Overview

This chapter explains the nursing management and assessment of patients with respiratory problems. Administration of oxygen therapy, managing patients with chest drains and tracheostomies, counselling patients regarding smoking cessation and performing cardiopulmonary resuscitation (CPR) will be discussed.

Respiratory therapy

Definition

The principle of respiratory therapy is the application of pharmacological and non-pharmacological means to improve breathing and therefore gaseous exchange. This will include an assessment of the cause of the impaired breathing, reversal of causes where possible and therapies to optimize respiratory function (Shelledy and Mikles 2002).

Anatomy and physiology

See also Chapter 11: Observations.

The respiratory system is a complex system that is responsible for the efficient exchange of the respiratory gases, primarily oxygen and carbon dioxide. The respiratory system is responsible for ensuring a continuous optimum supply of oxygen to the tissues and the elimination of carbon dioxide during expiration. Four separate functions are necessary to achieve optimal respiration (Marieb et al. 2012).

- 1 *Pulmonary ventilation*: adequate breathing and movement of air in and out of the lungs, ensuring a fresh supply of oxygen to the alveoli.
- 2 *External respiration*: ensuring adequate gas exchange, oxygen uptake and carbon dioxide unloading between the blood and the alveoli of the lungs.
- 3 *Transport of respiratory gases*: moving oxygen and carbon dioxide between the lungs and the body tissues. Transport is affected by the cardiovascular system and uses the blood as a carrying mechanism.
- 4 *Cellular respiration*: oxygen delivery and carbon dioxide uptake between the systemic blood and tissue cells.

The respiratory system is composed of the following structures.

- The two respiratory centres in the medulla oblongata and pons of the brain.
- The nose, mouth and connecting airways.
- The trachea, main bronchus, bronchioles and alveoli.
- The respiratory muscles: the diaphragm and the intercostal muscles.
- The respiratory nerves: the subphrenic nerve and the intercostal nerves.
- The bone structure of the thorax: the ribs, vertebrae and sternum.
- The lung parenchyma.
- The pleura (Urden et al. 2006).

Alteration, damage or blockage to any of the structures listed above may result in either respiratory impairment or respiratory failure. It is essential when considering respiratory function to remember the close association and dependence between the cardiovascular, neurological, musculoskeletal and respiratory systems (Marieb et al. 2012).

Tissue oxygenation

All the cells of the body require a continuous supply of oxygen to ensure growth and repair of tissues and optimum metabolism. Oxygen is drawn into the body through the nose and mouth; it then travels down the trachea and into the smaller airways and

alveoli of the lungs. Once it has reached the alveoli, oxygen in solution is able to transfer into the network of capillaries and from there travels via the venous network to all cells of the body. This tissue oxygenation is known as cellular oxygenation. Low oxygen levels are called hypoxia. In low oxygen conditions, anaerobic cellular oxygenation will occur, generating the waste product lactic acid. If the low oxygen state is allowed to continue, lactic acid will accumulate, leading to a metabolic acidosis and cell death (Berne 2004, Bersten et al. 2009, Guyton and Hall 2006, Hess 2000, Jenkins and Tortora 2013, Kumar and Clark 2009, Marieb et al. 2012, Pierson 2000, West 2008).

There are three components to oxygenation: oxygen uptake, oxygen transportation and oxygen utilization. *Oxygen uptake* is the process of extracting oxygen from the environment. *Oxygen transportation* is the mechanism by which the uptake of oxygen results in the delivery of oxygen to the cells. *Oxygen utilization* is the metabolic need for molecular oxygen by the cells of the body (Jenkins and Tortora 2013, Marieb et al. 2012).

In order for oxygenation to take place there needs to be an adequate cardiac output.

Oxygen uptake

The air that we breathe in during normal conditions from the atmosphere is composed of the following gases:

- oxygen 21%
- carbon dioxide 0.03%
- nitrogen 79%
- rare gases 0.003%.

Inspired air at sea level has a total atmospheric pressure of 760 mmHg. According to Dalton's Law, where there is a mixture of gases, each gas exerts its own pressure as if there were no other gases present. The pressure of an individual gas in a mixture is called the partial pressure and is denoted as P, which is then followed by the type of gas, so that the partial pressure of oxygen is written PO₂ (Tortora and Derrickson 2011).

