the position of the catheter at a level appropriate to the site of surgery or pain

(Weetman and Allison 2006) and the volume of the local anaesthetic agent infused (Chapman and Day 2001, Hall 2000).

Patient-controlled epidural analgesia

The use of patient-controlled epidural analgesia (PCEA) has gained popularity in recent years because it enables patients to control their analgesia. For patients with post-operative or chronic pain, PCEA is used more effectively in combination with a low-dose background infusion (Wheatley et al. 2001). This ensures a baseline level of analgesia which can then be supplemented by the patient when required.

Bolus injections

Bolus injections of local anaesthetic agents and/or opioids are used infrequently to manage post-operative pain but are more commonly used for managing labour pain (Grond et al. 2000). This procedure is usually performed by the doctor. However, bolus doses of low-dose concentrations may be given by nursing or midwifery staff as part of an advanced practice role, according to local policy. This should follow an agreed period of education and supervised practice, which must be documented.

This is a clean aseptic procedure. Most epidural/intrathecal infusion pumps allow a bolus dose to be programmed and delivered from the pump. This prevents the administration line and bacterial filter being accessed and thus minimizes the risk of introducing infection. Intrathecal bolus doses are usually only given by the doctor.

Classes of epidural and intrathecal drugs and mechanism of action

Three classes of drugs are commonly used to provide epidural or intrathecal analgesia: opioids, local anaesthetic agents and adjuvant drugs such as corticosteroids and clonidine.

Opioids

Whilst a number of different opioids have been used for epidural and intrathecal analgesia, two of the most commonly used are diamorphine and fentanyl (Bannon et al. 2001, Cook et al. 1997, Romer and Russell 1998). When either of these opioids is injected into the *epidural* space, part of the opioid dose:

- crosses the dura and arachnoid membrane and enters the CSF. From the CSF, a proportion of the drug is taken up into the spinal cord and reaches the opioid receptors in the spinal cord. Once bound to the opioid receptors, this results in blocking of pain impulses
- enters the systemic circulation and contributes to analgesia
- binds to the epidural fat and does not contribute to analgesia.

When opioids are placed directly into the CSF in the intrathecal space, they attach directly to the opioid spinal cord receptor sites (Urdan et al. 2006).

Fentanyl differs from diamorphine in that it is more lipid soluble. This means that it passes more easily into the CSF, gaining faster access to the opioid receptors and having a more rapid onset of action. Fentanyl also has a shorter duration of action (1–4 hours) compared to diamorphine (6–12 hours) (Macintyre and Schug 2007).

Local anaesthetic drugs

Commonly used local anaesthetic agents include bupivacaine, levobupivacaine and ropivacaine. They inhibit pain transmission by blocking sodium ion channels which are involved in the propagation of electrical impulses along the spinal nerves. In epidural analgesia, these drugs gain access to the nerve roots and the spinal cord by crossing the dura and subarachnoid membranes (Macintyre and Schug 2007).

The dose of a local anaesthetic agent will also determine which nerves are blocked. Low concentrations of bupivacaine (e.g. 0.100–0.125%) preferentially block nerve impulses in the smallest diameter

nerve fibres, which include the pain and temperature sensory fibres. As the larger diameter motor fibres are less likely to be blocked with concentrations of 0.100–0.125% bupivacaine, the incidence of leg weakness is reduced and the patient is able to mobilize.

Adjuvant drugs

Corticosteroids

Although not licensed for epidural or intrathecal use, corticosteroid injections are often used to relieve pain caused by inflammatory irritation of nerve roots (Papagelopoulos et al. 2001).

380

Clonidine

Clonidine is a mixed alpha-adrenergic agonist. Although its exact mechanism of action is unknown, clonidine is believed to enhance analgesia provided by spinal opioids and local anaesthetic drugs (Smith and Elliott 2001).

Legal and professional issues

There should be formal induction courses and regular updates for doctors, nurses, theatre and recovery staff who will be responsible for supervising patients receiving continuous epidural analgesia (Royal College of Anaesthetists 2004). The acute pain service or a clearly designated consultant anaesthetist from the anaesthesia department will be responsible for the immediate supervision of patients receiving local anaesthetic infusions. The National Patient Safety Agency (NPSA 2007) recommends that in addition to routine training and regular updates, additional training occurs when changes are made to protocols, medicine products

or medical devices. Routine training should include a programme to help healthcare staff gain competence and confidence in using infusion devices employed to deliver epidural/intrathecal analgesia, a theoretical understanding of how the drugs work, and the monitoring required to detect both drug- and procedure-related side-effects and complications (Box 8.15).

There have been reported fatal cases where epidural medicines have been administered by the intravenous route and intravenous medicines have been administered by the spinal route. In response to this, the NPSA (NPSA 2009) issued a Patient Safety Alert recommending that all epidural, spinal (intrathecal) and regional anaesthesia infusions and bolus doses should be given with devices with connectors that *will not* also connect with intravenous equipment – so-called ‘safer connectors’. Medical device and pharmaceutical manufacturers will have to supply devices with safer connectors, and NHS organizations will need to review and update their purchasing policies, procedures and clinical protocols.

Pre-procedural considerations

Equipment

Epidural or intrathecal catheters are inserted using:

- a Tuohy needle (a bevelled curved-tip needle to reduce the risk of accidental dural puncture, with 1 cm length markings, either 16 G or 18 G)
- an epidural/intrathecal catheter (a relatively stiff catheter made of polyamide, length 1000 mm with clear blue markings completely embedded in the catheter material)

Box 8.15 Example of competency role development profile for epidural analgesia for acute pain. Intended learning outcomes and elements of practitioner competency

Knowledge and understanding

You are expected to possess knowledge and understanding of the following.

- The normal anatomy of the spinal cord.
- The physiology of pain and measures of pain management.
- Education and information needs of the patient/family/carer with regard to the implications of having an epidural, to ensure valid consent is given.
- Contraindications for epidural analgesia.
- Infection control considerations before, during and after insertion of an epidural.
- Principles of epidural care and management including side-effects and complications of epidural insertion and epidural analgesia.
- Observations required during the administration of epidural analgesia and the rationale for the frequency of:
 - respiratory rate/sedation levels
 - cardiovascular status
 - temperature
 - epidural site
 - dermatomal blockade
 - pain assessment.
- The standard prescription for epidural analgesia for acute pain management.
- Deviations from the standard prescription available and situations in which they may be used.
- Pharmacology of epidurally administered local anaesthetics and opioids and their side-effects.
- The optimum infusion rate.
- When to stop and remove an epidural catheter.
- Implications of anticoagulant therapy prior to removing the epidural catheter.
- Considerations for analgesia once epidural analgesia is stopped.

Skills

You are expected to possess the following skills.

- Ability to care for the patient before, during and immediately after epidural insertion.
- Ability to check the epidural site; frequency of checks and what problems to look for.
- How to redress the epidural site and frequency of epidural site dressing changes.
- How to assess pain and the frequency of assessment.
- How to carry out a dermatomal blockade assessment and where to document it.
- Ability to change epidural infusion rate.
- Ability to change epidural infusion bag and awareness of the frequency of infusion bag changes.
- Ability to change and prime the infusion administration set and awareness of the frequency of change.
- Ability to deal with equipment problems:
 - proximal occlusion alarm
 - distal occlusion alarm
 - cassette not fitted
 - low battery.
- Ability to deal with administration problems:
 - catheter disconnection from bacterial filter
 - catheter occlusion
 - catheter leakage
 - the patient still has pain
 - side-effects of analgesia
 - complications of epidural catheter insertion.
- Procedure for removing an epidural catheter.
- Safe disposal of unused epidural infusion bags after discontinuing therapy.

- a bacterial filter (filters provide an additional degree of safety and control to prevent bacterial infections. Minimal dead space enables accurate dosing. A high-pressure resistance up to 7 bar enhances safety during manual injection)
- connector (to ensure safe catheter fixation)
- loss of resistance device (to aid clear identification of the epidural space).

The equipment often comes in prepared sterile disposable epidural trays or packs (Parizkova and George 2009a, 2009b).

Dressings

The dressing over the epidural/intrathecal exit site needs to fulfil the following three functions.

- To help secure the epidural/intrathecal catheter.
- To minimize the risk of infection.
- To allow observation of the site without disturbing the dressing.

A transparent moisture-responsive occlusive dressing (e.g. Tegaderm, OPSITE or IV 3000) fulfils these functions. The epidural/intrathecal site should be inspected daily and the dressing changed at least once weekly or more frequently if there is any serous discharge from the site (see Procedure guideline 8.14: Epidural/intrathecal exit site dressing change).

Pharmacological support

Combination of drugs used

Epidural or intrathecal infusions of local anaesthetic and opioid combinations are commonly used in the UK (Baker et al. 2004, Wheatley et al. 2001). The rationale behind their combined use is based on the observation that better analgesia is achieved with lower doses of each drug, therefore minimizing drug-related side-effects produced by higher concentrations (Curatolo et al. 1998, Fotiadis et al. 2004). Although the solutions used will vary with the clinical situation, combinations of fentanyl and a local anaesthetic such as levobupivacaine are often used. The use of premixed bags is recommended to minimize medication errors involving the epidural/intrathecal route (NPSA 2007).

Specific patient preparation

Patients undergoing epidural/intrathecal analgesia should always have a venous access device *in situ* before the procedure. This is because, although rare, a reaction to the opioid or local anaesthetic solution (e.g. respiratory depression or sympathetic blockade) may require immediate access to the venous system. The

Table 8.5 Optimal catheter location for different surgical sites

Surgical site	Catheter location
Thoracic	T6–T9
Upper abdominal	T7–T10
Lower abdominal	T9–L1
Hip/knee	L1–L4

procedure should be performed in a clinical area with access to full resuscitation equipment.

Patient information and consent prior to using epidural/intrathecal analgesia for intractable chronic or cancer pain

The following issues should be addressed with the patient, family and primary healthcare team prior to using epidural/intrathecal analgesia for intractable chronic or cancer pain.

- *Drug-related side-effects:* the concentration of analgesics needed to provide sufficient analgesia for patients with chronic cancer pain is often higher than the concentrations used post-operatively. As a result, drug-related side-effects such as motor weakness and urinary retention can occur. Some patients find these side-effects unacceptable and may prefer to avoid epidural/intrathecal analgesia altogether. Therefore, a discussion must take place with the patient and family to ensure that they are aware of these potential side-effects and are willing to continue with epidural/intrathecal analgesia (Wallace 2002).
- *Increased time in hospital:* the patient should also be informed that they will need to spend a period of time in hospital following insertion of the catheter, to allow for dose adjustment and ensure that side-effects are minimized and optimum pain management achieved.

Position of epidural or intrathecal catheter

Local anaesthetic drugs block nerve fibres at spinal segments adjacent to their site of administration. To ensure the local anaesthetic agent spreads to the dermatomes or nerves supplying the area of pain (e.g. the surgical site or the pain location caused by a tumour), the tip of the spinal catheter should be placed within the mid-dermatomal distribution of the pain site (Table 8.5). This achieves optimal analgesia using the least amount of drugs. If the catheter is placed below the dermatomes supplying the pain site then analgesia is likely to be inadequate (Macintyre and Schug 2007).

Procedure guideline 8.13 Epidural/intrathecal sensory blockade: assessment

Essential equipment

- Ice or single-use proprietary cold pack OR
- These can be discarded after each test to reduce cross-infection risk
- Ethanol spray
- Copy of a dermatome distribution figure or chart (see Figure 8.21)

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. Obtain informed verbal consent from the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent and to ensure the patient has time to assess information and ask questions (NMC 2013, C).

Procedure

- 2 Explain to the patient that they need to report:
 - if the temperature of the ice/cold changes or becomes warmer
 - if they cannot feel the ice/cold sensation at all.

This will indicate the dermatome level at which the epidural/intrathecal analgesia is working.

(continued)

Procedure guideline 8.13 Epidural/intrathecal sensory blockade: assessment (*continued*)**Action**

- 3 Remove any clothing that may restrict the assessment.
- 4 Test the ice/cold pack or spray on an area of the body that should not be affected by the epidural/intrathecal infusion (the face or the back of the hand).
- 5 Starting at the top of the chest (just above nipple level), place the ice/cold pack/spray above the incision or level of pain and ask the patient if this feels as cold as when placed on the test area. Continue this procedure down the torso and the legs if appropriate for the level of epidural/intrathecal analgesia and on the right and left of the body.

Rationale

- The ice or spray needs to be applied directly to the skin to undertake the assessment. **E**
- To ensure the patient can feel the cold sensation. **P**

Post-procedure

- 6 Document at what level the patient can detect a change as per the dermatome chart (see Figure 8.21).

Procedure guideline 8.14 Epidural/intrathecal exit site dressing change**Essential equipment**

- Sterile dressing pack including gloves
- Skin cleaning agent, for example chlorhexidine in 70% alcohol
- Transparent occlusive dressing

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands with soap and water. Clean trolley (or plastic tray in the community) with chlorhexidine in 70% alcohol with a paper towel.
- 3 Position the patient comfortably on their side or sitting forward so that the site is easily accessible without undue exposure of the patient.
- 4 Prepare trolley or tray with sterile field and cleaning solution.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To minimize cross-infection (Preston 2005, **C**).
To provide a clean working surface (Parker 2004, **E**).
- To maintain the patient's dignity and comfort. This is especially important when carers are attending to an area that is not visible to the patient (Chapman and Day 2001, **E**).
- To minimize risk of infection and ensure equipment is available (Preston 2005, **C**).

Procedure

- 5 Remove old dressing and place in disposable bag.
- 6 Wash hands with bactericidal handrub. Put on gloves and personal protective apron.
- 7 Observe site for any signs of infection such as redness, swelling or purulent discharge. If any of these are present contact the hospital anaesthetic/pain team for advice.
- 8 Clean site with skin-cleaning agent (chlorhexidine in 70% alcohol).
- 9 Apply transparent occlusive dressing over the whole area.
- 10 Ensure that the patient is comfortable.

- To prevent cross-infection (Fraise and Bradley 2009, **E**).
- To minimize the risk of microbial contamination (Fraise and Bradley 2009, **E**).
- To ensure careful monitoring of site to minimize the chance of any infection (Royal College of Anaesthetists 2004, **C**).
- To minimize the risk of infection (Hebl 2006, **R5**; Kinirons et al. 2001, **R1b**; Mimos et al. 1999, **R1b**).
- To anchor the epidural/intrathecal catheter, minimize the risk of infection and allow observation of the epidural/intrathecal site (Burns et al. 2001, **R1b**; Royse et al. 2006, **E**).

Post-procedure

- 11 Remove gloves and apron and dispose of all material in the clinical waste bag.
- 12 Wash hands with soap and water.

- To prevent environmental contamination (Preston 2005, **C**).
- To reduce the risk of cross-infection (Preston 2005, **C**).

Procedure guideline 8.15 Epidural/intrathecal catheter removal**Essential equipment**

- Sterile dressing pack including gloves
- Skin cleaning agent, for example chlorhexidine 0.5% in 70% alcohol
- Specimen container (if epidural catheter needs to be sent for bacterial culture)
- Occlusive dressing
- Alcohol handrub

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. Clean trolley (or plastic tray in the community) with chlorhexidine in 70% alcohol with a paper towel.	To minimize cross-infection (Preston 2005, C). To provide a clean working surface (Parker 2004, E).
3 Open dressing pack.	

Procedure

4 Wash hands and remove tape and dressing from catheter insertion site.	To minimize risk of cross-infection (Preston 2005, C).
5 Wash hands with bactericidal handrub. Put on gloves and personal protective apron. Gently, in one swift movement, remove the catheter. Check that the catheter is intact. This can be done by observing that the tip of the catheter is marked blue and that the 1 cm marks along the length of the catheter are all intact.	To minimize the risk of microbial contamination (Fraise and Bradley 2009, E). To ensure the catheter is removed intact with the minimum of discomfort to the patient. E
6 Clean around the catheter exit site using skin cleaning agent.	To minimize contamination of site by micro-organisms. E
7 Apply an occlusive dressing and leave <i>in situ</i> for 24 hours.	To prevent inadvertent access of micro-organisms along the tract. E

Post-procedure

8 The epidural/intrathecal tip may be sent for culture and sensitivity if infection is suspected, or according to local policy.	
9 Remove gloves and apron and dispose of all material in the clinical waste bag. Wash hands with soap and water.	To prevent environmental contamination (Preston 2005, C).
10 Document that the catheter was removed intact in nursing notes.	

Problem-solving table 8.2 Prevention and resolution (Procedure guidelines 8.13, 8.14 and 8.15)

Problem	Cause	Prevention	Suggested action
Headache.	Dural puncture.	Expertise of practitioner inserting the epidural.	Bedrest: headache will be less severe if patient lies flat. Replacement fluids either intravenously or orally to encourage formation of CSF. Administer analgesics for headache. If headache does not settle, contact the anaesthetic team who may consider an epidural blood patch to seal the puncture (Gaiser 2006).

(continued)

Problem-solving table 8.2 Prevention and resolution (Procedure guidelines 8.13, 8.14 and 8.15) (*continued*)

Problem	Cause	Prevention	Suggested action
Sedation and respiratory depression (opioid toxicity). Circumoral tingling and numbness, twitching, convulsions and apnoea (local anaesthetic toxicity).	If catheter migrates into a blood vessel, signs of opioid or local anaesthetic toxicity can occur.	Expertise of practitioner inserting the epidural. Careful monitoring of the patient to detect early symptoms.	Stop epidural infusion. Contact pain/anaesthetic team or summon emergency assistance. Treat the patient for complications of opioid or local anaesthetic overdose. If necessary, support ventilation (Chapman and Day 2001).
Apnoea, profound hypotension and unconsciousness.	If an epidural catheter migrates from the epidural space into the intrathecal space to the CSF, the analgesic solution may reach as high as the cranial subarachnoid space. If this occurs the respiratory muscles are paralysed together with the cranial nerves, resulting in apnoea, profound hypotension and unconsciousness. This is because intrathecal doses are calculated as one-tenth of the epidural dose and migration from the epidural space to the intrathecal space leads to a drug overdose.	Expertise of practitioner inserting the epidural. Careful monitoring of the patient to detect early symptoms.	Stop epidural infusion. Summon emergency assistance. Prepare emergency equipment to support respiration and ventilate lungs. Prepare emergency drugs and intravenous fluids and administer as directed. Prepare equipment for intubation.
Back pain and tenderness and nerve root pain with sensory and motor weakness.	Epidural haematoma.	Assessment of coagulation status before insertion and removal of the epidural/intrathecal catheter.	Urgent neurological assessment. Computed tomography (CT) or magnetic resonance imaging (MRI) scan to accurately diagnose if there is nerve or spinal cord compression. If a haematoma is diagnosed prepare patient for urgent surgery (Chapman and Day 2001). To avoid haematoma on removal of epidural in patients treated with prophylactic anticoagulants, see guidelines for timing of removal.
Back pain and tenderness. May have redness and purulent discharge from catheter exit site. May also develop nerve root signs with neuropathic pain and sensory/motor weakness.	Epidural abscess.	Maintain aseptic technique when accessing the epidural/intrathecal analgesic system. Monitor temperature regularly and check insertion site for evidence of infection.	If the epidural catheter is still <i>in situ</i> , remove and send tip off for culture and sensitivity. Treat with antibiotics. Carry out CT or MRI scan and refer for urgent neurosurgery to prevent paraplegia (Chapman and Day 2001).

Problem	Cause	Prevention	Suggested action
Headaches, fever, neck stiffness, photophobia.	Meningitis.	Maintain aseptic technique when accessing the epidural/intrathecal analgesic system. Monitor temperature regularly.	Assist anaesthetist/doctor to obtain CSF sample for microbiology analysis. Initiate antibiotic therapy as per hospital policy. Non-pharmacological measures for symptom management, for example dim lights. If the infection does not respond to antibiotics it may be necessary to remove the catheter and convert back to systemic analgesia until meningitis has resolved (Mercadante 1999).
Pain, paraesthesia, numbness in lower extremities that may progress to paresis.	Intrathecal catheter granuloma (an inflammatory mass that forms around the catheter tip).	In long-term therapy an intrathecal may be preferable to epidural to minimize the development of a granuloma due to the presence of the CSF.	MRI scan to diagnose the problem. Stop infusion (granulomas may resolve on their own once the infusion is stopped (Du Pen 2005).

Post-procedural considerations

Immediate care

Volume of infusion

The medication 'spread' within the epidural space is determined by the site of the epidural catheter, the patient's age and the volume of the drug being infused (Rockford and DeRuyter 2009). It is therefore important to maintain the hourly infusion rate at a volume which keeps the appropriate nerves blocked.

Effectiveness of blockade

The spinal nerves supply specific areas of skin known as dermatomes (see Figure 8.21). Sensitivity to changes in temperature (such as the cold of ice) along the sensory dermatome can be used to assess the level of epidural/intrathecal block (see Procedure guideline 8.13: Epidural/intrathecal sensory blockade: assessment). This level should be checked to ensure that the epidural/intrathecal is providing pain relief by covering the area of the site of pain, but is also necessary to maintain safety during the administration of epidural/intrathecal infusions. If the sensory block is too high (above T4) then there is an increased risk of respiratory and cardiac symptoms as a result of the local anaesthetic effects on nerves at this level, and if it is too dense it will cause unnecessary motor blockade.

Ongoing care

When caring for a patient receiving epidural or intrathecal analgesia, it is important to monitor the patient for the following:

- drug-related side-effects
- pain intensity
- signs of complications due to the procedure (see Problem-solving table 8.2)
- equipment-related problems, such as the catheter or the infusion pump (see Problem-solving table 8.2).