- Oxygen $0.21 \times 760 = 159$ mmHg (21 kPa)
- Carbon dioxide $0.03 \times 760 = 22.8$ mmHg (3.0 kPa)
- Nitrogen $0.79 \times 760 = 600$ mmHg (80 kPa)

The partial pressure of gases controls the movement of oxygen and carbon dioxide through the body between the atmosphere and the lungs, the lungs and the blood and finally the blood and the cells.

Gaseous exchange

Movement of gases is by diffusion. Diffusion is the movement of gas molecules from an area of relatively high partial pressure to one of lower partial pressure (Jenkins and Tortora 2013).

Diffusion of oxygen takes place from the alveolus into the pulmonary capillaries and movement of carbon dioxide from the capillary into the alveolus. From the alveolus, the oxygen diffuses from the capillaries into the tissues and mitochondria of the cells (Figure 9.1).

The alveolar oxygen partial pressure must be higher than the arterial oxygen partial pressure in order to push the oxygen through the alveolar membrane into the interstitial spaces and from there into the pulmonary capillaries.

As inspired air enters the respiratory tract, it encounters water vapour present in the upper airways which warms and humidifies it. Water vapour exerts its own partial pressure of 47 mmHg. The partial pressure of the water vapour must be subtracted from the total atmospheric pressure to give a corrected atmospheric pressure and partial pressure of each gas (Marieb et al. 2012).

- Corrected total atmospheric pressure $760 - 47 = 713$ mmHg
- Oxygen $0.21 \times 713 = 150$ mmHg (20 kPa)
- Carbon dioxide $0.03 \times 713 = 21$ mmHg (2.8 kPa)

Figure 9.1 Gas movement in the body is facilitated by partial pressure differences. Top of figure illustrates pressure gradients that facilitate oxygen and carbon dioxide exchange in the lungs. Bottom of figure shows pressure gradients that facilitate gas movements from systemic capillaries to tissues.

As oxygen continues to pass down the respiratory tract to the alveolus, it encounters carbon dioxide leaving the respiratory tract which also exerts a partial pressure, equal to 40 mmHg. This in turn must be subtracted to determine the correct values. Oxygen has a corrected value of $150 - 40 = 110$ – 100 mmHg (14.6–13.3 kPa).

Oxygen transportation

Oxygen is carried in the blood in two ways.

- *Dissolved in the plasma (serum):* only 2–3% is carried in this way as oxygen is not very soluble (Ahrens and Tucker 1999, Marieb et al. 2012). This is measured as the PaO_2 . There is 0.003 mL of blood for each 1 mmHg partial pressure oxygen. At 100 mmHg partial pressure, only 0.3 mL of oxygen would be carried per 100 mL of plasma.
- *Bound to haemoglobin in the red blood cells:* 95–98% of oxygen is carried in this way and is measured as the percentage of oxygen saturated (SaO_2). Each gram of haemoglobin can carry 1.34 mL of oxygen per 100 mL blood.

Haemoglobin is composed of haem (iron) and globulin (protein). Each haemoglobin molecule has four binding sites, each able to carry one molecule of oxygen. A haemoglobin molecule is said

Figure 9.2 Oxyhaemoglobin dissociation curve. With a PaO_2 of 8 kPa and more, saturations will remain high (flat portion of curve). NB: The middle red line is the normal position of the curve.

to be fully saturated with oxygen when all four haem sites are attached to oxygen. When fewer than four are attached, the haemoglobin is said to be partially saturated.

The bond between haemoglobin and oxygen is affected by various physiological factors that shift the oxygen dissociation curve to the right or left (Figure 9.2) (Jenkins and Tortora 2013, Marieb et al. 2012).

Oxyhaemoglobin curve shift to the right

When a shift occurs to the right, there is reduced binding of oxygen to haemoglobin and oxygen is given up more easily to the tissues. The saturation will be lower (Pierson 2000).

Factors that cause the curve to shift to the right are an increase in:

- body temperature due to infection, sepsis
- hydrogen ion content (acidaemia), known as the Bohr effect, due to infection, sepsis or other shock conditions
- carbon dioxide due to sepsis, pulmonary disease, postoperatively
- 2-3-DPG (an enzyme found in the red blood cells that affects haemoglobin and oxygen binding).

Oxyhaemoglobin curve shift to the left

When a shift occurs to the left, there is an increase in the binding of oxygen to the haemoglobin, oxygen is given up less easily to the tissues and cellular hypoxia can occur (Pierson 2000).

Factors that cause the curve to shift to the left are a decrease in:

- body temperature due to exposure, near drowning, trauma
- hydrogen ion content (alkalaemia)
- carbon dioxide
- 2-3-DPG.

Oxygen utilization

The relationship between the PaO_2 and the SaO_2 is represented as the oxygen dissociation curve. Oxygen uptake in the lungs is shown by the upper flat part of the curve. When the PaO_2 is between 8.0 and 13.3 kPa (60–100 mmHg), the haemoglobin is 90% or more saturated with oxygen. At this point of the curve, large changes in the PaO_2 lead to small changes in the SaO_2 of

haemoglobin, because the haemoglobin is almost completely saturated. Release of oxygen to the tissues is shown by the lower part of the curve. There is easy removal of oxygen from the haemoglobin for use by the cells. It is at this part of the curve that small changes in the PaO_2 cause major changes in the SaO_2 . This is important clinically (Guyton and Hall 2006, Hess 2000).

A patient's oxygen level must be kept at 8.5 kPa or above (60 mmHg). Below this level, desaturation can occur at a rapid rate, resulting in tissue hypoxia and cell death (Marieb et al. 2012).

Oxygen consumption

At rest, the normal oxygen consumption is approximately 200–250 mL/min. As the available oxygen per minute in a normal man is about 700 mL, this means there is an oxygen reserve of 450–500 mL/min. Factors that increase the consumption of oxygen include fever, sepsis, shivering, restlessness and increased metabolism (Bersten et al. 2009). It is difficult to say at which absolute level oxygen therapy is necessary, as each situation should be judged by the requirements for oxygen and the availability of oxygen. Therefore, all the above information needs to be taken into account together with the measurement of the arterial blood gases.

Generally, additional oxygen will be required when the PaO_2 has fallen to 8.5 kPa (60 mmHg) or less (Bersten et al. 2009).

Carbon dioxide excretion

The second function of the respiratory system is to excrete carbonic acid from the lungs during expiration. The normal level of carbon dioxide in the blood is 3.5–5.3 kPa. Carbon dioxide has a direct effect on the respiratory centre in the brain. As the carbon dioxide level rises and diffuses from the blood into the cerebrospinal fluid (CSF), it is hydrated and carbonic acid is formed. The acid then dissociates and hydrogen ions are liberated and as there are no proteins in the CSF to buffer the hydrogen ions, the pH of the CSF falls, which excites the central chemoreceptors and the respiratory rate is increased (Marieb et al. 2012).

Evidence-based approaches

Respiratory assessment

Once information about the person's past medical history has been obtained, one of the most reliable and important assessments is to closely observe and talk to the patient. During this time a patient's smoking status should be ascertained and, if appropriate, their smoking habits and the benefits of stopping should be discussed. For smoking cessation, brief interventions typically take about 5–10 minutes and may include one or more of the following.

- Simple opportunistic advice to stop.
- Assessment of patient's desire to stop.
- Offer of pharmacotherapy and/or behavioural support.
- Provision of self-help material and referral to more intensive support such as the NHS Stop Smoking services (NICE 2006).

Normal respiration is effortless and almost unconscious and the person can eat, drink and speak in full sentences without appearing breathless. Essential first steps in respiratory assessment are therefore to observe the person's breathing for the following.

- Ease and comfort.
- Rate.
- Pattern.
- Position the patient has adopted; for example, does the patient need to sit at 90° upright to breathe effectively?
- Rate and ease of breathing during speaking or movement.
- General colour and appearance: is there any evidence of greyness, cyanosis, pallor, sweating?
- Additional audible breath sounds: wheezing or stridor? (O'Driscoll et al. 2008)

Having rapidly made this assessment, other essential assessments are a chest X-ray and arterial blood gas, and a computed tomography (CT) scan or ventilation/perfusion (V/Q) scan may also be necessary (see Chapter 10: Interpreting diagnostic tests).