Drug-related side-effects

There are a number of drug-related side-effects associated with epidural/intrathecal opioids and local anaesthetic agents.

Opioids

- *Respiratory depression*: this is due to the action of opioids on the respiratory centre. Respiratory depression may occur at two different time intervals.
 - *Early*: usually within 2 hours of the opioid injection. This may occur if high blood levels of the opioid follow absorption from the epidural space into the systemic circulation (Macintyre and Schug 2007).
 - *Late*: this may not be seen for 6–12 hours after an opioid is given. It results from rostral migration of the drug in the CSF to the brainstem and respiratory centre (Macintyre and Schug 2007). This is less likely to occur with lipid-soluble opioids such as fentanyl.
- *Sedation*: although there may be many different causes of sedation, epidural/intrathecal opioids can cause sedation owing to their effect on the central nervous system. Opioid-induced sedation is often an early warning sign of respiratory depression.
- *Nausea and vomiting*: nausea and vomiting is caused by the action of opioids on the vomiting centre in the brainstem and stimulation of the chemoreceptor trigger zone in the fourth ventricle of the brain.
- *Pruritus*: although the exact mechanism is unknown, pruritus is presumed to be centrally mediated and a consequence of activation of opioid receptors in the spinal cord (Sands et al. 1998).
- *Urinary retention*: this is due to opioid inhibition of the micturition reflex which is evoked by increases in bladder volume.

Local anaesthetic agents

- *Hypotension*: this can be caused by two mechanisms. Firstly, local anaesthetic agents can spread outside the epidural/intrathecal space, blocking the sympathetic nerves. This results in peripheral vasodilation and hypotension. It is most likely to occur if a bolus dose of local anaesthetic agent (e.g. 10 mL of 0.25% bupivacaine) is given to improve pain control (Macintyre and Schug 2007). Secondly, if the local anaesthetic agent spreads above the T4 dermatome (nipple line), the cardio-accelerator nerves may become blocked, leading to bradycardia and hypotension (Macintyre and Schug 2007).

- *Motor blockade*: this will depend on the concentration and total dose of local anaesthetic agent used and the position of the epidural/intrathecal catheter (Hall 2000). Motor blockade occurs when the local anaesthetic agent blocks the larger diameter motor nerves. Leg weakness will occur if the motor nerves supplying the legs are blocked.
- *Urinary retention*: as with epidural/intrathecal opioids, blockade of the nerves supplying the bladder sphincter can cause urinary retention.

Routine monitoring of the patient for these side-effects must be carried out to facilitate early management. The patient's blood pressure, respiratory rate and peripheral tissue oxygenation should be monitored continuously initially and then according to local policy and as the patient's condition dictates.

For guidance on managing the side-effects associated with epidural/intrathecal opioids and local anaesthetic agents, see Table 8.6.

Table 8.6 Epidural/intrathecal infusions of local anaesthetic agents and opioids: management of side-effects

Problem	Cause	Suggested action
Respiratory depression	Increasing age Elderly patients are more susceptible to the side-effects of opioids due to age-related alterations in the distribution, metabolism and excretion of drugs	If respiratory rate falls to 8 breaths a minute or below: (a) Stop the epidural/intrathecal infusion (b) Summon emergency assistance (c) Commence oxygen via facemask and encourage the patient to take deep breaths (d) Review current analgesic prescription and consider reducing opioid and local anaesthetic doses before resuming the infusion (Macintyre et al. 2010)
	Concurrent use of systemic opioids or sedatives Patients receiving opioids by epidural/intrathecal infusion should not be given opioids by any other route unless given in the palliative care setting for breakthrough pain	(a) Stop the epidural/intrathecal infusion (b) Stay with the patient and monitor respiratory rate, sedation score and peripheral tissue oxygenation (using a pulse oximeter) continuously (c) Commence oxygen therapy (d) Consider giving naloxone if prescribed by anaesthetist or patient unrousable and naloxone already prescribed (when utilized for acute pain management) (e) Review analgesia: stop any other opioids prescribed and consider changing parameters of epidural/intrathecal infusion (McCaffery and Pasero 1999)
Sedation: <i>Mild</i> : patient drowsy but easy to rouse <i>Severe</i> : patient difficult to rouse	See Respiratory depression	(a) If patient has mild sedation, consider reducing the rate of the infusion or the dose of opioid or taking the opioid out of the infusion (b) If patient is difficult to rouse and opioid toxicity/overdose is suspected, follow management for respiratory depression
Hypotension	Patients with hypovolaemia Patients with a high thoracic epidural in whom the concentration of local anaesthetic agent and volume of infusion cause blockade of the cardio-accelerator nerves	If blood pressure falls suddenly: (a) Stop the epidural/intrathecal infusion (b) Summon emergency assistance (c) Administer oxygen via facemask or nasal cannula (d) Stay with the patient and monitor blood pressure at 5-minute intervals (e) Ensure polyfusor or Haemaccel or Gelofusine is readily available and use if prescribed by the anaesthetist (f) Vasoconstrictor agents such as ephedrine or metaraminol may need to be given by the anaesthetic team if hypotension does not respond to a fluid challenge of Haemaccel or Gelofusine (Macintyre and Schug 2007)

Problem	Cause	Suggested action
Motor blockade	More likely to occur when higher concentrations of local anaesthetic agents are given by continuous infusion If a high concentration of a local anaesthetic agent is administered via a low lumbar epidural/intrathecal catheter then the lumbar motor nerves are likely to be blocked, causing leg weakness	Do not attempt to mobilize patient if leg weakness is evident Contact pain or anaesthetic team for advice: reducing the concentration of the local anaesthetic agent or the rate of the epidural/intrathecal infusion may help to resolve this problem (Pasero and McCaffrey 2011)
Nausea and vomiting	Previous episodes of nausea and vomiting with opioids Exacerbated by low blood pressure	Regular administration of antiemetics Treat other causes, for example low blood pressure Consider use of non-pharmacological methods (e.g. stimulation of the P6 acupressure point)
Pruritus (usually more marked over the face, chest and abdomen)	Previous pruritus with opioids	Administer an antihistamine such as chlorpheniramine (may be contraindicated in patients who are becoming increasingly sedated) or a small dose of naloxone (administer with caution as this can easily reverse analgesia) If pruritus does not resolve, consider switching to another opioid or removing the opioid from the infusion (McCaffery and Pasero 1999)
Urinary retention	More likely to occur if opioids and local anaesthetic agents are infused in combination	Catheterize patient

Assessment of pain for patients with epidural analgesia

Pain should be assessed (at rest and on movement) at the same time that the patient's routine observations are carried out. Simple numerical (e.g. 0–10 where 0 is no pain and 10 is the worst pain imaginable) or verbal rating scales (e.g. none, mild, moderate, severe or very severe) can be used.

Inadequate post-operative pain management can lead to physiological complications (respiratory, cardiovascular, gastrointestinal and endocrine systems) and adverse effects (behavioural, such as reduced mobility, and psychological, such as increased anxiety and reduced mood) (Macintyre and Schug 2007). Thus, when patients are assessed the practitioner should ensure the patient can take a deep breath and cough and mobilize with a minimal level of pain to reduce the impact of the physiological, behavioural and psychological effects of undertreated acute pain.

When used for chronic pain management, the aim of epidural/intrathecal analgesia is to improve the overall quality of life of the patient. Although it is acceptable to use simple pain assessment rating scales, a more in-depth pain assessment scale may be used such as the BPI (Tan et al. 2004).

Equipment and prescription safety checks

When a patient is receiving a continuous infusion of epidural/intrathecal analgesia, it is advisable to carry out the safety checks given in Table 8.7 at least once per shift.

Removal of epidural/intrathecal catheter

Before an epidural/intrathecal catheter is removed, it is essential to consider the clotting status of the patient's blood. If the patient is fully anticoagulated a clotting profile must be performed and advice sought from the medical staff as to when the catheter can be removed. If the patient is receiving a prophylactic anticoagulant, the following guidelines are recommended (Horlocker and Wedel 1998, Rowlingson and Hanson 2005, Vandermeulen et al. 1994).

Low-dose low molecular weight heparin

If this is given once daily, the epidural/intrathecal catheter should be removed at least 12 hours after the last injection and several hours prior to the next dose. The timing will depend on the manufacturer's recommended guidelines; for example, for tinzaparin (Leo Laboratories Ltd), it is recommended that epidural or spinal catheters are removed a minimum of 4 hours before the next dose.

Unfractionated heparin

The epidural/intrathecal catheter should be removed following local guidelines and the advice of the anaesthetic/pain management team.

Table 8.7 Epidural/intrathecal analgesia: safety checklist

Checklist	Rationale
Check the prescription and rate of the epidural/intrathecal infusion	To ensure epidural/intrathecal drugs are being administered correctly
Check the epidural/intrathecal infusion/syringe pump extension set is connected to the epidural catheter and not to any other access device	To ensure drugs are administered via the correct route
Check the bacterial filter is securely attached to the epidural/intrathecal catheter	To prevent accidental disconnection of the catheter from the filter
Check that the dressing over the epidural/intrathecal catheter exit site is secure	To prevent catheter dislodgement and minimize the risk of contamination of the catheter site

Discharge planning

If it is anticipated that the patient will go home with a continuous epidural or intrathecal infusion, the patient's general practitioner and community nursing team should be consulted at the outset to determine whether they are willing to be involved and/or trained in the management of epidural/intrathecal analgesia care.

Arrangements should also be made with the primary health-care team for the provision of a suitable epidural/intrathecal pump and the supply of reconstituted syringes/infusion bags. Primary care teams, patients and their families will need to be trained and supplied with the appropriate equipment, drugs, catheter filters, information about the infusion pump, how to identify a catheter-related or systemic infection and what to do if pain occurs or complications arise. For implanted ITDD devices, the patient must be provided with all information to manage the system at home and when they will need to return for the pump to be refilled.

Contact numbers must be provided in case specialist advice is needed.

Complications

If pain is not controlled and the infusion has already been titrated according to hospital guidelines, the pain/anaesthetic team should be contacted for advice after checking the following.

- The catheter is still *in situ*.
- The catheter is still connected to the bacterial filter.
- There are no leaks within the system.
- The height of the epidural/intrathecal block. This will indicate whether the block has fallen below the upper limit of the incision or pain site. To check the height of the block, use a small piece of ice or cold solution (ethyl alcohol). Start at the top of the chest above the patient's incision or pain site. Gently dab the ice (or apply the cold solution) down each side of the patient's body (one side and then the other). Use a dermatome map to assess the upper and lower limits of where the sensation changes (see Figure 8.21).

If the height of the block has fallen below the upper limit of the incision or pain site, the pain/anaesthetic team may undertake the following: give the patient a bolus dose of local anaesthetic agent to re-establish the block and reposition the epidural catheter. If either of these fails, other methods of analgesia need to be considered.

Haematoma

An epidural haematoma can arise from trauma to an epidural blood vessel during catheter insertion or removal. Although the incidence of a haematoma occurring is extremely rare, particular care must be taken in patients receiving thromboprophylaxis. Initial symptoms include back pain and tenderness. As the haematoma expands to compress the nerve roots or the spinal cord, this proceeds to sensorimotor weakness (Chapman and Day 2001).

Abscess formation

Wheatley et al. (2001) note that infection can be introduced into the epidural space from an exogenous source via contaminated equipment or drugs or from an endogenous source, leading to bacteraemia which seeds to the insertion site or catheter tip. Alternatively, the catheter can act as a wick through which the infection tracks down from the entry site on the skin to the epidural/intrathecal space. Symptoms include back pain and tenderness accompanied by redness with a purulent discharge from the catheter exit site (Day 2001).

Complications specific to epidural analgesia

Dural puncture

This usually occurs when the dura mater is inadvertently punctured during the placement of the epidural catheter. The incidence of a dural puncture arising during placement of the

catheter is approximately 0.32–1.23% (Wheatley et al. 2001). The main symptom is a headache, which arises from leakage of CSF through the dura.

Catheter migration

Catheter migration is extremely rare, occurring in less than 0.2% of patients (Wheatley et al. 2001). The catheter may migrate into either a blood vessel or the CSF. If it migrates into a blood vessel, opioid or local anaesthetic toxicity will occur. Opioid toxicity results in sedation and respiratory depression. Local anaesthetic toxicity results in circumoral tingling, numbness, twitching, convulsions and apnoea (D'Arcy 2011). If the catheter migrates into the CSF, the epidural opioids and local anaesthetic agents may reach as high as the cranial subarachnoid space. If this occurs the respiratory muscles are paralysed together with the cranial nerves, resulting in apnoea, profound hypotension and unconsciousness (Macintyre and Schug 2007).

Complications specific to intrathecal analgesia

Meningitis

Meningitis is a rare complication of intrathecal analgesia. The epidural route is often considered safer as the intact dura serves as an effective barrier to the spread of infection to the subarachnoid space. In fact, similar infection rates are reported with both intrathecal and epidural administration (Mercadante 1999). The incidence of major infections varies widely but is reported by Ballantyne and Carwood (2005) as zero and as approximately 5% by Sloan (2004) for epidural and intrathecal therapy with external pump systems. If the patient presents with headaches, fever, neck stiffness or photophobia, they must be reviewed as a matter of urgency by the medical/anaesthetic team, as if meningitis is suspected CSF samples can be obtained and sent to microbiology for analysis, and antibiotic therapy initiated promptly (Baker et al. 2004, Day 2001).

Regional analgesia: local anaesthetic nerve blocks and infusions

Definition

The term 'regional analgesia' includes peripheral nerve blocks (arm, leg or head) and spinal blocks. The term 'spinal analgesia' refers to both the epidural and intrathecal routes and these have been discussed in the previous section.

Regional analgesia can be used for acute post-operative pain, trauma pain and chronic pain. It can either be a single injection ('single shot') or a continuous infusion such as a continuous peripheral nerve block (CPNB). CPNB can also be delivered as an ambulatory service where patients are discharged home with the infusion.

Anatomy and physiology and related theory

Regional analgesia blocks transmission of pain impulses through a nerve by depositing an analgesic drug (usually local anaesthetic with or without an opioid) close to the nerve, cutting off sensory innervation to the region it supplies. This can target either peripheral or central (spinal) nerves. Pain impulses are inhibited but some sensation of touch and muscle functions are intact. Regional analgesia gives relief of pain on movement. This facilitates early post-operative mobilization of patients, even after major surgery in frail patients. Infiltration of the wound with local anaesthetics followed by optimally dosed non-opioid and opioid analgesics is a good alternative for some types of surgery.

Specific regional analgesia nerve blocks

Specific types of regional analgesia nerve blocks can be used for different types of acute or chronic pain. Table 8.8 lists examples

Table 8.8 Examples of regional analgesia blocks

Type of block	Remarks
Brachial plexus block	The brachial plexus is the major nerve bundle going to the shoulder and arm. This block can also be used to manage pre-operative pain in shoulder injuries and also intractable cancer pain from tumours invading the brachial plexus such as those involving the breast and chest wall. Depending on the level of surgery, the anaesthetist will decide at what level to block the brachial plexus, e.g. for surgery at the shoulder, an interscalene or cervical paravertebral block performed at a location above the clavicle may be used. For surgeries below the shoulder joint or clavicle, an infraclavicular or axillary block may be used.
Paravertebral block	Paravertebral blocks can be utilized to numb a specific area in one part of the body depending on where the block is performed. For example, paravertebral blocks at the level of the neck can be used for thyroid gland or carotid artery surgery; blocks at the level of the chest and abdomen can be used for many types of breast, thoracic and abdominal surgery and blocks at the level of the hip can be used for surgeries involving the hip, knee and the front of the thigh.
Femoral nerve block	The femoral nerve provides sensation and motor function to the front of the thigh and knee. This block is commonly used for procedures that cover this area (such as surgery of the knee). It can also be used to provide analgesia for patients with hip fractures pre-operatively whilst they are waiting to go to theatre.
Sciatic and popliteal nerve block	The sciatic nerve provides sensation and motor function to the back of the thigh and most of the leg below the knee. This block is commonly used for surgery on the knee, calf, Achilles tendon, ankle and foot.
Lumbar plexus block	The lumbar nerves join to form the lumbar plexus. An anterior or posterior approach can be used. This block is commonly used for lower limb surgery such as hip and knee surgery, and for femoral shaft and neck fractures.
Intrathecal (spinal) central nerve blocks	Spinal blocks are forms of anaesthesia that temporarily interrupt sensation from the chest, abdomen and legs by injection of local anaesthetic medication in the vertebral canal, which contains the spinal cord, spinal nerves and cerebrospinal fluid. They can be used as a form of anaesthesia and are typically given as a single injection which will last for 2–6 hours depending on the type and volume of local anaesthetic given. If an opioid is given, such as morphine, this can produce analgesia lasting 12 hours (Macintyre et al. 2010). In chronic pain this method (intrathecal drug delivery – ITDD) can be used for the delivery of continuous infusions of analgesia.

of different regional nerve blocks and the procedures they can be used for.

Evidence-based approaches

Rationale

Regional analgesia approaches can be used for several reasons. The ability to provide selective analgesia with minimal adverse effects can be beneficial, particularly in older patients who may have co-existing conditions (Macintyre and Schug 2007, Parizkova and George 2009a, 2009b). By using a nerve block or a continuous infusion of local anaesthetic, pain relief can be superior to the use of opioids alone and the use of opioids can be minimized in the post-operative setting, resulting in fewer adverse effects, such as nausea, vomiting, sedation and pruritus (D'Arcy 2011, Le Wendling and Enneking 2008, Richman et al. 2006). Pain relief and functionality may also be improved.

Contraindications for regional analgesia nerve blocks/infusions

Bleeding

The risk of bleeding may be increased due to patient age, routine thromboprophylaxis and frequent use of antihaemostatic drugs, including platelet inhibitors.

Caution should be exercised in all patients with impaired coagulation, particularly around the timing of catheter removal.

Discharge planning

Inability to care for the continuous infusion at home when used in the ambulatory care setting.

Methods of administration

Regional analgesia can be administered as a single-shot injection where the effects last for several hours after the procedure or as a continuous infusion. CPNB can be utilized in both the inpatient and ambulatory care setting. CPNB analgesia infusion pumps can also be programmed to allow patients the option of bolus dosing in addition to the baseline continuous infusion rate.

Classes of drugs used in regional analgesia and mechanism of action

In peripheral nerve blocks the most common drug used is a local anaesthetic.

Commonly used local anaesthetic agents include bupivacaine, levobupivacaine and ropivacaine. Local anaesthetics bind directly within the intracellular portion of voltage-gated sodium channels. The degree of block produced by local anaesthetics is dependent upon how the nerve has been stimulated and on its resting membrane potential. Local anaesthetics are only able to bind to sodium channels in their charged form and when the sodium channels are open. They will cause numbness and loss of sensation and there may also be some loss of muscle function depending on the purpose of the block.

The dose of a local anaesthetic agent will also determine which nerves are blocked. Low concentrations of bupivacaine (e.g. 0.100–0.125%) preferentially block nerve impulses in the smallest diameter nerve fibres, which include the pain and temperature sensory fibres. As the larger diameter motor fibres are less likely to be blocked with concentrations of 0.100–0.125% bupivacaine, the incidence of motor weakness is reduced and the patient is able to mobilize.

Legal and professional issues

There should be formal induction courses and regular updates for doctors, nurses, theatre and recovery staff who will be responsible for supervising patients receiving continuous peripheral nerve blocks. The acute pain service or a clearly designated consultant anaesthetist from the anaesthesia department will be responsible for the immediate supervision of patients receiving local anaesthetic infusions. The NPSA (NPSA 2007) recommends that in addition to routine training and regular updates, additional training occurs when changes are made to protocols, medicine products or medical devices.

390

Staff competency

Nursing competencies for the nurse who monitors the patient with a CPNB should include knowledge of:

- anatomy and physiology of the spinal cord and column and neurological system
- purpose of the peripheral nerve catheter for pain management
- the CPNB process and signs and symptoms of peripheral nerve catheter misplacement
- effects of medication administered for CPNB
- untoward reactions to medication and management of complications.

Nursing care responsibilities include:

- observation
- any necessary procedures (e.g. reinforcing dressing, catheter removal)
- an understanding of the infusion pump in use
- documentation of care.

Pre-procedural considerations

Equipment

Continuous peripheral nerve block catheters are inserted using a hollow Tuohy-type needle connected to a nerve stimulator or an ultrasound which identifies the nerve and allows the correct placement of the catheter (D'Arcy 2011, Parizkova and George 2009a, 2009b). Once correct placement is confirmed, the catheter is threaded down the hollow center of the needle to the area that needs analgesia.

Dressings

The dressing over the CPNB catheter exit site needs to fulfil the following three functions.

- To help secure the CPNB catheter.
- To minimize the risk of infection.
- To allow observation of the site without disturbing the dressing.

A transparent moisture-responsive occlusive dressing (e.g. Tegaderm, OPSITE or IV 3000) fulfils these functions. The CPNB catheter site should be inspected daily.

Pharmacological support

In continuous peripheral nerve blocks local anaesthetic infusions are used. Rarely are other drugs combined in this approach.

Post-procedural considerations

Immediate and ongoing care

Monitoring the patient

When caring for a patient receiving regional analgesia, it is important to monitor the patient for the following:

- drug-related side-effects
- pain intensity

- signs of complications due to the regional analgesia procedure
- equipment-related problems, such as the regional analgesia catheter or the infusion pump.

Patient education

Patients in the ambulatory setting with CPNB need to accept responsibility for managing the catheter and infusion pump at home. Patient education needs to start in the pre-operative setting and extend to and be reinforced in the post-operative setting.