Having made a comprehensive assessment, the immediate cause of respiratory insufficiency should be corrected where possible. It is important to recognize that this may result from interruption to any part of respiration; for example, the patient may be in severe pain and appropriate pain management may improve their respiratory function, or conversely an opioid overdose may result in decreased or absent respiration and the antidote to the opioid will then need to be given. There may be a mechanical obstruction to respiration, such as an infective obstruction like epiglottitis, and the treatment is therefore directed at treating the infection whilst also oxygenating the patient (O'Driscoll et al. 2008).

Respiratory therapy therefore covers a wide area and will include any manipulation or management of alteration to any part of the respiratory tree. It may include pharmacological management including pain management, antidotes to drug toxicity, support and guidance on smoking cessation, antimicrobials for infections of the respiratory tract, respiratory stimulants, surgery to repair a ruptured diaphragm or to manage trauma, the insertion of a tracheostomy or chest drains, or a thoracoabdominal shunt for superior vena cava obstruction. Finally, positioning and physiotherapy play a major role in improving respiratory function (O'Driscoll et al. 2008).

Any person who is unable to maintain tissue oxygenation will need to receive supplemental oxygen until they are able to manage again on room air. This oxygen may be delivered in different ways depending on the severity of the condition and the level of hypoxia (Morton and Fontaine 2009).

Oxygen therapy

Definition

Oxygen therapy is the administration of oxygen at concentrations greater than that in ambient air with the intention of treating or preventing the symptoms and manifestations of hypoxia.

Evidence-based approaches

Rationale

Indications

- Respiratory failure, of which there are two types (Marieb et al. 2012, O'Driscoll et al. 2008, Tortora and Derrickson 2011).
 - Type 1, referred to as hypoxaemic respiratory failure (failure to oxygenate the tissues). The PaO_2 is <8 kPa (60 mmHg) while the carbon dioxide (PCO_2) is normal or low. Common causes include infectious conditions, pneumonia, pulmonary oedema and adult respiratory distress syndrome.
 - Type 2, referred to as hypercapnic (raised carbon dioxide) or respiratory pump failure. Alveolar ventilation is insufficient to excrete carbon dioxide accompanied by hypoxaemia (deficiency of oxygen in the arterial blood). The PCO_2 is >6 kPa (45 mmHg). Common causes include chronic obstructive pulmonary disease (COPD), chest wall deformities, drug overdose and chest injury (Kayner 2012).
- Acute myocardial infarction.
- Cardiac failure.
- Shock – haemorrhagic, bacteraemic and cardiogenic.
- Conditions in which there is a reduced ability to transport oxygen, for example anaemia.
- During anaesthesia.
- Post-operatively.

Box 9.1 Causes of respiratory failure**Common causes of type 1 respiratory failure (hypoxaemic) include the following:**

- COPD
- Pneumonia
- Pulmonary oedema
- Pulmonary fibrosis
- Asthma
- Pneumothorax
- Pulmonary embolism
- Pulmonary arterial hypertension
- Pneumoconiosis
- Granulomatous lung diseases
- Cyanotic congenital heart disease
- Bronchiectasis
- Acute respiratory distress syndrome (ARDS)
- Fat embolism syndrome
- Kyphoscoliosis
- Obesity

Common causes of type 2 respiratory failure (hypercapnic) include the following:

- COPD
- Severe asthma
- Drug overdose
- Poisonings
- Myasthenia gravis
- Polyneuropathy
- Poliomyelitis
- Primary muscle disorders
- Porphyrria
- Cervical cordotomy
- Head and cervical cord injury
- Primary alveolar hypoventilation
- Obesity-hypoventilation syndrome
- Pulmonary oedema
- ARDS
- Myxoedema
- Tetanus (Kayner 2012)

COPD, chronic obstructive pulmonary disease.

- Sleep apnoea.
- Severe pain.
- Asthma.
- Pulmonary embolus.
- Conditions that affect the neuromuscular control of breathing such as muscular dystrophy, Guillain-Barré.
- Severe trauma affecting the diaphragm, ribs, lungs or trachea.
- Tension pneumothorax.
- Pleural effusion (Kayner 2012).

Causes of respiratory failure are shown in Box 9.1.

Contraindications

No specific contraindications to oxygen therapy exist, but the following precautions or possible contraindications need to be considered.

- With increased PaO_2 ventilatory depression may occur in spontaneously breathing patients with elevated PaCO_2 .
- With high flow of fractional inspired oxygen (FiO_2), absorption atelectasis, oxygen toxicity and/or depression of ciliary and/or leucocytic function may occur.
- Supplemental oxygen should be administered with caution to patients suffering from paraquat poisoning and those receiving bleomycin.
- During laser bronchoscopy, minimal levels of supplemental oxygen should be used to avoid intratracheal ignition.
- Fire hazard is increased in the presence of increased oxygen concentrations.
- Bacterial contamination associated with certain nebulization and humidification systems is a possible hazard (Fischer 2006).

Anticipated patient outcomes

Outcome is determined by clinical and physiological assessment to establish adequacy of the patient response to oxygen therapy. It should be geared towards achieving desired oxygen saturations with the least FiO_2 setting (O'Driscoll et al. 2008).

Legal and professional issues**Competencies**

Nursing staff must be trained to adequately administer oxygen therapy and their competency should be assessed. They should check and document that a device is being used appropriately and the flow is as prescribed and appropriate for the patient's needs. Nursing and physiotherapy staff may assess patients, initiate and monitor oxygen delivery systems within the prescribed parameters, except in emergencies when oxygen should be given first and documented later (NPSA 2009).

Governance

Clinical governance leads in local hospitals and organizations should audit current practice and develop local policies and evidence-based guidelines to ensure that:

- oxygen is administered and prescribed according to national guidelines (NPSA 2009)
- all equipment used, such as humidification, continuous positive airway pressure (CPAP), Optiflow, chest drains and CPR equipment, is regularly checked for safety and staff are adequately trained to use and troubleshoot when problems occur.

Risk management

The use of medical equipment relating to oxygen therapy will be monitored as identified within the local hospital medical equipment policies. All incident reports relating to oxygen therapy and supportive respiratory equipment as stated in this chapter should be reviewed by local risk management committees in order to identify themes and trends and propose appropriate risk reduction measures to prevent reoccurrence and improve patient safety (BTS 2008, MHRA 2010, NPSA 2008, 2009).

Pre-procedural considerations

Before commencing oxygen therapy, it is essential that it should be prescribed as can be seen by the example prescription in Box 9.2. This should be in the form of parameters, for example 28–40% of oxygen to keep saturations (sats) >92%. This will allow nursing staff to alter the oxygen setting to achieve the target saturations without requiring a change to the prescription on each occasion, as well as individualizing treatment to meet the patient's needs. The only exception to this situation is during immediate management of critical illness or emergency situations when oxygen should be given without being formally prescribed (O'Driscoll et al. 2008).

Regular pulse oximetry monitoring must be available in all clinical environments where oxygen may be administered. Oxygen therapy will need to be adjusted to achieve target saturations rather than giving a fixed dose to all patients with the same disease. Nurses can make these adjustments without requiring a change to the prescription on each occasion. Most oxygen therapy will be from nasal cannulas rather than masks and will

Box 9.2 Example of oxygen section for hospital prescription charts

not be given to patients who are not hypoxaemic (except during critical illness) (O’Driscoll et al. 2008).

Equipment

Oxygen is an odourless, tasteless, colourless, transparent gas that is slightly heavier than air. Oxygen supports combustion so there is always a danger of fire when oxygen is being used. The following safety measures should be remembered.

- Oil or grease around oxygen connections should be avoided.
- Alcohol, ether and other inflammable liquids should be used with caution in the vicinity of oxygen.
- No electrical device must be used in or near an oxygen tent.
- Oxygen cylinders should be kept secure in an upright position and away from heat.
- There must be no smoking in the vicinity of oxygen.
- A fire extinguisher should be readily available.
- Care should be taken with high concentrations of oxygen when using the defibrillator in a cardiorespiratory arrest or during elective cardioversion.

All oxygen delivery systems should be checked at least once per day. Care should be taken to avoid interruption of oxygen therapy in situations including ambulation or transport for procedures (O’Driscoll et al. 2008).