Instructions need to be both verbal and written, and should include key contact numbers of healthcare professionals available around the clock in case problems occur.

Patient/family general education should include:

- medical equipment, i.e. patient guidelines on how to manage the infusion system at home
- observing for drug-related side-effects
- observing for procedure-related side-effects
- what to do if they have pain
- who to contact if they have any problems.

General instructions for discharge with the system include:

- do not drive or operate machinery, equipment (including sports/hunting) or tools for the duration of the block
- protect the operative limb due to motor loss and loss of feeling for the duration of the block
- keep the catheter site clean and dry
- warning signs to observe for such as infection, haematoma, compartment syndrome, local anaesthetic toxicity
- when to call for further advice and help and how to clamp the tubing
- the use of supplemental oral analgesia if they have pain
- catheter removal: is this at home by the patient, at home by the nurse or on return to the hospital?
- pain service and out-of-hours contact details for concerns or questions.

Table 8.9 demonstrates principles of care for a patient receiving CPNB infusion.

Complications

Complications can:

- be drug related
- arise from the insertion of the needle or catheter
- arise from the indwelling catheter.

Drug related: local anaesthetic systemic toxicity

Systemic toxicity results from the effects of local anaesthetic (LA) drugs on the central nervous system (CNS) and cardiovascular system. This may occur if excessive doses are given or if the CPNB catheter has migrated into a blood vessel and the dose of LA reaches the systemic circulation.

Signs and symptoms of systemic LA toxicity are:

- light-headedness
- circumoral numbness and numbness of tongue
- tinnitus, visual disturbances
- muscular twitching
- drowsiness
- unconsciousness
- convulsions
- coma
- respiratory depression
- cardiovascular depression.

Other complications can be related to the insertion of the needle or catheter (Box 8.16).

Table 8.9 Care of a patient receiving continuous peripheral nerve block infusion (CPNB)

	Comments
Observe for the warning signs of: <ul style="list-style-type: none"> • infection • haematoma (nerve compression) • nerve trauma • compartment syndrome 	<ul style="list-style-type: none"> • Increase in pain, continuous pain • Fever, chills, sweats • Bowel or bladder changes • Difficulty breathing • Redness, warmth, discharge or excessive bleeding from the catheter site • Pain, swelling or a large bruise around the catheter site
Observe for signs and symptoms of local anaesthetic systemic toxicity	<ul style="list-style-type: none"> • Dizziness, light-headedness • Blurred vision • Ringing, buzzing in the ears • Metallic taste in the mouth • Numbness and/or tingling of the fingers, toes or around the mouth • Drowsiness • Confusion
Dressing maintenance	Do not remove dressing as this may move/remove the catheter. The catheter dressing may be reinforced with clear occlusive dressing as needed, taking care not to move/remove the catheter
Monitoring/care of the infusion pump system	<ul style="list-style-type: none"> • The infusion pump is labelled as per prescription • The infusion pump is running at the prescribed rate • Check for kinks in tubing. If the tubing is kinked, massage that area of the tubing to facilitate flow • Troubleshooting any pump alarms
Other monitoring and care	<ul style="list-style-type: none"> • Assessment of the catheter site • Assessment of the integrity of the dressing • Assessment of the sensory, motor and vascular condition of the limb (capillary refill, colour and motor function of the affected extremity will help differentiate intended block from potential nerve compromise or ischaemic pain) • Limb positioning (maintain a neutral position) • Assessment of the skin with attention to the 'hot spots': the heel should be free from continuous contact with the pillow or bed • Patients may have difficulty with weight bearing if the lower limb has been blocked. Care should be taken to prevent falls and provide assistance when mobilizing
Patient/family education	<ul style="list-style-type: none"> • Ensure patient/carer is competent to continue care of the CPNB at home • Provide both written and verbal information; check patient understanding of information provided • Document information provided
Peripheral nerve catheter removal	<p>Indications for catheter removal:</p> <ul style="list-style-type: none"> • end of infusion • infection • failure to control pain • catheter leaking <p>Ensure the patient is comfortable during the removal procedure</p> <p>Follow local guidelines</p> <p>Inspect the catheter site for redness, swelling, inflammation</p> <p>Ensure the catheter is removed with the tip intact</p> <p>Send the tip to microbiology if indicated (e.g. infection)</p>

Entonox administration

Definition

Entonox (BOC 1995), a gaseous mixture of 50% nitrous oxide (N_2O) and 50% oxygen (O_2), is a patient-controlled, inhaled analgesic which is used for the short-term relief of acute pain (Stannard and Booth 1998). Nitrous oxide is a colourless, sweet-smelling gas with powerful analgesic properties, supplied in premixed cylinders (Bruce and Franck 2000). The gas is inhaled and self-administered by the patient using a demand valve system attached to a facemask or mouthpiece. The nitrous oxide

component of the gas acts as a powerful analgesic, producing similar physiological effects to opioids (Gillman and Lichtigfeld 1994), whilst the oxygen component has an antihypoxic effect (Faddy and Garlick 2005) and ensures good cerebral perfusion and enhanced recovery (Peate and Lancaster 2000).

Related theory

Although the exact mechanism of action of nitrous oxide is unknown, its effects take place within the pain centres of the brain and spinal cord and are related to the release of endogenous neurotransmitters such as opioid peptides and serotonin and the activation of certain opioid receptors (Fang et al. 1997, Gillman

Box 8.16 Complications relating to continuous peripheral nerve blocks (CPNB)

Bleeding

- The risk of bleeding increases with the increased age of the patient, routine thromboprophylaxis and frequent use of antihaemostatic drugs, including platelet inhibitors.
- Caution should be exercised in all patients with impaired coagulation, particularly around the timing of catheter removal.

Nerve injury

This may occur as a result of insertion of the needle or catheter during the CPNB. Most nerve injury results in residual paraesthesia only, and most of these resolve over time. However, there can be a more significant and often permanent injury.

Examples include:

- spinal cord damage following injection of local anaesthetic into the cord during interscalene blocks under general anaesthesia
- pneumothorax following brachial plexus blockade.

Infection

CPNB indwelling catheters carry a risk of infection and the risk increases with increasing duration of use.

Catheter or pump related

Problems with equipment may occur at any time. Simple problems may include kinked catheter or tubing. More complex problems such as pump errors, the catheter breaking and leaving a residual portion in the patient may also occur.

and Lichtigfeld 1998). N-methyl-D-aspartate (NMDA) receptor currents are inhibited by nitrous oxide and it is known that these receptors are involved with many CNS pathways (Jevtovic-Todorovic et al. 1998). The release of these neurotransmitters is thought to activate descending pain pathways which modulate pain transmission in the spinal cord (Maze and Fujinaga 2000). Pulmonary transfer of nitrous oxide is rapid, with onset of effect in seconds and full analgesic effect within 1–2 minutes. It is also rapidly eliminated from the blood, via the lungs, when inhalation ceases (Trojan et al. 1997).

Evidence-based approaches

Rationale

There are several advantages to using Entonox.

- As the gas is inhaled, it is painless when compared to systemic methods of administering analgesia (such as injections).
- It has a rapid onset of effect.
- The side-effects are few and are self-limiting as the gas is self-administered.
- It does not depress respiratory or cardiovascular function when used as directed.
- Effects wear off rapidly, usually within 5 minutes.
- The patient is in full control which provides reassurance that they have instant self-regulated access to analgesia which also provides a focus or distraction from the procedure taking place. These can both help reduce anxiety. Entonox also has sedative properties which can act as an anxiolytic (BOC 2011).

Because of these properties, Entonox is an ideal agent for short-term pain relief following injury or trauma and during therapeutic and investigative procedures. It is used in a variety of settings including accident and emergency (O'Sullivan and Benger 2003),

obstetrics (Rosen 2002), paediatrics (Bruce and Franck 2000, Pickup and Pagdin 2001), endoscopy/biopsy procedures (Forbes and Collins 2000, Manikandan et al. 2003) and the ambulance service.

Indications

- Wound and burn dressing, wound debridement and suturing.
- Normal labour.
- Changing or removing of packs and drains.
- Removal of sutures from sensitive areas, for example the vulva.
- Invasive procedures such as catheterization and sigmoidoscopy.
- Removal of radioactive intracavity gynaecological applicators.
- Altering the position of a patient who experiences incident pain.
- Manual evacuation of the bowel in severe constipation.
- Acute trauma, for example applying orthopaedic traction following pathological fracture, reduction of joint dislocation.
- Physiotherapy procedures, particularly post-operatively.

Contraindications

Entonox should not be used with any of the following conditions.

- Maxillofacial injuries (BOC 2000), as the patient may not be able to hold the mask tightly to the face or use the mouthpiece adequately. There is a risk of causing further damage to facial wounds and there may also be a significant risk of blood inhalation.
- Head injuries with impairment of consciousness.
- Heavily sedated patients, as they would be unable to breathe in the Entonox on demand and to potentiate sedation further may be hazardous.
- Intoxicated patients, as drowsiness and aspiration would be a hazard in the event of vomiting.
- Any condition in which gas is entrapped within the body and where its expansion may be dangerous, such as:
 - pneumothorax (artificial, traumatic or spontaneous)
 - air embolism
 - severe bullous emphysema
 - abdominal distension or bowel obstruction
 - decompression sickness or following a recent dive
 - following air encephalography
 - during myringoplasty
 - in patients who have received recent intraocular injection of gas (BOC 2011).
- The nitrous oxide constituent of Entonox passes into any air-filled cavity within the body faster than nitrogen passes out. As the gas expands, this is likely to result in a build-up of tension, which will increase the patient's symptoms.
- Laryngectomy patients, as they will be unable to use the apparatus.
- Temperatures of below -6°C as the gases separate (BOC 1995). If this occurs the cylinders will initially deliver a high concentration of oxygen but will eventually deliver nearly pure nitrous oxide.

Use during pregnancy and lactation

It has been suggested that prolonged exposure to high levels of nitrous oxide may affect a woman's ability to become pregnant (Axelsson et al. 1996). Mild skeletal teratogenic changes have been observed in pregnant rat embryos when the dam (pregnant mother) was exposed to high levels of nitrous oxide during the period of organogenesis. However, no increased incidence of fetal malformation has been discovered in eight epidemiological studies and case reports in humans (BOC 2011). No published material shows that nitrous oxide is toxic to the human fetus. Therefore, there is no absolute contraindication to its use in the first 16 weeks of pregnancy.

There are no known adverse effects to using Entonox during the breast-feeding period (BOC 2011).

Principles of care

Cautions

Prior to Entonox use, consideration should be given to the following.

- The high level of oxygen (50%) in Entonox may depress respiration in patients who have chronic obstructive pulmonary disease and are carbon dioxide (CO₂) retainers.
- Entonox should not be used as a replacement for intravenous analgesia or general anaesthesia in procedures requiring increased levels of medical intervention.
- If Entonox is used as the sole analgesic/sedative agent, the British Oxygen Company (BOC) 2011 data sheet recommends that driving or operating complex machinery is not recommended until:
 - the healthcare professional has judged that the patient has returned to normal mental status (Entonox can cause psychotropic effects)
 - the patient feels they are competent to drive after the relevant procedure is completed
 - at least 30 minutes has elapsed after the administration of Entonox has ceased.
- Additional care is needed when Entonox is administered to a patient who has been given concomitant medication.

Legal and professional issues

Healthcare professionals involved in the assessment, administration and continuing care of patients receiving Entonox should have undergone training to do so. To maintain patient safety, healthcare professionals need to understand the properties, applications and prescribing practices for any medicinal product, which includes all medical gases (BOC 2011). They should be able to demonstrate knowledge of the properties of the gas, precautions to be taken, actions in the event of an emergency and the correct operating procedures for equipment. Training should include:

- physical properties of the medical gas Entonox
- indications for its use
- protocols or policies for safe administration
- known side-effects and contraindications
- any other safety precautions
- methods of safe operation of the gas.

Training can be supplied by BOC Healthcare or a designated trainer and certificated.

Prescribing of Entonox

In a number of healthcare settings, nurses, midwives and physiotherapists may be able to administer Entonox without a written prescription from a doctor providing there is a local Patient Group Direction to allow this. Where this is the case, Entonox can be used more readily and time is not wasted waiting for a medical prescription. Non-medical prescribers who have completed the relevant training as an independent prescriber may also prescribe Entonox if this is within their area of competence.

Pre-procedural considerations

Equipment

Cylinders

Entonox cylinders are available from the BOC in a variety of sizes. All cylinders have blue and white markings on their shoulder (Figure 8.22). The lightweight smaller cylinders have the following advantages.

- They are easier to carry.
- They have a live contents gauge.
- Changing an empty cylinder is simple because it is not necessary to fit a regulator or use a cylinder key.

Figure 8.22 Entonox cylinder and hose.

The smaller size cylinders tend to be used in ambulances and by midwives for their portability in home births. Some clinical areas may have piped Entonox, such as accident and emergency departments, high-dependency units and critical care units. The larger cylinders which require a trolley to move them around are more suitable for ward areas.

Demand apparatus

There are a number of different companies that supply the demand apparatus for self-administered Entonox use. Examples include the Ease demand valve (Sabre Medical) and the Carnet single patient use demand valve (Figure 8.23).

Bacterial filters and mouthpieces/facemasks

Because Entonox equipment is a potential source of cross-infection, bacterial filters (single use only) should be fitted between the facemask or mouthpiece and demand valve if the demand valve is not for single use (Chilvers and Weisz 2000). Facemasks and mouthpieces must also be single use only and disposable once therapy ceases. Local policies must also be followed for the cleaning/sterilization of non-disposable equipment between patient use.

Assessment

The patient's ability to administer Entonox safely and effectively (particularly the very young or old) must be assessed prior to use. Patients should be able to:

- understand the instructions for Entonox use
- hold the demand valve to self-administer the gas
- inhale the gas through the mask or mouthpiece whilst breathing normally (patients who have impaired lung function may not be able to inhale the gas sufficiently to provide adequate analgesia).

Pharmacological support

Entonox is designed for self-administration by the patient. This method of administration makes use of a demand unit which

Figure 8.23 Patient using Entonox demand valve.

safeguards the patient from excessive inhalation of Entonox. The demand unit ensures that gas can be obtained only by the patient inhaling from the mouthpiece or mask and producing a negative pressure. The gas flow stops when the patient stops inhaling and removes the mouthpiece or mask from their face. Thus patients are able to self-regulate the dose of Entonox (a method of patient-controlled analgesia). Therefore, the patient must hold the mask firmly over the face or mouthpiece to the lips to produce an air-tight fit and breathe in before the gas will flow. Expired gases escape by the expiratory valve on the handpiece. It is essential to adhere to this method of self-administration as it is then impossible for patients to overdose themselves because, if they become drowsy, they will relax their grip on the handset and the gas flow will cease when no negative pressure is applied. However, should inhalation continue, light anaesthesia supervenes and the mask drops away as the patient relaxes. Entonox may be self-regulated, but additionally may be administered by attendant medical personnel trained in its use, for example within obstetric/accident and emergency units, and accident ambulances.

Entonox has an oxygen content 2.5 times that of air and is therefore a good way of giving extra oxygen as well as providing analgesia.

Duration and frequency of administration

The duration and frequency of Entonox administration should always be tailored to individual patient needs. Because prolonged exposure to Entonox causes inactivation of vitamin B₁₂, impaired folate metabolism and pernicious anaemia (BOC 2011), it is recommended that:

- Entonox is used on a short-term rather than a long-term basis
- it should not be used for more than a total of 24 hours, or more frequently than once every 4 days (BOC 2011)
- if daily use is required for more than 4 days, this should be accompanied by close supervision and haematological monitoring (blood tests) to check for changes in red and white blood cells (BOC 2011). Consideration should also be given to the administration of B₁₂ and folate supplements.

Procedure guideline 8.16 Entonox administration	
Essential equipment <ul style="list-style-type: none">• Entonox cylinder and head• Sterile bacterial filter• Facemask and/or mouthpiece• Method of documentation	
Pre-procedure	
Action <ol style="list-style-type: none">1 Explain and discuss the procedure with the patient.	Rationale <p>To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).</p> <p>To reduce patient anxiety (Royal College of Anaesthetists 2006, C).</p> <p>To ensure the patient has no underlying medical problems that contraindicate the use of Entonox (BOC 2011, C).</p>
Procedure	
<ol style="list-style-type: none">2 Turn on the Entonox supply from the cylinder.	To ascertain whether there is any Entonox in the cylinder (BOC 1998, C).
<ol style="list-style-type: none">3 Examine the gauge to determine how much gas is in the cylinder.	To ensure an adequate supply of gas throughout the procedure (BOC 1998, C).
<ol style="list-style-type: none">4 Ensure that the patient is in as comfortable a position as possible.	To promote patient comfort (BOC 1998, C).

5 Demonstrate how to use the apparatus by holding the mask tightly to your face, replacing the mask/mouthpiece that you have used. Explain to the patient that when they breathe in and out regularly and deeply, a hissing sound will be heard, indicating that the gas is being inhaled.	To ensure that the patient understands what to do and what to expect before any painful procedure commences (BOC 1998, C).
6 Allow the patient to practise using the apparatus.	To enable the patient to adopt the correct technique and for the nurse to observe the analgesic effect of the gas before the procedure commences (BOC 1998, C).
7 Encourage the patient to breathe gas in and out for at least 2 minutes before commencing any painful procedure.	To allow sufficient time for an adequate circulatory level of nitrous oxide to provide analgesia. When the patient inhales, gas enters first the lungs then the pulmonary and systemic circulations. It takes 1–2 minutes to build up reasonable concentrations of nitrous oxide in the brain (BOC 1998, C).
8 During the procedure, encourage the patient to breathe in and out regularly and deeply.	To maintain adequate circulatory levels, thus providing adequate analgesia (BOC 1998, C).
9 Evaluate the effectiveness of Entonox with the patient throughout and following the procedure, by verbal questioning and encouraging the patient to self-assess the analgesic effect.	To establish whether the Entonox has been a useful analgesic for the procedure. This should then be documented to assist any subsequent procedures, for example dressing changes (BOC 1998, C).
10 At the end of the procedure observe the patient every 5–10 minutes until the effects of the gas have worn off. Observe the patient for up to 30 minutes.	Some patients may feel a transient drowsiness or giddiness and should be discouraged from getting out of bed until these effects have worn off. It is rare for the patient to experience transient amnesia (BOC 1998, C).
Post-procedure	
11 Turn off the Entonox supply from the cylinder.	To avoid potential seepage of gas from the apparatus (BOC 1998, C).
12 Depress the diaphragm under the demand valve.	To remove residual gas from tubing (BOC 1998, C).
13 Follow local policies/guidelines for the cleaning and sterilization of expiratory valve and tubing, and facemask (or disposal if single use). Filters and mouthpieces should be discarded after use.	To reduce the risk of cross-infection (BOC 1998, C).
14 Record the administration on appropriate documentation.	To promote continuity of care, maintain accurate records and provide a point of reference in the event of any queries (BOC 1998, C ; NMC 2010, C).

Problem-solving table 8.3 Prevention and resolution (Procedure guideline 8.16)

Problem	Cause	Prevention	Suggested action
Patient not experiencing adequate analgesic effect.	Entonox cylinder empty.	Check before procedure commences.	Change to a full cylinder.
	Apparatus not properly connected.		
	Patient not inhaling deeply enough (BOC 2000).	Education of patient prior to starting procedure.	Encourage the patient to breathe in until a hissing noise can be heard from the cylinder. Reassess suitability of patient for Entonox use. The patient may not be strong enough to inhale deeply or may have reduced lung capacity.
	Patient inhaling pure oxygen, that is, cylinder has been stored below -6°C and nitrous oxide has liquified and settled at the bottom of the cylinder.	All cylinders should be stored horizontally at a temperature of 10°C or above for 24 hours before use (BOC 1995).	Initially safe, but later the patient may inhale pure nitrous oxide and be asphyxiated. Discontinue the procedure. Ensure adequate warming of the cylinder and inversion of the cylinder to remix the gases adequately.

(continued)

Problem-solving table 8.3 Prevention and resolution (Procedure guideline 8.16) (continued)

Problem	Cause	Prevention	Suggested action
	Not enough time has been allowed for nitrous oxide to exert its analgesic effect.	Allow at least 2 minutes of Entonox use before commencing the procedure.	Stop procedure. Allow 2 minutes of Entonox use. Restart procedure.
Patient experiences generalized muscle rigidity.	Hyperventilation during inhalation (BOC 2000).	Education of patient prior to starting procedure.	Discontinue Entonox and allow the patient to recover. Explain the procedure again, stressing deep and regular inspiration. Use a mouthpiece in place of a mask.
Patient unable to tolerate a mask.	Smell of rubber, feeling of claustrophobia.	Assess patient preference to use either mask or mouthpiece before Entonox use.	Use a mouthpiece in place of a mask.
Patient feels nauseated, drowsy or giddy.	Effect of nitrous oxide accumulation (BOC 2000).	None.	Discontinue Entonox administration: the effect will then rapidly disappear. Restart Entonox use; if the same effect occurs stop using Entonox and use alternative analgesia.
Patient afraid to use Entonox.	Associates gases with previous hospital procedures, for example anaesthesia before surgery (BOC 2000).	Assess suitability of patient for Entonox use. Address fear and anxiety issues before starting Entonox use.	Reassure patient and reiterate instructions for use and short-term effects.

Complications

Effects such as euphoria, disorientation, sedation, nausea, vomiting, dizziness and generalized tingling are commonly described. These are generally minor and rapidly reversible (BOC 2011).

Inappropriate inhalation of Entonox will ultimately result in unconsciousness, passing through stages of increasing light-headedness and intoxication. The treatment is moving to fresh air, mouth-to-mouth resuscitation and, if necessary, the use of an oxygen resuscitator (BOC 1995).

Management of ascites

Definition

Abdominal paracentesis is a technique used to drain a pathological collection of ascitic fluid from the abdomen (Campbell 2001). This technique is performed to help diagnose the cause of ascites (diagnostic paracentesis) or to relieve the discomfort associated with this condition (therapeutic paracentesis) (McGibbon et al. 2007).

Anatomy and physiology

The peritoneum is a semi-permeable serous membrane consisting of two separate layers: the parietal layer and the visceral layer. The parietal layer covers the abdominal and pelvic walls and the undersurface of the diaphragm. The visceral layer lines and supports the abdominal organs and the parietal peritoneum (Figure 8.24). The space between the parietal and visceral layers is known as the peritoneal cavity (Thibodeau and Patton 2010). The normal peritoneal cavity has a small amount of free fluid of approximately 50 mL (McGibbon et al. 2007).

In a healthy individual, fluid is produced from the capillaries lining the peritoneal cavity and is drained by lymphatic vessels under the diaphragm. The fluid is collected by the right lymphatic duct which drains into the vena cava. The peritoneum forms the

largest serous membrane in the body (Tortora and Derrickson 2011). However, in patients with malignant ascites, this balance of production and drainage is disrupted and ascitic fluid collects in the peritoneal cavity (Box 8.17).

Figure 8.24 Peritoneum of female in lateral view.

Box 8.17 Functions of the peritoneum

- The peritoneum is a serous membrane that enables the abdominal contents to glide over each other without friction.
- It forms a partial or complete cover for the abdominal organs.
- It forms ligaments and mesenteries which help to keep the organs in position.
- The mesenteries contain fat and act as a store for the body.
- The mesenteries can move to engulf areas of inflammation and this prevents the spread of infection.
- It has the power to absorb fluids and exchange electrolytes.

Source: Adapted from Thibodeau and Patton (2010), Tortora and Derrickson (2011).

Related theory

Ascites can be caused by non-malignant conditions such as cirrhosis of the liver, advanced congestive heart failure, chronic pericarditis and nephrotic syndrome. Cirrhosis of the liver is the most common cause of ascites and in this clinical condition the development of ascites indicates a poor prognosis (Hou and Sanyal 2009, Sargent 2006).

Malignant conditions such as metastatic cancer of the ovary, stomach, colon or breast can also cause ascites. If a definitive diagnosis is needed to establish cause, to aid staging and possible surgical intervention, then a peritoneal tap and analysis of fluid will be useful (Marincola and Schwartzentruber 2001).

It is not possible to distinguish between malignant and benign ascites by physical examination or radiographic techniques so invasive testing is necessary to differentiate the two types (Sangisetty and Miner 2012).

The pathogenesis of ascites differs depending on its primary related factors. Cirrhotic ascites is more recently believed to be related to portal hypertension (Hou and Sanyal 2009, Lee and Grap 2008). The increased pressure occurs due to fibrosis and scarring of the liver from chronic liver disease, causing obstruction to venous flow (Whiteman and McCormick 2005). In the case of heart failure and constrictive pericarditis, the heart loses its ability to pump blood and this causes a back-up of blood and increases pressure into the portal venous system, leading to portal hypertension and ascites (Lee and Grap 2008).

The pathogenesis of malignant ascites is not as well understood as non-cancer-related ascites is (Seike et al. 2007) but cytokines, mechanical obstruction and hormonal influence are thought to be related. Cytokines such as vascular endothelial growth factor (VEGF) and vascular permeability factor (VPF) regulate vascular permeability. The obstruction of lymphatic drainage by the disseminating malignant cells in the peritoneal cavity reduces absorption of peritoneal exudates (Seike et al. 2007). This reduction activates the renin-angiotensin-aldosterone system and leads to sodium retention, which then further exacerbates the ascites.

Ascites is often accompanied by debilitating symptoms as large amounts of fluid collect in the peritoneal cavity, causing an increase in intra-abdominal pressure and resulting in pressure on internal structures. The fluid accumulation may occur over several weeks or rapidly over a few days (Lee and Grap 2008). Symptoms initially include vague abdominal discomfort, which can go on to affect the respiratory and gastrointestinal systems, depending on the amount of fluid present. Pressure on the diaphragm decreases the intrathoracic space and causes shortness of breath. Gastric pressure may cause anorexia, indigestion or hiatus hernia. Intestinal pressure may result in constipation, bowel obstruction or decreased bladder capacity. Patients also become increasingly fatigued, finding simple daily tasks difficult

(Slusser 2014). Additionally, body image can be affected even when minimal distension is present.

Cytological confirmation of malignant cells is difficult, with only a 50% chance of success (Fentiman 2002).

Evidence-based approaches**Rationale**

There is much debate about whether it is safe to drain large volumes of fluid rapidly from the abdomen. One concern is that profound hypotension may follow because of the sudden release of intra-abdominal pressure and consequent possible vasodilation (Lee et al. 2000). However, following a local study and literature search, Stephenson and Gilbert (2002) suggest that up to 5 litres of fluid may be safely drained over a few hours. They also state that it is not necessary to drain the abdomen until dry. In cases of cirrhosis, however, Moore and Aithal (2006) suggest that all fluid should be drained to dryness in a single session as rapidly as possible over 1–4 hours, assisted by gentle mobilization of the cannula or turning the patient on their side if needed.

It is generally not necessary to have intravenous fluid or albumin replacement. However, patients with ascites who have large tumours, cirrhosis of the liver or renal impairment may require slower drainage of fluid and possible fluid replacement, depending on their clinical condition. Abdominal and peritoneal tumours can cause ascites to develop independently of the circulatory system and therefore hypotension is not usually seen as the ascites is drained (Klee 2004).

A small study has shown that the success of blind paracentesis is directly related to the amount of fluid present (44% with 300 mL and 78% with 500 mL) (McGibbon et al. 2007). The literature suggests the use of ultrasound-guided paracentesis to confirm the presence of ascites and also to identify the best site to perform paracentesis, particularly when a small amount of fluid is present (McGibbon et al. 2007).

Indications

- To obtain a specimen of fluid for analysis for diagnostic purposes (diagnostic paracentesis).
- To relieve the symptoms associated with ascites, both physical and psychological (therapeutic paracentesis).
- To administer substances such as cytotoxic drugs (e.g. bleomycin, cisplatin) or other agents into the peritoneal cavity, to achieve regression of serosal deposits responsible for fluid formation (Hosttetter et al. 2005).

Contraindications

- *Relative contraindications:* pregnancy, severe bowel distension and previous extensive abdominal or pelvic surgery (McGibbon et al. 2007). When relative contraindications are present, paracentesis without the assistance of ultrasound (blind paracentesis) is not recommended (McGibbon et al. 2007).
- *Absolute contraindication:* clinically evident fibrinolysis or disseminated intravascular coagulation (McGibbon et al. 2007).

Preparatory investigations

The patient's clinical condition and purpose of the procedure must be taken into account when deciding what investigations are necessary but most pre-procedure investigations include a blood screen and ultrasound examination. To keep intrusion to a minimum for palliative patients, fewer investigations may be performed. Blood is usually checked for full blood picture, urea and electrolytes, creatinine, liver function test, plasma proteins and coagulation screen (Hewish 2006). In the case of a diagnostic paracentesis, the ascitic fluid should be analysed for cell count, bacterial culture, total protein and albumin (Hou and Sanyal 2009).

Methods of managing ascites

Interventions used to treat ascites range from an aggressive approach to a purely palliative approach. There have been few definitive studies that have evaluated the different approaches in the treatment of malignant ascites (Hosttetter et al. 2005). While paracentesis is effective, ascites recurs, requiring repeated procedures. This fact imposes a further burden on patients and their families (Mercadante et al. 2008). Treatment for ascites may include use of diuretics, paracentesis, diet low in sodium, instillation of peritoneal agents or the insertion of long-term catheters. However, the literature available is mostly generated from studies with patients suffering from acute or chronic liver failure; this should be taken into account when managing patients with non-malignant ascites.

- *Paracentesis*: the most common way of managing ascites as it has an immediate effect in 90% of cases (Campbell 2001, Marincola and Schwartzentruber 2001).
- *Sodium-restricted diet*: the amount of fluid retained in the body depends on the balance between sodium ingested in the diet and sodium excreted in the urine. A reduced sodium intake of 2 g/day is considered a realistic goal (Sargent 2006).
- *Diuretics*: useful mainly in cirrhotic-type ascites. This may be used for malignant ascites together with a restriction of salt and fluid intake, and has been found to be effective in about one-third of patients (Hosttetter et al. 2005, Sangisetty and Miner 2012). Additionally, it appears to be more effective for management of patients with small-volume ascites (only diagnosed by ultrasound). Spironolactone is the diuretic of choice (Hou and Sanyal 2009). The most effective way of monitoring the fluid loss is by weighing the patient daily (Sargent 2006).
- *Instillation of intraperitoneal agents*: cytotoxics, sclerosants and biological substances have been tried in an attempt to control the recurrence of ascites. To date, intraperitoneal agents have not been proven, unequivocally, to have a greater beneficial effect than the use of diuretics (Fentiman 2002).
- *Long-term catheters*
 - Peritoneovenous shunt: generally used in patients with long-term prognosis. These shunts drain ascitic fluid into the superior vena cava and require a general anaesthesia for insertion (Mamada et al. 2007, Seike et al. 2007).
 - PleurX drain: tunnelled catheter placed under ultrasound and fluoroscopic guidance. This device is associated with low rates of serious adverse clinical events, catheter failure, discomfort and electrolyte imbalance (Courtney et al. 2008). Additionally, it may allow patients to avoid spending added time in hospital for repeated paracentesis.
 - Peritoneal port-catheter: similar to but larger than central venous access ports in order to make access easier and to decrease possible catheter occlusion (Ozkan et al. 2007). Very limited number of studies supporting its use.

Anticipated patient outcomes

Nursing and medical care of patients with malignant abdominal ascites should be aimed at improving quality of life by relieving suffering caused by the symptoms (Cope 2005). Each patient should be carefully assessed with consideration of their individual circumstances, maintaining respect for their wish to have or not have interventional treatment (Campbell 2001).

Legal and professional issues

Competencies

The procedure is performed by a doctor or a trained practitioner in paracentesis assisted by a nurse throughout. There is no accredited pathway or course for learning this clinical skill and specific

training has to be negotiated and developed locally (Vaughan 2013).

Pre-procedural considerations

Equipment

The equipment should be prepared by the health professional performing the paracentesis or by a colleague familiar with the technique. The essential equipment includes a sterile abdominal paracentesis set, a sterile dressing pack, a sterile receiver, a sterile specimen pot, a local anaesthetic, needles and syringes, chlorhexidine 0.5% in 70% alcohol, an adhesive dressing, a large sterile drainage bag or container, gate clamps and sterile gloves.

Nurses should describe the equipment to be used during paracentesis to the patient. This may be more relevant when looking after a patient undergoing the procedure for the first time to whom the size of the catheter used may be concerning.

Assessment and recording tools

A detailed and consistent nursing assessment is important when caring for patients requiring paracentesis. Nurses should pay particular attention to the cause of the ascites and the frequency with which the procedure is occurring. The involvement of the palliative care team can at this stage be indicated. In cases of ascites secondary to cirrhosis, nurses should pay special attention to unresolved issues surrounding alcohol abuse, offering support and information to the patient and family. As well as assessing the patient's psychological well-being, nurses must pay attention to the skin condition and pain levels.

In preparation for the paracentesis, nurses should measure the patient's girth around the umbilicus and check the patient's weight before the procedure. The same chart should be used to record all subsequent measurements so a comparison can be made.

Pharmacological support

The health professional performing the paracentesis must use a local anaesthetic and lidocaine at the concentration of 1% is often the drug of choice. The lidocaine is injected subcutaneously initially with a 25 G needle and subsequently with a 23 G needle until optimal pain control is achieved, not to exceed the maximum dose of 4.5 mg/kg (or 200 mg). Optimal pain control can take between 2 and 5 minutes after the drug is injected and it is important for the practitioner to assess the effectiveness of the local anaesthetic before starting the drainage of ascites. Lorazepam at a dose of 1 mg can be of benefit prior to the procedure for patients who are anxious, due to its muscle relaxant and anxiolytic effects.

Non-pharmacological support

Nurses should enquire about the patient's fears and concerns regarding paracentesis. For some patients, music or relaxation, physical relaxation and visualization techniques are of great benefit so use of these approaches should be considered, if available.

Specific patient preparation

Education

Nursing interventions for patients undergoing abdominal paracentesis include education about the nature of the procedure, what results can realistically be expected, and the risks and benefits. Information should also be given about post-procedure care of the puncture site and about the importance of diet and fluid intake to replace proteins and fluid lost in the ascitic fluid. It is essential that the patient, family and carer are involved in the discussion so that an informed and joint decision may be made in order to achieve the best possible outcome.

Procedure guideline 8.17 Abdominal paracentesis

Essential equipment

- Sterile abdominal paracentesis set containing forceps, scalpel blade and blade holder, swabs, towels, suturing equipment, trocar and cannula (or other approved catheter and introducer), connector to attach to the cannula and guide fluid into the container (Figure 8.25)
- Sterile dressing pack
- Sterile receiver
- Sterile specimen pots
- Local anaesthetic
- Needles and syringes
- Chlorhexidine 0.5% in 70% alcohol
- Adhesive dressing
- Large sterile drainage bag or container (with connector if appropriate to attach to cannula)
- Gate clamps
- Sterile gloves and apron
- Sharps bin

Optional equipment

- Weighing scales
- Tape measure

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient is involved in the decision and understands the procedure, the agreed aim, the risks and benefits. Informed consent may then be obtained (Campbell 2001, R5 ; Cope 2011, R5 ; NMC 2013, C).
2 Ask the patient to empty their bladder.	If the bladder is full there is a chance of it being punctured when the trocar is introduced (McGibbon et al. 2007, E).
3 Weigh the patient before the procedure and record.	To assess weight changes and fluid loss. E
4 Ensure privacy.	To maintain dignity (DH 2006a, C).
5 Measure the patient's girth around the umbilicus before procedure and record. Mark the position in the abdomen where the drain will be inserted using a skin marker.	This provides an indication of fluid shift and how much fluid has reaccumulated. E
6 Lie the patient supine in bed with the head raised 45–50 cm with a backrest.	Normally the pressure in the peritoneal cavity is no greater than atmospheric pressure, but when fluid is present, pressure becomes greater than atmospheric pressure. This position will aid gravity in the removal of fluid and the fluid will drain of its own accord until the pressure is equalized. E

Procedure

7 Wash hands.	To minimize risk of contamination. E
8 Perform the procedure using an aseptic technique. Always perform the procedure in hospital with a second, appropriately trained, person.	To minimize risk of contamination. E To ensure patient safely at all times. E
9 Bring equipment to bedside in a cleaned trolley. Remove the sterile abdominal paracentesis pack from its outer wrapping and open it on the trolley.	To minimize the risk of infection. E
10 Lay out the remaining equipment except the apron.	To facilitate access to the equipment. E To create a clean working area. E
11 Put on a disposable plastic apron and gloves.	To protect the professional and patient from the risks of cross-infection. E
12 Clean hands with bactericidal alcohol handrub.	To minimize the risk of infection. E
13 Clean the skin thoroughly at marked site for the paracentesis with an antiseptic solution, for example chlorhexidine 0.5% and alcohol solution, and allow to dry. Drape with sterile towels.	To reduce the risk of local and/or systemic infection. The peritoneal cavity is normally sterile (Fraise and Bradley 2009, E ; Lee et al. 2000, R5).
14 Administer local anaesthetic.	To minimize pain during the procedure. E

(continued)

Procedure guideline 8.17 Abdominal paracentesis (*continued*)

Action	Rationale
15 Once the anaesthetic has taken effect, the doctor will make an incision into the skin of the abdomen (the position may have been marked previously in radiology following ultrasound).	To minimize pain during the procedure and thus maximize patient comfort and facilitate co-operation. E
16 The trocar and cannula are inserted via the incision.	To ensure correct insertion of the trocar and cannula. E
17 The trocar is removed and disposed of in a sharps container.	To reduce the risk of accidental needlestick injury (NHS Employers 2011, C).
18 Attach the closed drainage system to the cannula using a connector if appropriate. Apply appropriate dry dressing to ensure the drain exit site is protected and the drain is taped firmly in position.	A sterile container with a non-return valve is necessary to maintain sterility. To reduce local and/or systemic infection. E
19 Collect ascitic fluid from the cannula with a syringe (20–100 mL as instructed by the doctor) and send for cytology.	If necessary, in order to diagnose the cause of ascites (Fentiman 2002; Hosttetter et al. 2005, R5).
20 If the cannula is to remain in position, sutures may be inserted, by the doctor, adjacent to the cannula and looped around it to prevent it becoming dislodged and to prevent local trauma to the patient.	To ensure cannula remains <i>in situ</i> . To reduce risk of trauma to the patient. E
Post-procedure	
21 Dispose of the equipment and remove gloves and apron.	To reduce the risk of environmental contamination (Fraise and Bradley 2009, E).
22 Monitor the patient's blood pressure, pulse and respirations hourly.	To observe for signs of shock and/or infection. E
23 Observe the rate and nature of the drainage. Reduce flow of fluid using the clamp available in the tube if the patient complains of abdominal pain.	To ensure safe and unobstructed drainage. E
24 Monitor the patient's fluid balance daily, reviewing the intake and output. Review biochemistry results daily.	After removal of large amounts of peritoneal fluid, fluid moves from the vascular space and reaccumulates in the peritoneal cavity. Ascitic fluid contains protein in addition to sodium and potassium. Problems of dehydration and electrolyte imbalance may be present. E
25 Weigh patient after the procedure and record.	To assess weight changes and fluid loss. E
26 Measure the patient's girth around the umbilicus after the procedure and record.	This provides an indication of fluid shift and how much fluid has reaccumulated. E

Figure 8.25 Example of sterile equipment tray for abdominal paracentesis.

Problem-solving table 8.4 Prevention and resolution (Procedure guideline 8.17)

Problem	Cause	Prevention	Suggested action
Patient exhibits shock.	Major circulatory shift of fluid or sudden release of intra-abdominal pressure, vasodilation and subsequent lowering of blood pressure.	Monitor blood pressure and consider administration of intravenous fluid if volumes larger than 5 litres are expected to drain.	Clamp the drainage tube with a gate clamp to prevent further fluid loss. Record the patient's vital signs. Refer to the medical staff for immediate intervention.
Cessation of drainage of ascitic fluid.	Abdomen is empty of ascitic fluid.		Check the total output of ascitic fluid given on the patient's fluid balance chart. Measure the patient's girth; compare this measurement with the preabdominal paracentesis measurement. Suggest to medical staff that the cannula should be removed. Discontinue the drainage system.
	Patient's position is inhibiting drainage.	Teach patient to avoid exerting pressure on the drainage tubing.	Change the patient's position, that is, move the patient upright or onto their side to encourage flow by gravity. Encourage patient to mobilize.
	The ascitic fluid has clotted in the drainage system.	Keep drainage bag on a stand and lower than the puncture site to facilitate drainage by gravity.	'Milk' the tubing. If this is unsuccessful, change the drainage system aseptically. Refer to the medical staff.
Cannula becomes dislodged.	Ineffective sutures or trauma at the puncture site.	Collaborate with medical staff when applying suture or alternatively apply secure dressing. Tube is taped to the skin further down to prevent pulling with movement at the puncture site.	Apply a secure dry dressing. Reassure patient. Inform the medical staff.
Pain.	Pressure of ascites or position of drain.	Offer analgesia 30 minutes prior to procedure. Apply dressing, allowing enough padding around the puncture site but avoiding drain movement within abdomen.	Identify cause. Anchor drain securely to avoid pulling at insertion site or movement within abdomen. Assist patient with repositioning. Administer appropriate prescribed analgesic, monitor the patient's response and inform medical staff.

Post-procedural considerations

Immediate care

Observations must be carried out every 30 minutes for 2 hours and hourly for 4 hours to detect early signs of shock, cardiovascular compromise and infection so that medical staff can be informed and action can be taken promptly. Drainage of the fluid must be monitored regularly, volumes recorded on a fluid balance chart and blockages detected and managed. Patients may require assistance to move and position themselves, and may experience pain, requiring careful repositioning or appropriate analgesia. The drain should be taken out when the desired amount of fluid has been removed or symptom relief achieved (Moore and Aithal 2006).

Ongoing care

The patient's renal function should be checked following this procedure to ensure that any signs of dehydration or pre-renal failure are treated as early as possible.

Education of patient and relevant others

Patients should be informed that leakage following removal of drain may happen and should be reported promptly.

Complications

- *Bleeding*: manifest as either an abdominal wall haematoma or a haemoperitoneum. The likelihood of requiring a transfusion following paracentesis is less than 1% (McGibbon et al. 2007).
- *Local infection or peritonitis*: there is the theoretical risk of introducing infection into the ascitic fluid, which can be minimized by the use of sterile technique. A swab from the site of the cannula should be obtained for culture review and a dry dressing applied.
- *Bowel or bladder perforation*: this risk is decreased by ensuring the patient has an empty bladder and avoiding sites of scarring on the abdomen when inserting the cannula, as this may indicate internal adhesions between the bowel and peritoneum.

End-of-life care

Definition

There is considerable ambiguity surrounding the terms end-of-life care, palliative care and terminal care and they are often used interchangeably but are not synonymous.

Palliative care

Palliative care is the active, total care of the patient whose disease is not responsive to curative treatment. Control of pain, of other symptoms and of social, psychological and spiritual problems is paramount. Palliative care is interdisciplinary in its approach and encompasses the patient, the family and the community in its scope. Palliative care affirms life and regards dying as a normal process: it neither hastens nor postpones death (European Association for Palliative Care 2014).

Recent advances in healthcare mean that many people now live with advanced, incurable illness for many years. This has been acknowledged by the WHO which reviewed its definition of palliative care to advise that palliative care is 'applicable from early in the course of illness in conjunction with other therapies which aim to prolong life' (WHO 2002).

End-of-life care (EOLC)

A component of palliative care has been defined as care that helps all those with advanced, progressive, incurable conditions to live as well as possible until they die. It enables the supportive and palliative care needs of both patient and family to be identified and met throughout the last phase of life and into bereavement. By definition, EOLC encompasses the holistic assessment and management of physical care, pain and other symptoms which includes the provision of psychological, social, financial, spiritual and practical support for both the patient and their family/carers in their place of choice, during the last year of life and includes care given after bereavement (National Council for Palliative Care 2008).

Terminal care

Care that is given during the terminal phase. This is an ill-defined period of irreversible decline that signifies imminent death. This is usually a period of several days but may be as short as a few hours; occasionally this can be as long as a couple of weeks (Maltoni and Amadori 2001).

The term 'families and carers' is used throughout this chapter though it is acknowledged that not all family are carers and not all carers are family.

Anatomy and physiology

In the days and hours leading up to an expected death, many physiological changes present as signs and symptoms that represent the closing down of the body before death. These can be alarming if not understood (Field et al. 1997). It is important for healthcare professionals to have an understanding of this process so that they can provide information and reassurance for patients and families. The following are common.

- Decreased social interaction – sleeping more.
- A decreasing level of consciousness leading eventually to coma, except in those few patients who remain awake until a few minutes before they die.
- Decreased food and fluid intake – no hunger or thirst.
- Changes in elimination – reduced urine output and bowel motions, occasional incontinence.
- A weaker pulse (but regular unless previously arrhythmic).
- A gradual drop in blood pressure, though at this stage it should not be routinely taken. It is important that healthcare professionals review the continued need for all interventions and discontinue any that are no longer felt to be conferring benefit to the patient (Ellershaw and Murphy 2011).
- Shallower, slower breathing, which varies in depth, often in a Cheyne–Stokes pattern.

- Cooling and clamminess of the skin from the periphery inwards.
- Cyanosis of the skin on the extremities and around the mouth.

The breathing will ultimately stop, followed several minutes later by cessation of the heart (Harlos 2010).

Related theory

Enabling people to die in comfort and with dignity is hugely important for the patient, their families and carers and is a core function of the NHS (NEoLCP 2011). There is evidence to indicate that the final elements of care not only have an impact at the time but also on the subsequent bereavement process (King's Fund 2008). *The End of Life Care Strategy* (DH 2008) is considered a blueprint for improving the care of all dying patients regardless of their diagnosis. Care for those approaching the end of life is often challenging and emotionally demanding but, if staff have the necessary knowledge, skills and attitudes, it can be one of the most important and rewarding areas of care (NEoLCP 2010).

End-of-life care has come to the forefront of international government health policies, including *The End of Life Care Strategy* (DH 2008) and *Quality Markers and Measures for End of Life Care* (DH 2009). The four countries of the UK have advocated numerous initiatives to enhance EOLC in the public and private sectors, integrated EOLC pathways being one example (Watts 2012). *The End of Life Care Strategy* (DH 2008) set guidance aimed at improving care and choices for all people regardless of their diagnosis and place of care. The principal aims are to improve the quality of care for those approaching the end of their life and to enable greater choices and control about their place of care and death. The strategy, which focuses on the role of health and social care, states that high-quality EOLC should be available wherever the person may be: at home, in a care home, in hospital, in a hospice or elsewhere (DH 2008).

The National End of Life Care Programme (NEoLCP 2010) was developed to implement the strategy. The programme advocates the following core principles for delivery of EOLC.

- Treat individuals with dignity and respect.
- Provide information and support to families and carers.
- Recognize and respect an individual's spiritual and religious needs.
- Provide effective pain and symptom management.
- Provide care after death.
- Ensure care is person centred and integrated.
- Provide a safe, comfortable environment for care.

Early identification that a patient is dying is a key element in quality EOLC. A major challenge for all staff is knowing how and when to open up a discussion with individuals, their relatives and others involved within their care, about what they wish for as they near the end of their life. Nurses are ideally placed to identify the various clinical triggers that indicate when someone could be in their last year of life, thus enabling and facilitating effective care planning. Agreement needs to be reached by the MDT caring for the individual and there should be negotiation as to which clinician is best placed to communicate this to the patient and their family/carers. It is important that healthcare professionals recognize that sometimes the individual and their families and carers may struggle to consider the future and therefore conversations and care should be guided and planned sensitively and appropriately (NEoLCP 2011).

This planned approach can lead to improved outcomes in terms of both patient care and best use of NHS resources. Early discussion enables the patient to have more control over their care and should result in the more frequent use of advance care planning (NEoLCP 2011).

Evidence-based approaches

Palliative care is a relatively new specialty in nursing and medicine; its services operate in different ways and vary in funding

(voluntary or NHS), team composition, staff to patient ratio, out of hours care, and treatment regimens used. Palliative care's evidence base is comparatively small and, consequently, applying an evidence-based approach is not always easy. Higginson (1999) points out that an absence of evidence does not mean that a service or treatment is not effective, just that we have not validated its efficacy.

Outcomes such as quality of care and quality of life measures, including quality of death and the best resolution of the bereavement process, are extremely hard to determine, especially when patients are frail and ill. Thus, many studies exclude quality of life as an outcome variable or include only patients who can complete questionnaires. The challenge is to ensure that those aspects of care that are hard to measure do not become a lower priority than aspects, such as survival or function, that are easy to measure (Higginson 1999). However, in order to promote greater use of clinical protocols, best practice guidelines within services and guidance on the most effective models of care, more research evidence is undoubtedly needed.

Evidence suggests that those patients and carers who have had the opportunity to discuss EOLC about 3 months before death:

- are significantly less likely to receive inappropriate aggressive medical treatment
- have significantly reduced levels of depression
- have significantly better adjustment post bereavement (Shipman et al. 2008).

Care before death

Recognition of the dying phase

Care of the dying patient starts with a recognition from the multiprofessional team that the terminal phase has begun. This has been cited as perhaps the single most important factor in enabling the achievement of all the factors associated with a 'good death' (Faull and Nyatanga 2012).

It has been suggested that the following characteristics are central to a good death from medical, nursing and patient perspectives.

- Control.
- Comfort.
- Closure.
- Trust in healthcare providers.
- Recognition of impending death.
- An honouring of personal beliefs and values (Kehl 2006).

Evidence suggests that the dying phase can be difficult to identify. A study by Veerbeek et al. (2008) showed that of 489 deaths in several settings, the dying phase was only identified on the day of death for 50% of patients. The study also found that recognition of the dying phase decreased the chance of the patient having diagnostic interventions (57% versus 39%); 88% of patients in the study had received therapeutic interventions during the dying phase. Barriers to recognizing dying included a reluctance by healthcare professionals to make a diagnosis of dying; 'prognostic paralysis' has been described, whereby clinicians of patients with uncertain illness trajectories prevaricate when considering end-of-life issues (Stewart and McMurray 2002). Health professionals are often concerned that discussions about prognosis will cause distress and damage hope, and that there may be insufficient time to have such discussions. These same concerns are often voiced by patients and families (Maguire and Pitceathley 2002).

In an attempt to overcome these barriers, four basic criteria for recognizing the terminal phase are widely acknowledged. The presence of two or more of the following, commonly preceded by a progressive period of decline and where no other reversible cause is present, is said to denote the terminal phase of life.

- The patient is unable to get out of bed.
- The patient is semi-comatose.

- The patient is only able to take sips of fluid.
- The patient is no longer able to take tablets.

Nursing care during this period does not simply represent a continuation of previously given care, nor, necessarily, the complete cessation of all 'active treatment' measures which may previously have been undertaken. As with all aspects of nursing care, assessment of the individual patient and their family will help to determine the appropriate next steps, which can vary greatly from person to person. It is important that family members and carers of people approaching the end of life are involved in the provision of care. They need therefore to be closely involved in decision making with the recognition that they have their own needs (DH 2008).

Preferred priorities of care and death

Enabling patients to be cared for and to die in a place of their choice is a central tenet to the delivery of good-quality EoLC, and is an important aspect of meeting the psychosocial needs of patients and their relatives in the last days of life (DH 2008). NICE (2004) guidelines recognized the importance of addressing patients' needs and preferences. They encourage sharing of information and good communication and documentation of patients' and carers' choice of care. They allow multidisciplinary teams and other services to plan and reduce inappropriate admissions and interventions, and help patients to prepare for the future and think about their values and beliefs. The *Preferred Priorities for Care* (PPC) document is designed to help people with advance care planning and enable them to prepare for the future. It gives them an opportunity to think about, talk about and write down their preferences and priorities for care at the end of life (NEoLCP 2011).

More recently, preferred place of care and death in place of choice have been used in the Commissioning for Quality and Innovation payment framework (NEoLCP 2010) which is seen as a lever for service improvement in many acute settings.

Nurses play a key role in assessing the patient's and carer's complex needs relating to preferred place of care and death. It is possible that carers may become tired or ill and informal carers may need more support to understand the complexity of looking after dying patients (Hudson 2005). Often these communications are extremely sensitive and need to be facilitated by an objective outsider who is able to voice the fears and concerns of all those involved. All resources should therefore be discussed and explored, especially for those who have no family or friends, or live in a deprived area where hospital admission is highly likely (Welch et al. 2010).

In communal settings, where possible, single room accommodation should be offered to patients and families or carers. This can provide a feeling of homeliness, allows dying people to rest, gives them privacy and enables them to have family to stay for extended periods without intruding on others (Waller et al. 2008). Nurses should be mindful that some dying patients do not wish to have a single room which they see as isolating. This too should be respected. There is evidence that although the witnessing of a death can be distressing, if this is well managed the process can be comforting for other patients (Payne et al. 1996).

Advance care planning

Advance care planning refers to 'the process by which patients, together with their families and healthcare practitioners, consider their values and goals and articulate their preferences for future care' (Tulsky 2005, p.360). Comprehensive advance care planning (ACP) can help to avoid certain courses of action such as inappropriate readmission to hospital. Ahearn et al. (2013) performed a retrospective study of 100 randomly selected notes which revealed that preferred place of death was not discussed with 92% of patients. The study also found in 10 patients that if ACP had occurred prior to acute decline, a better alternative to acute hospital admission could have been considered, thus allowing patients with a poor prognosis to die in their normal place of residence or a hospice.

Advance decisions to refuse treatment (ADRT)

These allow people who are 18+ years to make a legal decision to refuse, in advance, a proposed treatment or the continuation of that treatment, if at the relevant time the person lacks the capacity to consent to it. ADRTs can only be made by those who are deemed to have the mental capacity to do so, and allow only for the refusal of treatments – they cannot enforce the provision of specified treatments in the same circumstances (DH 2012).

Advance decisions to refuse treatment must be made in writing, be signed and witnessed, and must expressly state that the decision stands even if the person's life is at risk (DH 2012). They can be withdrawn verbally or in writing and are not considered valid if the person has conferred Lasting Power of Attorney on another person. Equally they can be invalidated if the person has done anything which is clearly inconsistent with the original advance decision, for example any change in religious faith.

The Mental Capacity Act (2005) contains statutory guidance about ADRTs. If ADRTs comply with all the tests set out in the Mental Capacity Act, they will be legally binding, so must be respected as if the person who had made the advance decision had capacity and refused the treatment at the time the decision was required. Please refer to the Mental Capacity Act (2005) for comprehensive information relating to ADRTs and Chapter 4: Communication.

Discharging patients for end-of-life care at home or nursing home

For individuals who wish to be discharged to their home or a care home, access to specialist palliative care and 24/7 advice and support are vital (NEoLCP 2011). Proactive working and a complex combination of services across many different settings are crucial; prior to discharge, nurses should ensure that appropriate referrals are made to specialists within the team who will work in partnership with primary and community care services to facilitate the patient's safe discharge.

Patients who are being discharged from hospital for EOLC at home will have their care delivered by a variety of multidisciplinary and multiagency teams, including GP practices, local care homes, pharmacies, hospices, ambulance services, local hospitals and local authority and voluntary sector support services whose aim should be to work together to meet the needs of the patient and their families and carers and ensure a rapid and seamless discharge (NEoLC 2012). Nurses must communicate effectively with other members of the health and social care teams, sharing with them the information necessary to provide the patient with safe, effective and timely care.

This move, between differing health and social care settings, at this very emotional time, can cause great anxiety for patients, their family and carers. It is imperative that nurses give reassurance and clear and concise information relating to responsibility for care and supply all necessary contact details (NEoLC 2012).

For care home and home settings, it is essential that the GP is notified immediately of any patient who is being discharged for EOLC. This will enable them to make arrangements to review the patient as soon as possible; it is crucial that the GP reviews the person regularly and at least every 14 days, both from a care point of view and in order that a Medical Certificate of Cause of Death (MCCD) can be appropriately issued without involving the coroner. The community nurses and hospice teams must be contacted and issued with all the necessary paperwork and information relating to the patient's urgent discharge. Any anticipatory drugs should be prescribed.

The End of Life Care Strategy (DH 2008) identified the need to improve co-ordination of care, recognizing that people at the end of life frequently received care from many different organizations. The subsequent national development of locality registers (now known as electronic palliative care co-ordination systems) was identified as a mechanism for enabling co-ordination between health and social care professionals involved in a patient's care. One such record, 'Co-ordinate my Care', has shown that in areas

where these records are used, the successful achievement of preferred place of death has increased for those patients who have expressed a preference (Read 2012). Patients who are being discharged for EOLC at home should, where possible, be consented for the appropriate local electronic record in order to ensure that their wishes are adhered to.

Legal and professional issues

Next of kin

Despite the widespread use of the term 'next of kin' (NOK), it is not clearly defined by law (Advisory Services Alliance 2010) and should not be confused with the 'nearest relative', a legal term used in mental health (Mental Capacity Act 2005). The NOK has no legal liabilities, rights to medical notes or personal possessions (Dimond 2004). Healthcare staff should respect the patient's wishes when identifying who is next of kin and who should be contacted in the event of their death: this could be a partner, relative or friend (Connecting for Health 2011).

Given the wide variety of relationships and family structures that can exist, it can be easy to make incorrect assumptions about the roles people have (DH 2005b). It is important that the ward or department establishes and documents at the earliest moment possible who is the NOK, who should be informed in the event of a death and who has permission to take any property away, visit, sit with the deceased or make decisions for them. If the deceased person was living in a care home but died in hospital, the care home should be informed because the staff may be aware of the patient's wishes and NOK details.

Documentation should contain not only the address and telephone number of the next of kin but also their relationship to the patient. If possible, a second contact person should also be recorded. These details should be confirmed with the patient if possible rather than transcribed from previous documentation.

In the event of the patient's condition deteriorating, it is vital that the person(s) identified by the patient as the NOK are informed. Nursing staff should also establish whether the NOK wishes to be contacted during the night and document this in the patient's notes.

If the NOK is not present at the time of death, the hospital will have to inform them that the death has occurred. In some cases of sudden death the police will inform the next of kin. Telling someone that a relative or friend has died has to be done with care and sensitivity, and all staff need to have some form of training to allow them to carry out this role sensitively and confidently. It may include being involved in a supportive conversation which may have to be continued later if time is restricted. Wherever possible, hospitals need to respond to the needs of the next of kin at the time they are informed of the death. This can involve phone conversations, making arrangements for the next of kin or others to come to the hospital, and even contacting other people on their behalf (DH 2005b).

In the event of no NOK being identified by the patient, healthcare staff should notify those identified in their local policy who will be responsible for registering the death at the town hall and liaising with the appropriate funeral directors to organize a contract funeral, if necessary. Contract funerals are organized by the local borough. Under Section 46 of the Public Health (Control of Diseases) Act 1984, the council has a statutory obligation to carry out the funeral arrangements of a person who dies within the local area where there is no one else willing or able to deal with the funeral arrangements, for whatever reason.

Hospital staff and volunteers do not have right of entry into the home of the deceased (even if they have the key). Nor do they have the right to go through the deceased's papers in order to identify a friend or relative who could help. In line with partnership working, NHS staff should consult the local protocols with other relevant agencies such as the police and Social Services who may be able to help in identifying relatives or others with responsibility (DH 2005b).

Marriages at the end of life

On occasion, critically or terminally ill patients may request assistance in arranging a marriage or civil partnership in the hospital. For patients too ill to be moved to a place registered for the ceremony (i.e. a register office or place of worship), it is possible to request a ceremony within a hospital or at the bedside.

The hospital chaplain or other religious official and the relevant manager will provide assistance in making necessary arrangements for patients who need a marriage/civil partnership ceremony within the hospital.

Where the parties to a marriage wish this to occur by any non-Church of England ceremony or where a civil marriage/civil partnership is required, the registrar must perform this under licence. The intended spouse/partner of the patient must give notice of the marriage/civil partnership personally to the superintendent registrar.

If the couple wish to be married according to the rites of the Church of England, they should be advised to approach the Church of England chaplain, or the vicar or rector of the parish in which the patient resides and then apply for a special licence to the appropriate registrar for their locality.

In all circumstances the registrar will need a letter, signed by a registered medical practitioner, stating that the patient is too ill to be moved and is not expected to recover. The letter will also confirm that the patient has capacity and does understand the nature and purpose of the marriage/civil partnership ceremony.

The registrar will also need a letter giving permission for the marriage/civil partnership to take place on hospital grounds.

Notice of the intended marriage/civil partnership must also be given to the ward sister/charge nurse so that she/he can adequately accommodate a celebration if desired by the patient and future spouse.

Last will and testament

There are times when a patient may wish to make a will in hospital and some may not be able to complete this process independently. Healthcare staff must ensure that a doctor has reviewed the patient to assess that he/she has capacity to make decisions (Mental Capacity Act 2005) and to record this in the patient's medical notes.

Where possible, wills should be drawn up professionally and patients should be encouraged to seek the assistance of a solicitor, particularly if this concerns complex property or financial matters. Patients may ask nurses to sign a will for them. The Royal College of Nursing (RCN 2013) states that though there is nothing in law preventing a nurse from witnessing a will, it advises against the signing of legal documents as this could lead to involvement in legal cases should there be a later dispute. It is therefore more appropriate for someone who is independent of the patient to undertake this task. This is endorsed by the Nursing and Midwifery Council, who remind nurses of the importance of maintaining clear professional boundaries and being impartial at all times (NMC 2015). All healthcare professionals should consult their hospital's local policy relating to the signing of last wills or any other legal documents.

Rarely, there may be circumstances where a healthcare professional (HCP) is the only person who can realistically witness a signature. This may be when the patient has no apparent relatives or friends, is living remotely from others or is terminally ill (though not mentally incompetent) and there is some urgency for a witness. In these exceptional circumstances, it is acceptable for nurses to witness the signature, although there is no obligation to do so unless local policy demands it. In all cases, the nurse should record the witnessing of the signature in the patient's notes as well as a record of why the HCP was needed to be the signatory witness (RCN 2013).

Most hospitals have will templates available for use. Equally, a patient may choose to draft his or her own will. Both are valid but, where at all possible, the patient should be strongly encouraged to seek a solicitor's advice.

Organ donation

Organ donation is an important consideration at the end of life. Current law is an opt-in system for donation, so express wishes must be made by patients or families (next of kin). Wherever possible, assess the dying person's wishes regarding organ, tissue and body donation and document this in a way that is consistent across organizations and accessible at the time of death (NICE 2011). Patients who have previously expressed a wish to donate (or carry a donor card), or whose family has expressed such a wish, might need specific preparation. Further information can be found at www.organdonation.nhs.uk/.

Euthanasia and assisted suicide

Euthanasia is the act of deliberately, by act or omission, ending a person's life to relieve suffering. For example, a doctor who gives a patient with terminal cancer an overdose of muscle relaxants to end their life would be considered to have carried out euthanasia. In the UK, euthanasia is against the law and carries a maximum penalty of life imprisonment.

Assisted suicide is the act of deliberately assisting or encouraging another person to commit, or attempt to commit, suicide. If a relative of a person with a terminal illness were to obtain powerful sedatives, knowing that the person intended to take an overdose of sedatives to kill themselves, they would be assisting suicide (DH 2013a).

Both euthanasia and assisted suicide are illegal in the UK despite current campaigns to change the law. Nurses must not therefore participate in either process. They should, however, be aware that those patients who approach healthcare professionals with a request for assisted suicide or euthanasia will be doing so from a position of significant vulnerability and must be treated with respect, care and compassion. Commonly, these requests stem from a fear of pain, indignity and dependence and it is imperative to ensure that patients are offered adequate opportunities to express these fears (Dowler 2011). Nurses have a duty of care to ensure that patients' concerns are communicated to the MDT in order that the appropriate specialist physical, psychosocial and spiritual support is offered to minimize their distress.

Artificial hydration

The patient has the right to refuse artificial hydration and those who are unable to communicate their wishes retain this right through advance refusal. Discussions with the patient or relatives and carers may result in the negotiation of a plan of care whereby artificial hydration is commenced for an agreed period, on the understanding that this will be discontinued if it is causing distress to the patient. The appropriateness of artificial hydration will depend on regular assessment of the intervention.

This subject requires skilled and experienced communication (see Chapter 4: Communication).

Pre-procedural considerations

Communication

Excellent communication is paramount in all areas of nursing practice but more so when dealing with dying patients and their relatives. If patients and their relatives and carers are to make educated end-of-life decisions, they need to have nurses who can engage and have open, honest and unambiguous dialogue (NNCG 2011). Nurses must have the confidence to raise the issue of planning for future care and death as well as responding to patients and families that raise these issues themselves (Henry and Wilson 2012). When it is recognized that the patient is dying, it is important that agreement is reached between medical and nursing teams, patients and their families about clinical decisions (NCCG 2011). This may include decisions relating to EOLC pathways, cardiopulmonary resuscitation or whether treatment ceilings are required. If an implanted cardiac device is *in situ* it is important to assess whether it should be

left in place, as it may affect the dying phase. Pacing therapy is not normally discontinued but the deactivation of implantable cardiac defibrillators needs to be considered (British Heart Foundation 2007).

Fallowfield (2005) warns that healthcare professionals tend to underestimate patients' desire for information and advises that individualized assessment is necessary to clarify the information needs of patients, relatives and carers. It is vital that nurses remember that they are the patient's advocate; they need to ensure that individuals have sufficient space and time to reflect and discuss their concerns. Nurses must also remember that the patient and their families and carers may struggle to consider the future; conversations and care should therefore be guided sensitively. Communication is influenced by patients' and families' cultural and spiritual beliefs, which will also affect patients' information needs at the end of life. Nurses are more closely involved with patients and therefore ideally placed to establish their feelings and preferences concerning end-of-life wishes. These may include who they wish to be present at the time of their death or how they wish families and carers to be informed of their death. Ensuring that healthcare professionals at all levels have the skills to communicate with and care for the dying is critical to the success of improving EOLC (DH 2008). Please see Chapter 4: Communication for further information relating to communication skills.

Prognosis

Prognostication is an uncertain art and often only when wise after the event can these judgements be verified (GMC 2010). Over the past 20 years there has been a major shift in attitudes regarding disclosure of information to patients; more recently the culture is for complete disclosure. However, healthcare professionals should always be mindful of the individual needs of patients, families and carers and sensitively establish the amount of disclosure a patient and family wishes.

Guidance suggests that someone is approaching the end of life when they are likely to die within the next 12 months (Murray et al. 2005), whether from advanced, progressive, incurable conditions or general frailty and co-existing conditions; they may be at risk of dying from a sudden acute crisis in their existing condition or life-threatening acute conditions caused by sudden catastrophic events.

Those close to a patient who is at the end of life stage may want or need information about the patient's diagnosis and about the likely progression of the condition or disease. This will help them set goals and priorities and help them provide care, as well as enabling them to recognize and respond to changes in the patient's condition. If a patient has capacity to make decisions, you should check that they agree to you sharing this information (Watson et al. 2009). If a patient lacks capacity to make a decision about sharing information, it is reasonable to assume that, unless they indicate otherwise, they would want those closest to them to be kept informed of relevant information about their care.

Watson et al. (2009) assert that prognostication is not just about passing on clinical details and predictions of disease progression; it also involves assessing the following.

- What does the patient actually want to know? Too much information can be as harmful as inadequate information.
- How is the patient dealing with the information that is being given?
- How can the patient be helped to deal with the implications of the news?

To discuss prognostication without regard for the implications of those facts is to increase the risk of dysfunctional communication taking place.

Discussions surrounding prognosis should be undertaken by professionals confident in advanced communication skills and with the appropriate experience to offer an approximation on the

grounds of their clinical knowledge and experience. Following communication about prognosis, advice and support should be offered for those who are finding the situation emotionally challenging. Sources of support may include patient and carer support and advocacy services, counselling and chaplaincy services. It is important that support is also offered to healthcare professionals (GMC 2010).

The principles of breaking bad news should be adhered to in undertaking discussions about prognosis.

Principles of care for dying patients

End-of-life care pathways were intended to exemplify a high standard of care through the terminal phase of palliative care into bereavement. The Liverpool Care Pathway for the Dying Patient (Ellershaw et al. 1997), commonly shortened to LCP, was developed by the Royal Liverpool University Hospital and the Marie Curie Hospice in Liverpool as a model of best practice in end-of-life-care (O'Hara 2011). It incorporated 'gold standard' care associated with the hospice setting into mainstream healthcare and was welcomed as a means of enabling professionals of all specialties to provide the best possible multidisciplinary care for their patients as they enter the terminal phase. The LCP was endorsed by successive national policy frameworks (DH 2003a), the *End of Life Care Strategy* (DH 2008), *Quality Markers and Measures for End of Life Care* (DH 2009), General Medical Council guidance (GMC 2010) and the NICE quality standard for EOLC for adults (NICE 2011).

However, EOLC pathways were criticized for reducing care of the dying to a flow diagram and a tick box exercise that did not improve patient care (Kelly 2003). Allen (2010, p.48) contests that EOLC pathways have transformed and changed into a 'hybrid ensemble' of clinical and management agendas.

Following substantial criticism of the LCP in the media and elsewhere, the government requested an independent review of its use. A panel led by Baroness Julia Neuberger consulted professional bodies and reviewed relevant literature. They also consulted members of the public who described their personal experiences around usage of the LCP.

Following the consultation, a report entitled *More Care, Less Pathway: A Review of the Liverpool Care Pathway* was produced (DH 2013a). The review panel noted that before the introduction of the LCP into hospitals, the care that patients received at the end of life was variable, with many examples of poor care. They fully acknowledged the valuable contribution that approaches like the LCP have made in improving the timeliness and quality of clinical decisions in the care of dying patients, and urged that the overall findings of the review did not result in clinicians defaulting back to treating dying patients as though they are always curable for fear of censure. The review panel stated that, used correctly, the LCP could provide a model of good practice for dying patients. However, the evidence examined showed that the LCP had not always been used appropriately and had come to be seen as a generic protocol, intended to be applicable for all patients in the last hours or days of their lives, and that this was the wrong approach. The panel therefore recommended that the LCP be replaced by 'an end of life care plan for each patient backed up by condition-specific good practice guidance' (DH 2013a, p.47).

The importance of individually tailored care for those in the terminal phase of their lives, and their relatives, cannot be over-emphasized. No framework, pathway or care plan is a substitute for careful assessment, information giving, listening, referral and skilled intervention. Each person will require slightly different care in one way or another and, as with all areas of nursing care, assumptions should never be made solely on the basis of previous preferences, sociocultural or religious stereotypes.

However, some principles and interventions, whilst not to be applied without bearing in mind the individual's needs, are important and should be routinely considered, even if not undertaken for each patient. These principles should reflect the ethos of

palliative care and integrate the physical, psychological, social and spiritual aspects of care which are at no time more important than in the terminal phase of life (Watts 2013).

Guidance on many different aspects of terminal care, including comfort measures, the anticipatory prescription of medicines, the discontinuation of inappropriate interventions (including resuscitation) and care of the relatives and carers (both before and after the death of the patient), should be included in these principles of care.

Pharmacological support

Pharmacological symptom management can improve the quality of life of patients with a severe life-limiting illness. Depending on a person's position on the disease trajectory and their goals of care, drugs, including chemotherapy, may be prescribed to actively treat disease, prevent, reduce or eliminate symptoms or slow the disease process. A patient approaching the terminal phase may choose to have antibiotics to treat their symptomatic urinary tract infection but may decline to have antibiotics to treat a recurring episode of severe pneumonia (Clary and Lawson 2009). Palliative care, with its gradual shift in transition from curative and life-prolonging treatment toward palliative quality of life treatments, can relieve significant medical burdens and maintain a patient's dignity and comfort.

Symptoms such as pain, dyspnoea, nausea and vomiting should be treated proactively according to local regimens. Tumour-related bowel obstruction where surgery is not appropriate can be managed medically, also adhering to local policy. Normalizing the environment for patients may prevent delirium but pharmacological intervention may be needed as per local guidelines (Clary and Lawson 2009). Excessive respiratory secretions, which may lead to the phenomenon of the 'death rattle', can be a very distressing symptom for families and relatives and needs sensitive explanation and reassurance that this is unlikely to be distressing the patient and the reasons for the management of choice which may be pharmacological but can also include non-pharmacological measures such as positioning the patient.

Any intervention should be consistent with the patient's preferences and goals, especially in the context of palliative care. If investigations or tests cannot possibly lead to a change in the patient's management, the investigation or test is not indicated. Currow et al. (2013) report that 20% of people take at least eight medications at the time of referral to a specialist palliative service, adding that many people admitted to palliative care services had an increase in prescribed medications as death approached, with reductions in long-term medications often surpassed by initiation of drugs for symptom management. Acknowledging that patients' rights to adequate medication are not lessened because they have a shorter prognosis, they point out that frail and vulnerable patients have diminished capacity for withstanding adverse drug reactions which increase the risk of iatrogenic harm. There is, therefore, a greater responsibility on those prescribing medication to palliative patients to optimize all medications, balancing benefit and risk, monitoring and adjusting for each individual in the context of a changing clinical picture (Currow et al. 2013).

Many medications for chronic conditions are continued in spite of changes in a person's prognosis that may render the initial intentions unnecessary or inappropriate. Changes in body composition and eating habits may affect blood glucose levels, requiring adjustment of diabetes management such as frequency and targets of monitoring and appropriateness of medication indication and dosage. Cessation of long-term medications often occurs as a result of suspected adverse drug reaction or loss of the oral route of administration rather than planned care. However, cessation of long-term medications without careful discussion with patients or their families carries the potential for both physiological and psychological harm (Clary and Lawson 2009). It can be extremely difficult for patients or families who for a lifetime have monitored blood glucose levels to suddenly let go of this practice.

At all times there should be clear discussion with patients and their families relating to the goals of treatment as well as specific time lines for reviewing these and if necessary discontinuing them; this is especially important when considering fluids, nutritional supplements and oxygen. It should also be pointed out to patients and their families that if symptoms, such as those previously mentioned, have not been an issue earlier in their trajectory then these may not necessarily be a problem at the end of life. Equally, they should be reassured that discontinuing medications or treatments does not mean a discontinuation of care, which will be delivered with competence and compassion right to the end of life. This reassurance alongside good management of physical symptoms allows patients and loved ones the space to work out unfinished emotional, psychological and spiritual issues and, thereby, the opportunity to find affirmation at life's end (Clary and Lawson 2009).

A patient's compliance relating to medication may be affected by concern about addiction, side-effects or incorrectly thinking that if pain killers are taken 'too soon' they will be without sufficient analgesia 'when pain gets worse'. As a result, people with severe symptoms may not use medicines even when effective management is available. This is particularly pertinent to opioids. Involving pharmacists to counsel patients can have a positive influence and improve patient outcomes. Team-based multidisciplinary care is considered integral to palliative care because of the complex biomedical and psychosocial needs of palliative care patients. Similar to palliative care, optimizing medication outcomes should have a multidisciplinary approach. Pharmacists are well placed to promote proactive review of pharmacotherapy. They can provide advice for other healthcare professionals and also facilitate discussion with patients to reset therapeutic goals to ensure they understand the reasons for, and are happy with, any proposed changes (Clary and Lawson 2009).

Non-pharmacological support

Research has indicated that non-pharmacological approaches to physical and psychological symptoms may be of benefit to EOLC patients (Booth et al. 2011). Non-pharmacological measures can help to empower patients at a time when the majority of their symptom management is prescriptive. There is a body of literature concerning the non-pharmacological management of breathlessness (Booth et al. 2011, Corner 1996). This model advocates the involvement of the multidisciplinary team to draw on all resources available, e.g. using the physiotherapist to give advice on breathing exercises and the occupational therapist to teach relaxation techniques.

Florence Nightingale (1859) wrote of the effect that the environment had on health, highlighting the negative effects of factors such as noise, lack of air, light and sleep. Booth et al. (2011) also advocate assessment of the environment, acknowledging the benefits of a bright well-ventilated room with the positioning of a fan to reduce the sensation of breathlessness for patients. This multidisciplinary model should not be limited to the care of breathlessness and should be considered for all aspects of patient care for optimum outcomes.

The essence of non-pharmacological interventions is both holistic and heuristic (Taylor 2007). Nurses, who often spend most time with patients during EOLC, are often best placed to assist patients with non-pharmacological interventions. The element of reassurance or 'presence' is very important: knowing when to touch or not to touch a patient or relative, when to simply sit quietly with the patient or draw up a chair for a deeply anxious relative. Nursing routines, performed in a calm reassuring manner, bring normality to interactions, providing a sense of safety and security. These fundamental aspects of care are often extremely simple but are not always evident to those that do not have experience or specialist skills in relation to caring for EOLC patients. Specific non-pharmacological techniques such as relaxation techniques, counselling and music therapy are discussed in other chapters in this book.

Physical care

Physical discomfort can be one of the greatest concerns as patients with a terminal illness anticipate dying. NICE (2004) guidelines advise that patients expect to be offered optimal symptom management at the end of life and recommend that this should be achieved in all healthcare settings, particularly in the community where effective well-managed symptom management can reduce unnecessary hospital admissions.

There should be a holistic assessment of the patient's needs followed by comprehensive care planning and regular review of symptoms. It is absolutely essential that the patient is central to the process of assessment and planning at all times (NEoLCP 2010). Nurses should be competent to build on this assessment in a dynamic, sensitive, consistent manner and observe and record subtle changes (NEoLCP 2011). They must be aware of the significance and governance risks involved when assessments are not comprehensive. This will often involve consideration of changes of equipment to keep the patient comfortable. Ensuring a pressure-relieving mattress is made available for patients either in their own home or in hospital is of paramount importance in order to ensure that pressure area care is maintained. However, many patients do not like the pressure-relieving mattress and will not wish to have this. In this situation the nurse's role is to advise the patient and their relative of the risk involved without alarming them unduly. Switching to a 24-hour syringe pump for patients who are unable to swallow medication must be considered alongside the patient's feelings of being attached to a pump that may limit their mobility in the home. All discussions should be documented clearly and contemporaneously.

Communication with other members of the multidisciplinary team can be an excellent resource when assessing the patient's need; the expertise of the patient's key worker, occupational therapist or social worker is often invaluable. Use of assessment tools such as the Pepsi-Cola aide memoire and the distress thermometer can also aid assessment (NEoLCP 2011).

Meeting the physical needs of patients at the end of life is aimed at providing as much comfort as possible. The change from curing to caring means providing comfort with the least invasive procedures, and maintaining privacy and dignity becomes paramount. If these physical needs are controlled to a manageable level, patients and their families and carers will be able to focus on maintaining hope, reaffirming important connections and attaining a sense of completion.

Table 8.10 lists some common physical symptoms present during the terminal phase of life and any management changes specific to the patient who is dying. Pain, sickness, nausea and respiratory tract secretions have been cited as the four most common symptoms (Ellershaw et al. 2010). Information relating to these and many of the other symptoms experienced in the terminal phase, including mouth care, nutrition and elimination, is discussed in relevant chapters of this book.

Psychosocial care

Ongoing psychosocial assessment, support and care of the patient and their relatives are extremely important as death approaches. Research has shown that improving psychosocial interventions alleviates distress for EOLC patients (Lloyd-Williams 2003). However, provision may need to be adjusted according to the changing needs of the patient – many will experience increasing anxiety and distress, increased feelings of social isolation and, alongside this, a decrease in physical energy available to them for dealing with these concerns. Relatives will naturally be distressed by the deterioration of the patient and may exhibit signs of grief even before death occurs. Nurses should ensure that, wherever possible, the physical environment is conducive to patients and relatives being able to express their thoughts and emotions, and that appropriately trained staff are available to listen and support them.

Alleviating distress when patients no longer feel connected with the world and are angry that their body has failed them can be challenging for healthcare professionals. Patients may find it difficult to discuss threats to their personhood and it is only through effective communication and interpersonal skills that nurses can address these issues (Lloyd-Williams 2003).

Evidence suggests that real change in EOLC will only happen if patients are allowed to prepare for and face death by expressing fears, hopes and desires (Neuberger 2004). Some management strategies prevent this; for example, medication to alleviate anxiety may also block fear. As a result, the source of fear or anxiety will not be understood and the cause will not be addressed. Patients have reasons to be afraid and allowing them to express their anxiety is crucial (Cannaerts et al. 2004).

The importance of psychosocial care should never be underestimated and psychological management should be considered just as important as physical management across primary, acute and tertiary care (Lloyd-Williams 2003). All healthcare professionals need to understand and recognize patients with complex psychosocial needs and be able to make comprehensive assessments of the distressing issues that patients may face. Nurses should be aware of their own limitations in this area and seek the support of specialists when needed.

Psychological, social and spiritual factors may exacerbate physical suffering. For instance, depression amplifies pain and other somatic symptoms. When physical, psychological and spiritual sources of distress are inseparably intermixed, causing 'total pain syndrome', a fully integrated clinical approach that addresses the multiple dimensions of suffering is required (Lloyd-Williams 2003).

Spiritual and religious care

Considerable energy and debate continue to be devoted to defining and exploring the concept of spirituality and its relationship to religion (NEoLCP 2011). Spiritual care has risen in visibility in health services over the last two decades, from a position where it was equated with religious care and regarded as the sole province of chaplains to one where a broad concept of spirituality is employed and spiritual care is recognized as having relevance for all sectors and to lie potentially within the remit of all health and social care workers. However, this perceptual shift has not necessarily occurred at the level of practice and there is anecdotal and other evidence of continuing uncertainty and ambiguity over how, when and where spiritual need should be addressed.

The (UK) Standards for Hospice and Palliative Care Chaplaincy affirm that assessment of spiritual and religious need should be available to all patients and carers, including those of no faith. Spiritual needs are defined as exploring the individual's sense of meaning and purpose in life; exploring attitudes, beliefs, ideas, values and concerns around life and death issues; affirming life and worth by encouraging reminiscence about the past; exploring the individual's hopes and fears regarding the present and future for themselves and their families/carers; exploring the 'why' questions in relation to life, death and suffering.

Each patient and their relatives should have the opportunity to express, in advance, any religious, cultural or practical needs they may have for the time of death or afterwards, particularly regarding urgent release for burial or cremation. This can be done as part of the advance care planning process or it can be completed nearer the point of death (NNCG 2011). It is important to try to discuss these with the patient, as even where relatives share a common faith, there may be differences in the way each person practises. It is vital that assumptions are not made on the basis of a previously disclosed religious preference; for example, not all Catholic believers will want to be given the sacrament of the sick. Further information about religious/cultural perspectives and practices is given in Table 8.11.

Table 8.10 Guidelines for symptom control

Symptom	Management changes
Pain (see Chapter 9: Respiratory care)	<p>Good assessment is a necessary precondition for effective pain management (Cherny 2010)</p> <p>Levels of pain may increase, decrease or remain stable. Analgesics may need to be rationalized and/or administered via a different route (e.g. subcutaneous syringe pump) as the patient may no longer be able to swallow</p> <p>Levels of consciousness, lucidity and respiratory rate will all be commonly altered during the terminal phase. It is important to bear this in mind when assessing the effects and side-effects of analgesic medications</p> <p>Some discomfort can be caused by immobility and pressure on the skin. If appropriate (i.e. if it will not cause patient or relative distress), the patient should be moved to a pressure-relieving mattress. Otherwise regular skin care should be carried out as tolerated (see Chapter 5: Elimination for further information)</p>
Nausea/vomiting	<p>Nausea and vomiting may increase, decrease or remain stable. Comprehensive assessment is paramount. In light of assessment reverse the reversible. Consider the complications of the disease process as well as side-effects of drugs (Faull and Woof 2002)</p> <p>Antiemetics may need to be rationalized and/or administered via a different route (e.g. subcutaneous syringe pump) as the patient may no longer be able to swallow</p> <p>Because the insertion of a nasogastric tube is considered a fairly invasive and uncomfortable procedure, it is unlikely to be appropriate for the management of nausea and vomiting in the terminal care setting. Those nasogastric tubes already <i>in situ</i> should remain unless causing distress to the patient</p> <p>Injectable hyoscine hydrobromide (Buscopan) or octreotide should be considered to dry gastric secretions in those patients with mechanical vomiting secondary to bowel obstruction</p>
Respiratory secretions	<p>'Noisy', 'bubbly' breathing or 'death rattle' in the terminal phase of life affects approximately 50% of dying patients (O'Donnell 1998) and is the result of fluid pooling in the hypopharynx. Non-pharmacological methods should be used alongside medication. These can include distraction techniques, relaxation therapy and a hand-held fan. A multidisciplinary team approach with the physiotherapist, occupational therapist and palliative care team is often needed (Robinson and English 2010)</p> <p>Changing the position of the patient in the bed may reduce the noisiness of breathing. It is important to reassure family that the patient is not drowning or choking, and is unlikely to be distressed by the symptom themselves</p> <p>Antimuscarinic (hyoscine butylbromide) or anticholinergic (glycopyrronium or hyoscine hydrobromide) drugs are often used in this setting and can be administered subcutaneously via a syringe pump</p>
Agitation/restlessness	<p>Confusion, delirium, agitation and restlessness are all terms used to describe patient distress in the last 48 hours of life. The symptom is fairly common with up to 88% of patients experiencing symptoms in the last days or hours of life (Lawlor et al. 2000). Careful assessment should include consideration of any precipitating factors including medications, reversible metabolic causes, constipation, urinary retention, hypoxia, withdrawal from drugs or alcohol, uncontrolled symptoms and existential distress</p> <p>Clear, concise communication, continuity of carers if possible, the presence of familiar objects and people and a safe immediate environment can all be helpful nursing interventions</p> <p>Where the cause of the symptoms cannot be established or cannot be reversed, anxiolytics, antipsychotics or sedation may need to be considered. This may need to be discussed with relatives instead of the patient. It is important that the nurse is present for these conversations in order to facilitate reassurance of the relatives throughout</p>
Breathlessness	<p>Breathlessness may be a new symptom in the terminal phase or may worsen from its pre-existing state. Careful assessment is important as this symptom will usually involve physiological, psychological and environmental factors</p> <p>Low-dose opioids and anxiolytics can be of use for breathlessness, though as with other medications, the route of administration may need to be altered. Nebulized bronchodilators and oxygen may also be of benefit. Where the symptom is causing severe distress and is intractable, sedation may need to be considered in discussion with the patient and relatives (Booth 2006)</p> <p>Relaxation exercises, open windows or electric fans and massage may also be of benefit if the patient can tolerate these</p>
Constipation	<p>The focus of care with regard to constipation should remain on patient comfort. Oral laxatives are inappropriate if the patient cannot swallow and rectal interventions should only be undertaken if the patient is clearly distressed by this symptom</p>

Table 8.11 Cultural and religious considerations in the care of the dying patient and their care after death

	Beliefs about death	Cultural or religious routines	Preparing the body	Post-mortem/transplantation	Specific burial requirements	For further information contact
Baha'i	Baha'is have a great respect for life, believing each person has a soul that comes into being at conception. During the lifetime the spiritual attributes are acquired for the next stage of existence that follows death	The body is to be treated with great respect as it is considered to be the vehicle of the soul. Friends and relatives will say the prayers for the dead	The body is to be washed and wrapped in plain cotton or silk. A special ring will be placed on the finger of the patient and is not to be removed	Organ donation is considered praiseworthy	Embalming and cremation are forbidden. The burial should take place no more than an hour's journey from the place of death	UK Bahai: www.bahai.org.uk
Buddhism	Death viewed as very important as it is a time of transition before rebirth as the person moves towards Nirvana – the freedom from suffering, death and rebirth	There is no one specific ritual but a state of calm is necessary. An example may be: • A monk may be called to recite prayers/ lead meditation • The family wanting the body to remain in one place for up to 7 days for the rebirth to take place. (It is recognized this is not possible in a health-care setting)	At all times the body should be treated with greatest care and respect. When washing has taken place the body should be wrapped in a plain white sheet	No objections	Prefer cremation as symbol of impermanence of the body	Buddhist Hospice Trust: www.buddhisthospice.org.uk
Christianity/Anglican/Church of England	God's forgiveness is available to all who ask because of the selfless/sinless death of Jesus Christ on the cross. As Christ was resurrected, death has been overcome and eternal life is a gift from God available to all who believe and seek forgiveness	Priest or minister may attend to say prayers. Primarily to support relatives and friends Prayers may be offered but these will be informal in most situations Priest requested to recite prayers for the dying and then prayers for the dead	No specific requests No specific requests A religious icon such as a crucifix or rosary may accompany the patient's body	No objections	No preference Burial has in the past been preferred	Hospital Chaplaincies Council: www.nhs-chaplaincy-spiritualcare.org.uk
Nonconformist/Free Church						
Roman Catholicism						
Church of Jesus Christ of Latter Day Saints (Mormon Church)	Earthly life is viewed as a test to see if individuals are fit to return to God on death. Death is viewed as a temporary separation from loved ones		The body should be washed and dressed in a shroud. Some may wear a religious undergarment which must remain in place after the patient has died	No religious objection	Burial preferred	Church of Jesus Christ of Latter Day Saints: www.ldschurch.org

	Beliefs about death	Cultural or religious routines	Preparing the body	Post-mortem/transplantation	Specific burial requirements	For further information contact
Christian Scientist		There are no specific rituals associated with death	Females only to touch female body	This is generally not supported unless there is a legal requirement for it	Prefer cremation	For details of local Christian Science Church: www.christianscience.org.uk
Hinduism	Hindus believe that all human beings have a soul that passes through successive cycles of birth and rebirth. It is believed that eventually the soul will be purified and join the cosmic consciousness	<p>Last rites include:</p> <p>Tying a thread around the neck or wrist to bless the dying person</p> <p>Sprinkling holy water from the Ganges on them</p> <p>Placing a sacred Tulsi leaf in their mouth</p> <p>If possible, placing the person on a sheet or mat on the floor to symbolize closeness to Mother Earth, freedom from physical constraints and the easing of the soul's departure</p>	<p>Close family members led by the eldest son usually wash the body. They may be distressed if a non-Hindu touches the body so gloves should be worn. A female must only be touched by a female and a male by a male. The body should be covered by a plain white sheet.</p> <p>All religious objects should remain in place</p>	Only if absolutely necessary. If a post-mortem does take place, the organs must be returned to the body	Cremation within 24 hours of death arranged by the eldest son	National Council of Hindu Temples: www.hinducounciluk.org
Islam	Death is a mark of transition from one state of being to another. Muslims are encouraged to accept death as part of the will of Allah	<p>The time before death is important for extending forgiveness to family and friends.</p> <p>The Koran is recited until the point of death</p>	<p>The body should be turned to the right (Qibla; Mecca) if this hasn't happened before the patient dies.</p> <p>The relatives will close the eyes and bandage the lower jaw so the mouth doesn't gape. Flex the joints of the arms and legs to stop them becoming rigid. A complete cleansing (Ghusal) will then take place performed by the relatives (this may take place after the body has been removed from the ward).</p> <p>The body will be wrapped in a Caffan. If there isn't one available, a sheet will do.</p> <p>A female must be handled by female nursing staff and a male by male staff.</p> <p>Maintaining modesty and dignity is essential</p>	This is not acceptable, primarily because it will delay burial but also because the person may still be able to perceive pain	Burial will take place as quickly as possible	Muslim Council of Great Britain: www.mcb.org.uk/downloads/Death-Bereavement.pdf

Post-procedural considerations

Nursing care does not end when the death of the patient occurs; it extends beyond death to provide care for the deceased person and support to their family and carers (NNCG 2011). This physical care given by nurses following death in hospitals has been traditionally referred to as 'last offices'. However, this chapter will refer to 'care after death', a term more appropriate in our multicultural society (NNCG 2011).

Care after death (last offices)

Definition

'Care after death' has historically been referred to as 'last offices', a term related to the Latin *officium*, meaning service or duty which was associated with the military. This term also had religious connotations from its association with 'last rites', a Christian sacrament and prayer administered to the dying (Quested and Rudge 2003). It is used to refer to the final act performed on a person's body. Last offices, sometimes referred to as 'laying out', was the term for the nursing care given to a deceased patient which demonstrates continued respect for the patient as an individual (NMC 2015). More recently, there has been a move away from the term 'last offices' and its link with the military and religious association with 'last rites', to the terminology of 'care after death'. This move is appropriate for a variety of reasons. The term 'last offices' only applies to the physical care of the deceased body. 'Care after death' is a broader term that better reflects a multicultural society and also embraces all the differing nursing tasks involved, including the ongoing support of the family and carers (NNCG 2011).

Even though they have died, patients are still referred to as patients or people throughout this section.

Related theory

Death threatens the orderly continuation of social life, according to Seale (1998). Care after death can mark the social transition of the person and the biological death of the patient, and begins the process of handing over care to the family and funeral director. This care can be considered as an important act in the rite of passage in moving the deceased person into the world of the dead (van Gennep 1972) and is a procedure that people in all cultures recognize.

Care after death is the final act a nurse will carry out for the patient and remains associated with ritual (Pattison 2008a,b). Nursing care for a patient who has died has historical roots dating back to the 19th century (Wolf 1988). However, contemporary nursing practice has moved away from the ritualistic practices of cleansing, plugging, packing and tying the patient's orifices to prevent the leakage of body fluids to encompass much more than simply dealing with a dead body (Pattison 2008a,b, Pearce 1963). Consideration now has to be given to legal issues surrounding death, the removal (or non-removal) of equipment, washing and grooming, and ensuring correct identification of the patient (Costello 2004). The *End of Life Care Strategy* (DH 2008) emphasizes care after a patient has died, and in particular it points to the value of integrated care pathways in managing administrative and psychosocial care. This corresponds to a good death theory where being treated with dignity is an underlying premise (Kehl 2006, Smith 2000), and good death encompasses all stages of dying and death (NNCG 2011, Pattison 2008a,b). This principle, therefore, continues after death.

Carrying out such an intimate act that in many cultures would be carried out only by certain family or community members requires careful consideration by nurses and adequate preparation of procedures. This should include family members where possible. Since 60.6% of all men and women who die in England and Wales will die in an institution (hospice, hospital, care home) (ONS 2009), it is predominantly nurses who carry out after-death care, prior to patients being moved to mortuaries or undertakers. Quested and Rudge (2003) suggested that this aspect of care is largely invisible to other healthcare workers.

Evidence-based approaches

Care after death has its nursing foundation in traditional cultures although it is a nursing routine which does not have a large amount of research-based evidence (Cooke 2000). For nurses, this care should be seen as a privilege and treated with the utmost sensitivity. There is only one chance to get it right so it is imperative that nurses ensure the wishes of the family and carers are, where possible, adhered to. New guidance has been developed to assist nurses with this complex aspect of care (NNCG 2011). This new guidance encourages nurses to honour the integrity of the person who has died and places the deceased and their carers at the 'focus of the care whilst continuing to balance the legal and coronial system and the health and safety of staff' (NNCG 2011).

Care after death can have symbolic meaning for nurses, often providing a sense of closure. It can be a fulfilling experience as it is the final demonstration of respectful, sensitive care given to a patient (Nearney 1998) and also the family (Speck 1992). Philpin (2002) advises that there has been a move away from practice that is considered unscientific; however, care after death is a time when nurses must be mindful and show respect for patients' rituals and cultures as well as insight into the symbolic meanings that patients and their families hold dear. This can be a major source of comfort and structure for the patients and families at this traumatic time (Neuberger 2004, Wolf 1988).

It should be noted that many parts of the nursing procedures relating to care after death are based on general principles of infection prevention and control, and safe working. Care of the patient who has died must therefore take into account health and safety guidelines to ensure families, healthcare workers, mortuary staff and undertakers are not put at risk (HSAC 2003). This chapter incorporates this guidance with broader national guidance where appropriate. It aims to ensure that patients who have died are treated with respect and dignity even after death, that legalities are adhered to and that appropriate infection prevention and control measures are taken. *Patients Who Die in Hospital* (DH 2005b) and *What to Do After a Death* (DH 2006b) provide information for families and carers and focus on procedures around the legalities of organizing funerals.

Indications

- When a patient's death has been verified and documented.
- For adult patients who have died in hospital or in a hospice.

Contraindications

When to consult for further guidance before undertaking procedures.

- If a patient who has died is indicated for a post-mortem.
- If a patient who has died is a candidate for organ donation.

Legal and professional issues

Nurses should be aware of the legal requirements for care of patients after death as it is essential that correct procedures are followed (Green and Green 2006). It is particularly important that nurses are aware of deaths that require referral to the coroner (discussed later) as this will facilitate the correct personal care and enable nurses to prepare the family for both a potential delay in the processing of the MCCD and also the possibility of a post-mortem examination (NNCG 2011).

Guidance relating to vulnerable adults is available (MCA 2005). If after death safeguarding issues are raised, it is important to follow the local policy and ensure that concerns are communicated with relevant agencies such as Social Services, police and coroner.

Every effort should be made to accommodate the wishes of the patient's relatives (Neuberger 2004). The UK is an increasingly multicultural and multifaith society which presents a challenge to nurses who need to be aware of the many different religious and cultural rituals that may accompany the death of a patient.

There are notable cultural variations within and between people of different faiths, ethnic backgrounds and national origins. This may affect approaches to death and dying (Neuberger 2004). This needs to be remembered when administering care after death in order to avoid presumptions. While those who have settled in a society with a dominant faith or culture other than their own might appear to increasingly adopt that dominant culture, they may choose to retain their different practices at times of birth, marriage or death (Neuberger 1999). Approaches to death and dying also reveal as much about the attitude of society as a whole as they do about individuals within that society (Field et al. 1997).

Practices relating to care after death will vary depending on the patient's cultural background and religious practices (Nearney 1998). Table 8.11 provides a guide to cultural and religious variations in attitudes to death and how individuals may wish to be treated. This information is not designed to be a 'fact file' (Gilliat-Ray 2001, Gunaratnam 1997, Smaje and Field 1997) of information on culture and religion that seeks to give concrete information. Such a 'fact file' would not be appropriate as we need to be aware that whilst death and death-related beliefs, rituals and traditions can vary widely among each cultural group, within any given group there may be varying degrees of observance of these issues (Green and Green 2006), from orthodox to agnostic and atheist. Categorizing individuals into groups with clearly defined norms can lead to a lack of understanding of the complexities of religious and cultural practice and can depersonalize care for individuals and their families (Neuberger 1999, Smaje and Field 1997).

Expected deaths may be very different from those where a patient has died suddenly or unexpectedly (Docherty 2000). In certain cases the patient's death may need to be referred to the coroner or medical examiner for further investigation and possible post-mortem (DH 2003b). If those caring for the deceased are unsure about this then the person in charge of the patient's care should be consulted before care after death has commenced. If the death is going to be referred to the coroner, advice must be sought before interfering with anything that might be relevant to establishing the cause of death.

Pre-procedural considerations

Before undertaking care after death, several other events must take place.

Verification and certification of death

Death should be confirmed or verified by appropriate health-care staff. The process of verifying death is not in itself a statutory process and can be performed by nurses as well as doctors (Academy of Medical Royal Colleges 2008). The NMC states that nurses may confirm death has occurred provided there is an explicit policy or protocol to allow such action and provided that the death is expected (NMC 2015). Nurses and other healthcare professionals must therefore be aware of local guidance, which should be in line with national guidance, regarding the criteria for verifying death. It is good practice for verification to occur as soon as possible.

The professional verifying the death is responsible for confirming the identity of the deceased person (where known) using the terminology of 'identified to me as'. This requires name, date of birth, address and NHS number (if known) (NNCG 2011). Details of the date and time death occurred should be documented in the notes and/or care pathway documentation along with the name and contact details of the responsible practitioner. Any relevant devices (such as cardiac defibrillators) should also be recorded as well as the verifier's own name and contact details in the nursing, medical or ambulance documentation (NNCG 2011). The certifying medical practitioner has overall responsibility for identifying and communicating the presence of any implanted devices or radioactive substances. They are also responsible for identifying the appropriate person to deactivate and remove implants, to liaise with the appropriate medical physics department regarding

radioactive treatments and advise mortuary staff and funeral directors. If relatives have any concerns about the death, these should also be documented.

Unexpected deaths must be confirmed by a medical doctor (and usually a senior medical doctor). Confirmation of death must be recorded in the medical and nursing notes and care pathway documentation if necessary. If the death is suspicious or unexplained, a special forensic post-mortem may be required and means the family and carers can only view the body with agreement from the police and coroner. In many instances the restrictions will be minimal but, if the death is thought to be suspicious, it is important that forensic evidence is not contaminated; there should therefore be no removal of indwelling devices or other such equipment from the patient (NNCG 2011).

A registered medical doctor who has attended the deceased person during their last illness is required to give a MCCD (Home Office 1971). It is good practice to ensure that when the death need not be referred to the coroner, the MCCD is issued within 1 working day so burial or cremation arrangements can commence (NNCG 2011). The certificate requires the doctor to state on which date he/she last saw the deceased alive and whether or not he/she has seen the body after death (this may mean the certificate is completed by a different doctor from the one who confirmed death). Out-of-hours medical examiners (ME) can now certify death where there is a cultural/religious requirement to bury, cremate or repatriate patients quickly (DH 2008). The ME can also certify for reportable deaths where a post-mortem is not deemed necessary (DH 2008). The ME is an independent health professional who determines the need for coroner referral.

Burial and cremation

For those who need a burial within 24 hours, this remains at the discretion of the local births and deaths registrar in each council and depends on the individual opening hours and on-call facilities. Local hospital policy should outline procedures for out-of-hours death registration, and certification and burial is usually easier to accommodate than cremation within 24 hours.

Repatriation to another country needs further documentation, alongside the death certification and registration documents. This varies according to the country to which the person is being repatriated. Only a coroner or ME is authorized to permit the body to be moved out of England or Wales. A *Form of notice to a coroner of intention to remove a body out of England* (Form 104) is required which can be obtained from coroners or registrars. This form needs to be given to the coroner along with any certificate for burial or cremation already issued. The coroner's office will acknowledge receipt of notice and inform the family when repatriation can occur. Coroner authorization normally takes up to four working days so that necessary enquiries can be made. In urgent situations, this can sometimes be expedited and the coroner's office and relevant High Commission will have further information relating to this. In terms of infection control, different levels of packing of body orifices may be required by different countries. Those involved with repatriation must be informed if there is a risk of cross-infection (HSAC 2003). Funeral directors will assist with transportation issues.

Referral to a coroner

If the patient's death is to be referred to a coroner or ME, this will affect how their body is prepared. The need for referral to a coroner or ME needs to be ascertained with the person verifying the death (DH 2008). Preparation in this situation differs according to how the patient died. Broadly, two types of death are referred to the coroner:

- those from a list of cases where the coroner must be informed (which includes deaths within 24 hours of an operation, for example)
- cases where the treating doctor is unable to certify the cause of death (Home Office 2002, HTA 2006).

The DH website at www.dh.gov.uk gives more information about when to refer to the coroner or ME and when post-mortems are indicated.

Requirement for a post-mortem

Post-mortems can affect preparation after death, depending on whether this is a coroner's post-mortem (sometimes referred to as a legal post-mortem because it cannot be refused) or a post-mortem requested by the consultant doctor in charge to answer a specific query on the cause of death (also referred to as a hospital or non-legal post-mortem). A coroner's post-mortem might require specific preparation but the coroner or ME will advise on this and should be contacted as soon as possible after death to ascertain any specific issues. Individual hospitals, institutions and NHS trusts should provide further guidance on these issues. If the patient is to be referred to the coroner, cap off catheters and ensure there is no possibility of leakage. Do not remove any invasive devices until this has been discussed with the coroner (HTA 2006).

If the patient is *not* to be referred to the coroner, invasive and non-invasive attachments, such as central venous access catheters, peripheral venous access cannulas, Swan–Ganz catheters, tracheal tubes (tracheostomy/endotracheal) and drains, can all be removed.

If a post-mortem is necessary, the patient's family or carers may have questions that need to be sensitively answered. The DH (2003b) has published a simple guide to what actually takes place at a post-mortem.

Organ donation

Consider if the patient was a candidate for organ or tissue donation. Patients who previously expressed a wish to be a donor (or carry a donor card), or whose family has expressed such a wish, might need specific preparation. If an individual's wishes regarding organ and tissue donation were not formally recorded before death, consent can be sought from a nominated representative or someone else in a qualifying relationship, if they believe the deceased wanted to donate. Whole-body donation can only be agreed by individuals themselves and not by anybody else after death (HTA 2011). Advice on consent is available from NHS Blood and Transplant (NHSBT) specialist nurses organ donation (SN-OD) who are based in acute trusts or by contacting NHSBT directly (www.uktransplant.org.uk/ukt).

Infectious patients

The practitioner who verified the death is responsible for ascertaining whether the person had a known or suspected infection and whether this is notifiable. The Health and Safety Executive has issued guidelines on the handling of bodies with infections and nurses, doctors and other healthcare professionals should be aware of related local infection control policies and reporting responsibilities (HSE 2003). It is vital that processes are in place to protect confidentiality, which continues after death, but this does not prevent the use of sensible rules to safeguard the health and safety of all those who may care for the deceased.

Families and carers should also be supported in adhering to infection prevention and control procedures if they wish to assist in personal care after the death of an infectious patient. There are a few, very rare, exceptions where it is not possible for families to participate.

- If the patient has had any of the following infections prior to death: typhus, severe acute respiratory syndrome, yellow fever, anthrax, plague, rabies and smallpox. Assistance with care after death or viewing is not permitted because of the high risk of transmission of these infections (Healing et al. 1995).
- If the patient was exposed to radiation. Patients may have been treated with radioactive material as therapy or may have been exposed to it in accidental circumstances. Always seek expert radiation protection advice before beginning care after death in such cases.

If the patient was infectious, it needs to be established whether it is a notifiable infection, for example hepatitis B, C or tuberculosis, or non-notifiable (Healing et al. 1995, HPA 2010, HSAC 2003). There are additional requirements for patients with blood-borne infections, therefore the senior nurse on duty should be consulted and the local infection control policy adhered to. In the UK, notifiable infections must be reported via a local authority 'proper officer' and this is the attending doctor's duty. Infection prevention and control contacts in local trusts or services can provide more help and guidance around notification. Placing the patient who has died in a body bag is advised for all notifiable diseases and a number of non-notifiable infectious diseases (i.e. HIV, transmissible spongiform encephalopathies, e.g. Creutzfeldt–Jakob disease). A label identifying the infection must also be attached to the patient's body. Specific guidance is outlined in the procedure.

Certain extra precautions are required when handling a patient who has died from an infectious disease. However, the deceased will pose no greater threat of infection than when they were alive. It is assumed that staff will have practised universal precautions when caring for all patients, and this practice must be continued when caring for the deceased patient (HSAC 2003).

Porters, mortuary staff, undertakers and those involved with the care of patients who have died must also be informed if there is a danger of infection (HSAC 2003).

Patient and family considerations

Some families and carers may wish to assist with personal care after death, and within certain cultures it may be unacceptable for anyone other than a family member or religious leader to wash the patient (Green and Green 2006). It may also be required for somebody of the same sex as the patient to undertake the personal care after death (Neuberger 2004). Families and carers should be supported and encouraged to participate if possible as this may help to facilitate the grieving process. If children are involved, nurses should be mindful of their needs and should consider the physical environment. Adults may require guidance on how best to convey the news of a deceased relative to children (NNCG 2011).

Spiritual needs

Spiritual needs relating to preparation of the patient who has died can be diverse. The patient's previous wishes should be established where possible and should always take precedence (Pattison 2008a,b). If not previously documented, try to determine patients' previous wishes from family or carers. The patient's last will and testament might have instruction on this, or advance decisions or advance care plans might have information. Families, carers or members of the patient's community or faith may wish to participate in the care after death. If this is the case, they must be adequately prepared for this with careful and sensitive explanation of the procedure to be undertaken. Families may request other items to accompany the patient who has died to the mortuary and funeral home. This might be an item of sentimental value, for instance, or an item of jewellery and this should be discussed with the NOK and documented and witnessed in accordance with local policy.

Certain religious artefacts must never be removed from the patient, even after death, for example the five Ks in Sikhism (Kesh – uncut hair, Kangha – the wooden comb which fixes uncut hair into a bun, Kara – an iron, steel or gold bracelet worn on the right wrist, Kirpan – a symbolic sword worn under clothing in a cloth sheath or as a brooch or pendant, and Kacha – undergarments) (Neuberger 2004).

The information given above and in Table 8.11 is for guidance only. Families may require all, part or none of these actions to be carried out. The information has been adapted from Hollins (2009), Speck (1992), Pattison (2008a, 2008b), Neuberger (2004) and Green and Green (2006).

Regardless of the faith that the patient's record states they hold, wishes relating to care after death may differ from the conventions of their stated faith. Sensitive discussion is needed by nurses to establish what is wanted at this time. If patients are of a faith not listed above or hold no religious beliefs, ask the relatives to outline the patient's previously expressed wishes, if any, or establish the family's wishes. Furthermore, the patient may be non-denominational and/or the family members may be multid denominational so all possibilities must be taken into account.

Additional considerations

It is important to inform other patients, particularly if the person has died in an area where other people are present (such as a bay or open ward), and might know the patient. Residents in communal settings, such as care homes and prisons, have often built

significant relationships with other residents and members of staff (Moss et al. 2002). It is important to consider how to address their needs within the boundaries of patient confidentiality. If the person has died in an environment where other people may be distressed by the death then sensitively inform them that the patient has died, being careful not to provide information about the cause and reason for death (NNCG 2011). Senior staff should offer guidance in the event of uncertainty about how to deal with the situation.

Finally, carry out all personal care after death in accordance with safe manual handling guidance and where possible within 2–4 hours of death. This is because rigor mortis can occur relatively soon after death, and this time is shortened in warmer environments (Berry and Griffie 2006). It is best practice to do this with two people, one of whom needs to be a registered nurse or a suitably trained person (NNCG 2011).

Procedure guideline 8.18 Personal care after death

Essential equipment

- Disposable plastic apron
- Disposable plastic gloves
- Bowl of warm water, soap, patient's own toilet articles
- Disposable wash cloths and two towels
- Disposable razor or patient's own electric, comb and equipment for nail care, a razor if there is a request for the patient to be shaved (see notes re shaving below)
- Equipment for mouth care, including equipment for cleaning dentures
- Identification labels × 2 or as defined in local policy
- Documents required by law and by organization/institution policy, e.g. notification of death forms
- Shroud or patient's personal clothing: night-dress, pyjamas, clothes previously requested by patient, or clothes which comply with deceased patient/family/cultural wishes
- Body bag if required (if there is actual or potential leakage of bodily fluids and/or if there is infectious disease)
- Labels for the patient's body defining the nature of the infection/disease (HSAC 2003)
- Gauze, tape, dressings and bandages if wounds, puncture sites or intravenous/arterial devices
- Plastic bags for clinical and domestic (household) waste
- Laundry skip and appropriate bags for soiled linen
- Clean bedlinen
- Record books for property and valuables
- Bags for the patient's personal possessions
- Disposable or washable receptacle for collecting urine if appropriate
- Sharps bin if appropriate

Optional equipment

- Caps/spigots for urinary catheters (if catheters are to be left *in situ*)
- Goggles
- Full gowns
- 3M masks (if highly infectious) (HSAC 2003)
- Petroleum jelly
- Suction equipment and absorbent pads (where there is the potential for leakage)
- Card or envelope to offer lock of hair as appropriate (Pattison 2008a)

Pre-procedure

Action

- 1 Apply gloves and apron, gowns/masks/goggles if the patient is infectious.
- 2 If the patient is on a pressure-relieving mattress or device, consult the manufacturer's instructions before switching off.
- 3 Lay the patient on his/her back with the assistance of additional nurses and straighten any limbs as far as possible (adhering to your own organization's manual handling policy). If it is not possible to lay the body flat due to a medical condition then inform the mortuary or relevant staff and the funeral director.

Rationale

Personal protective equipment (PPE) must be worn when performing personal care after death, and is used to both protect yourself and all of your patients from the risks of cross-infection (HSAC 2003, **C**; Loveday et al. 2014, **C**; RCN 2005, **C**).

If the mattress deflates too quickly it may cause a manual handling challenge to the nurses carrying out personal care after death. **E**

To maintain the patient's privacy and dignity (NMC 2015, **C**) and for future nursing care of the body. Stiff, flexed limbs can be difficult to fit easily into a mortuary trolley, mortuary fridge or coffin and can cause additional distress to any carers who wish to view the body. However, if the patient's body cannot be straightened, force should not be used as this can be corrected by the funeral director (Green and Green 2006, **E**).

- | | |
|--|--|
| <p>4 Remove all but one pillow. Close the mouth and support the jaw by placing a pillow or rolled-up towel on the chest or underneath the jaw. Do not bind the patient's jaw with bandages. Some people have deformed jaws that will never close – notify the funeral director if this is the case.</p> | <p>To avoid leaving pressure marks on the face, which can be difficult to remove.</p> |
| <p>5 Remove any mechanical aids such as syringe drivers, heel pads, etc. Apply gauze and tape to syringe driver/IV sites and document disposal of medication (adhering to your own organization's disposal of medication policy). Consider leaving prosthetics <i>in situ</i> as appropriate (e.g. limb, dental or breast prosthetics).</p> | |
| <p>6 Close the patient's eyes by applying light pressure to the eyelids for 30 seconds. If this is unsuccessful then explain sensitively to the family/carers that the funeral director will resolve the issue. If corneal or eye donation is to take place, close the eyes with gauze moistened with normal saline.</p> | <p>To maintain the patient's dignity (NMC 2015, C) and for aesthetic reasons. Closure of the eyelids will also provide tissue protection in case of corneal donation (Green and Green 2006, E).</p> |
| <p>7 Do not tie the penis. Spigot any urinary catheters. Pads and pants can be used to absorb any leakage of fluid from the urethra, vagina or rectum.</p> | |
| <p>8 Leakages from the oral cavity, vagina and bowel can be contained by the use of suctioning, drainage and incontinence pads respectively. Patients who do continue to have leakages from their orifices after death should be placed in a body bag following personal care after death. The packing of orifices can cause damage to the patient's body and should only be done by professionals who have received specialist training. It might be helpful to manage self-limiting leakages with absorbent pads and gently rolling the patient who has died to aid drainage of potential leakages.</p> | <p>Leaking orifices pose a health hazard to staff coming into contact with the patient's body (Green and Green 2006, E; HSAC 2003, C). Ensuring that the patient's body is clean will demonstrate continued respect for the patient's dignity (NMC 2015, C). The packing of orifices is considered unnecessary, as it increases the rate of bacterial growth that can occur when these areas of the patient's body are not allowed to drain naturally (Berry and Griffie 2006, E). However, there are certain situations where it is necessary (in severe leakage or where repatriation is required). A body bag is also necessary in these cases.</p> |
| <p>9 Exuding wounds or unhealed surgical scars should be covered with a clean absorbent dressing and secured with an occlusive dressing (e.g. Tegaderm). Stitches and clips should be left intact. Consider leaving intact recent surgical dressings for wounds that could potentially leak, e.g. large amputation wounds.</p> | <p>The dressing will absorb any leakage from the wound site (Naylor et al. 2001, R2b).</p> |
| <p>10 Stomas should be covered with a clean bag. Reinforcement of the dressing should be sufficient.</p> | <p>Open wounds and stomas pose a health hazard to staff coming into contact with the body (RCN 2005, C). Disturbing recent large surgical dressings may encourage seepage and leakage (Travis 2002, E).</p> |
| <p>11 a Remove drainage tubes, unless otherwise stated.
b Record the tubes and devices that have been removed and those that have been left <i>in situ</i>. Open drainage sites need to be sealed with an occlusive dressing (e.g. Tegaderm).
c Mortuary staff or appropriate healthcare staff should determine with the funeral director collecting the body their capacity to remove lines, drains, indwelling catheters, etc. If they are unable to remove these then the mortuary staff or those designated should attend to this before releasing the body. When a family collects the deceased all lines, drains and indwelling catheters should be removed.</p> | <p>Open drainage sites pose a health hazard to staff coming into contact with the patient's body (RCN 2005, C).
When a death is being referred to the coroner or ME or for post-mortem, all lines, devices and tubes should be left in place (Green and Green 2006, E).
The funeral director may need to ensure same-day burial and the family may wish to bathe and dress the body (NNCG 2011, C).</p> |
| <p>12 Wash the patient, unless requested not to do so for religious/cultural reasons or carer's preference. It is best to let the funeral directors shave the body if necessary. If the family/carers request that the body is shaved, sensitively discuss the consequences and document this in the notes. If shaving is to be carried out, apply water-based emollient cream to the face first. Be aware that some faith groups prohibit shaving.</p> | <p>For hygienic and aesthetic reasons. As a mark of respect and point of closure in the relationship between nurse and patient (Cooke 2000, E).
Shaving the body whilst still warm can cause bruising and marking which only appears days later (NNCG 2011, C).</p> |

(continued)

Procedure guideline 8.18 Personal care after death (*continued*)

Action	Rationale
13 It may be important to family and carers to assist with washing, thereby continuing to provide the care given in the period before death. Prepare them sensitively for changes to the body after death and be aware of manual handling and infection control issues.	It is an expression of respect and affection, part of the process of adjusting to loss and expressing grief (Berry and Griffie 2006, E).
14 Mouth and teeth should be cleaned with foam sticks or a toothbrush. Insert clean dentures if the patient normally used them. Apply petroleum jelly to the lips and perioral area.	Teeth and mouth are cleaned for hygienic and aesthetic reasons (Cooke 2000, E) and to remove debris. Petroleum jelly can prevent skin excoriation or corrosion if stomach contents aspirate.
15 Remove all jewellery (in the presence of another nurse) unless requested by the patient's family to do otherwise. Jewellery remaining on the patient should be documented on the notification of death form. Record the jewellery and other valuables in the patient's property book and store the items according to local policy. Avoid the use of the names of precious metals or gems when describing jewellery to prevent potential later confusion. Instead, use terms such as 'yellow metal' or 'red stone'. Rings left on the patient's body should be secured with tape, if loose. Be aware of religious ornaments that need to remain with the deceased.	To meet with legal requirements, cultural practices and relatives' wishes (Green and Green 2006, E).
16 Dress the patient appropriately (use of shrouds is common practice in many hospitals), or as the family's wish before they are transferred from the ward. The body should never be transferred naked or released to a funeral director from an organization without a mortuary. Be aware that soiling can occur. In community settings the community nurse may offer to do this, or the family may want to do it themselves, in which case they should be advised sensitively on the potential for soiling.	Honouring the rituals and cultures of patients' families and carers can be a major source of comfort and structure at what for some is an extremely traumatic time (Wolf 1988, E). For family and carers viewing the patient's body or religious or cultural reasons and to meet families' or carers' wishes (Green and Green 2006, E).
17 Ensure a correct hospital or organizational patient identification label is attached to the patient's wrist and attach a further label to one ankle. As a minimum, this should identify their name, date of birth, address, ward (if an inpatient) and ideally their NHS number. Complete any documents such as notification of death cards. Copies of such cards are usually required (refer to hospital policy for details). Tape one securely to clothing or shroud.	
18 Provided no leakage is expected and there is no infectious disease present, the body can be then transferred to the body store or mortuary as per local policy which may use a body bag or else the body is wrapped in a sheet. If leakage is expected or if the patient was infectious, a body bag should be used. If the leakage is continuous, place it on absorbent pads in the body bag and advise the mortuary or funeral director. If a sheet is used, do not tape too tightly.	To avoid actual or potential leakage of fluid, whether infection is present or not, as this poses a health hazard to all those who come into contact with the deceased patient. The sheet will absorb excess fluid (HSAC 2003, C). This can cause disfigurement.
19 Tape the second notification of death card to the outside of the body bag.	For ease of identification of the patient's body in the mortuary (Green and Green 2006, E).
20 Request the portering staff to remove the patient's body from the ward and transport to the mortuary. In hospital settings, it is best practice for porters to take the body from the ward to the mortuary within 1 hour of request so it can be refrigerated within 4 hours of death. This ensures that tissue donation can take place (if requested).	To avoid decomposition which occurs rapidly, particularly in hot weather and in overheated rooms. Many pathogenic organisms survive for some time after death and so decomposition of the patient's body may pose a health and safety hazard for those handling it (Cooke 2000, E). Autolysis and growth of bacteria are delayed if the patient's body is cooled.

21 The privacy and dignity of the deceased on transfer from the place of death are paramount. The body should be placed in an appropriate container to avoid causing distress to others and bed areas that will be passed should be screened off as the body is removed.	To avoid causing unnecessary distress to other patients, relatives and staff.
22 Remove gloves and apron. Dispose of equipment according to local policy and wash hands.	To minimize risk of cross-infection and contamination (RCN 2005, C).
23 Record all details and actions within the nursing documentation.	To record the time of death, names of those present, and names of those informed (NMC 2010, C).
24 Transfer property and patient records to the appropriate administrative department.	The administrative department cannot begin to process the formalities such as the death certificate or the collection of property by the next of kin until the required documents are in its possession (Green and Green 2006, E).

Problem-solving table 8.5 Prevention and resolution (Procedure guideline 8.18)

Problem	Cause	Prevention	Action
Relatives not present at the time of the patient's death.	Possible unexpected death; uncontactable family.	Preparation of family for event of death where appropriate.	Inform the relatives as soon as possible of the death. Consider also that they may want to view the patient's body before personal care after death has been completed.
Relatives or next of kin not contactable by telephone or by the general practitioner.	Out of date or missing contact information.	Ensure next of kin contact information is documented and up to date.	If within the UK, local police will go to next of kin's house. If abroad, the British Embassy will assist.
Death occurring within 24 hours of an operation.	n/a	In relation to documentation, ensure information around circumstance of death is documented and handed over to relevant healthcare staff.	All tubes and/or drains must be left in position. Spigot or cap off any cannulas or catheters. Treat stomas as open wounds. Leave any endotracheal or tracheostomy tubes in place. Machinery can be disconnected (discuss with coroner) but settings must be left alone. Post-mortem examination will be required to establish the cause of death. Any tubes, drains, etc. may have been a major factor contributing to the death.
Unexpected death.	n/a	As above.	As above. Post-mortem examination of the patient's body will be required to establish the cause of death.
Unknown cause of death.	n/a	As above.	As above.
Patient brought into hospital who is already deceased.	n/a	Not preventable but, where possible, ensure patients' families are prepared for all eventualities, particularly if palliative care patients whose death is expected, and that family know who to call and what to do in the event of death.	As above, unless patient is seen by a medical practitioner within 14 days before death. In this instance the attending medical officer may complete the death certificate if he/she is clear as to the cause of death.
Patient who dies after receiving systemic radioactive iodine.	There is a potential risk of exposure to radiation (IPEM 2002).	Radiation protection should be undertaken according to local policy.	Ensure those in contact with the patient's body are aware and pregnant nurses should not be involved in care for these patients. For further information refer to local policy for radiation protection.

(continued)

Problem-solving table 8.5 Prevention and resolution (Procedure guideline 8.18) (*continued*)

Problem	Cause	Prevention	Action
Patient who dies after insertion of gold grains, colloidal radioactive solution, caesium needles, caesium applicators, iridium wires or iridium hair pins.	There is a potential risk of exposure to radiation (IPEM 2002).	Radiation protection should be undertaken according to local policy when removing wires. Physicist may remove radioactive wires/needles, etc. themselves, depending on source.	Inform the physics department as well as appropriate medical staff. Once a doctor has verified death, the sources are removed and placed in a lead container. A Geiger counter is used to check that all sources have been removed. This reduces the radiation risk when completing these procedures. Record the time and date of removal of the sources. Ensure those in contact with the patient's body are aware and pregnant nurses should not carry out nursing care for these patients. For further information refer to local policy for radiation protection.
Patient and/or relative wishes to donate organs/tissues for transplantation.	n/a	Discussion around transplantation should occur with families/NOK wherever appropriate (as deemed by clinical team). Exceptions apply.	As stated in the Human Tissue Act 1961, patients with malignancies can only donate corneas and heart valves (and more recently tracheas). Contact local transplant co-ordinator as soon as a decision is made to donate organs/tissue and before care after death is attempted. Obtain verbal and written consent from the next of kin, as per local policy. Prepare patient who has died as per transplant co-ordinator's instructions. For further guidance see www.organdonation.nhs.uk/ .
Patient to be moved straight from ward to undertakers.	n/a	n/a	Contact senior nurse for hospital. Contact local register office as release of Certificate for Burial or Cremation ('green' document) needs to be obtained. Liaise with chosen funeral directors and the deceased's family. Perform personal care as per religious/cultural/family wishes. Obtain written authority for removal of person by the funeral directors, from the next of kin. Document all actions and proceedings (Travis 2002).
Relatives want to see the person who has died after removal from the ward.	n/a	n/a	Inform the mortuary staff in order to allow time for them to prepare the body. Occasionally nurses might be required to undertake this in institutions where there are no mortuary staff. The patient's body will normally be placed in the hospital viewing room. Ask relatives if they wish for a chaplain or other religious leader or appropriate person to accompany them. As required, religious artefacts should be removed from or added to the viewing room. The nurse should check that the patient's body and environment are presentable before accompanying the relatives into the viewing room. The relatives may want to be alone with the deceased but the nurse should wait outside in order that support may be provided should the relatives become distressed. After the relatives have left, the nurse should contact the portering service who will return the deceased patient to the mortuary.

Post-procedural considerations

Immediate care

Since there is a time limit to how long a patient should remain in the heat of a ward (there could potentially be early onset of rigor mortis), the senior nurse will have to exercise discretion over

when to send the patient to the mortuary. This will vary according to family circumstances (there could be a short delay in a relative travelling to the ward/area) and to the ward situation (side rooms are obviously easier for the family/other patients). As a general rule, 1–2 hours would be considered the upper limit for a patient to remain in the ward area, after care after death has been completed.

Viewing the patient

Families may wish to view the patient in a viewing room. Again, it is important to ensure that the patient is in a presentable state before taking the family to see them.

Bereavement support

The bereaved family may find it difficult to comprehend the death of their family member and it can take great sensitivity and skill to support them at this time. Explaining all procedures as fully as possible can help understanding for the practices at the end of life. Offering bereavement care services may be useful to families for that difficult period immediately after death and in the future. National services such as CRUSE (www.cruse.org.uk) can be useful if local services aren't known. There may be extreme distress; this is a difficult situation to handle and other family members are likely to be of most comfort and support at this point. The family member may wish for their GP to be contacted.

Maintain a high degree of sensitivity when outlining the process after a patient has died since families frequently have to attend the hospital in the very near future to collect the documentation for registering the death.

Education of patient and relevant others

Helping the family to understand procedures after death is the role of many people in hospital but primarily this will fall upon those who first meet with the family after their relative has died. The Home Office leaflet *What to Do after a Death* can help families.

If the family suggest that they feel the death was unnatural or even that it was interfered with, we have a responsibility to explore these feelings and even outline their legal entitlement to a post-mortem.

- Prepare the family for what they might see.
- Invite the family into the bed space/room.
- Accompany family but respect their need for privacy should they require it.
- Anticipate questions.
- Offer the family the opportunity to discuss care (at that time or in the future).
- Offer to contact relatives on behalf of the family.
- Advise about the bereavement support services that can be accessed. Arrange an appointment with facilities.
- Provide them with a point of contact with the hospital.

Some families may wish for a memento of the patient, such as a lock of hair. Try to anticipate and accommodate these wishes as much as possible.

Support of nursing staff and others

End-of-life care has been described as challenging, complex and emotionally demanding but, if staff have the necessary knowledge, skills and attitudes, it can be one of the most important and rewarding areas of care (DH 2008, Poncet et al. 2007). Providing EOLC can expose staff to risks of emotional burnout or post-traumatic stress (Mealer et al. 2007). To prevent this, a supportive and nurturing environment for all those who provide EOLC is necessary. Patison (2011) agrees, stating that the practical and emotional support needed by staff cannot be overestimated. She advises that this can be provided by mentorship and clinical supervision as well as staff counselling but warns that consideration needs to be given to workload and skill mix to enable this to take place. This support should extend to doctors and all members of the multidisciplinary team because the emotional implications of dealing with EOLC affect all (Ho et al. 2011).

The palliative care team can be a useful resource in providing informal teaching and educational support for staff relating to EOLC issues. This is often achieved by joint patient care or meetings with family members. This experiential learning can be valuable especially for junior team members who may have more confidence to ask questions on a one-to-one basis.