Oxygen delivery

Any oxygen delivery system will include these basic components.

- *Oxygen supply*, from either a piped supply or a portable cylinder. All medical gas cylinders have to conform to a standardized colour coding: oxygen cylinders are black with a white shoulder and are labelled ‘Oxygen’ or ‘O₂’. Since 2004, small portable oxygen cylinders have been in use: these are totally white and are a C-size cylinder.
- A *reduction gauge*: to reduce the pressure to atmospheric pressure.
- *Flowmeter*: a device that controls the flow of oxygen in litres per minute.
- *Tubing*: disposable tubing of varying diameter and length.
- *Mechanism for delivery*: a mask or nasal cannulas (Table 9.1).
- *Humidifier*: to warm and moisten the oxygen before administration.
- *Water trap* if humidifier in use (O’Driscoll et al. 2008).

Nasal cannulas

Nasal cannulas (Figure 9.3) consist of two plastic prongs that are inserted inside the anterior nares and supported on a light frame. Advantages to the patient are that they may seem less claustrophobic and do not interfere with eating, drinking and communication (Fell and Boehm 1998). Nasal cannulas provide an alternative to a mask, but can be used only where the patient requires a low percentage of oxygen and are usually used with flow rates of 1–4 litres of oxygen per minute and provide approximately 28–35% oxygen (Table 9.2). They cannot be attached satisfactorily to an external humidification device but in many cases the oxygen will be humidified as it passes through the nasal passages into the trachea (Marieb et al. 2012). They are generally well tolerated and

are useful post-operatively or where the patient requires minimal support and are also used in the chronic setting where a patient at home requires long-term oxygen therapy.

Simple semi-rigid plastic masks

Simple semi-rigid plastic masks (Figure 9.4) are low-flow (5–10 L/min) masks which entrain the air from the atmosphere and therefore are able to deliver a variable oxygen percentage (anything from 40% to 60%). Oxygen concentrations vary depending on the flow rate and the patient’s breathing pattern (Table 9.3). Large discrepancies between the delivered FiO₂ and the actual amount

Figure 9.4 Simple semi-rigid plastic mask.

received by the patient will occur, dependent on the patient's rate and depth of breathing (O'Driscoll et al. 2008). These masks are useful for patients who need a higher percentage of oxygen temporarily whilst the cause of their hypoxia is treated. This type of mask may be worn for hours or several days, but should be used in conjunction with a humidifier if used for more than 12 hours.

Note that if the oxygen flow on this mask is less than 5 L/min, increased resistance to breathing occurs, causing a possible build-up of CO₂ within the mask, resulting in rebreathing (O'Driscoll et al. 2008).

If the patient requires 60% oxygen or more, expert help should be sought as the patient may require more invasive respiratory support (NICE 2007).

Non-rebreathing mask (high-concentration reservoir mask)

Non-rebreathing masks (Figure 9.5) are similar to the simple semi-rigid plastic masks with the addition of a reservoir bag, which allows the oxygen to be delivered at concentrations between 60% and 90% when used at flow rates of 10–15 L/min (O'Driscoll et al. 2008). Oxygen flows into the bag and mask during inhalation and the valve prevents expired air from flowing back into the bag.

Note that if the oxygen flow is too low, the carbon dioxide can accumulate in the reservoir bag and fail to meet the patient's requirements, resulting in an increase in carbon dioxide (Pierce 1995). This device should only be used in the presence of expert nursing and medical support and usually during emergency intervention or before more invasive ventilatory therapy is instituted.

Fixed performance masks or high-flow masks (Venturi-type masks)

Venturi-type oxygen masks deliver high-flow oxygen via a Venturi adaptor (Figure 9.6). The adaptors are colour coded according to

**Figure 9.5** Non-rebreathing mask.**Figure 9.6** Venturi barrels.

the percentage of oxygen they deliver with different oxygen flow rates. Venturi masks are available in the following concentrations: 24%, 28%, 35%, 40% and 60%. Venturi masks with 24% and 28% are suited to those at risk of CO₂ retention (O'Driscoll et al. 2008).

Tracheostomy mask

Tracheostomy masks perform in a similar way to the simple semi-rigid plastic facemask (see Figure 9.4). The mask is placed over the tracheostomy tube or stoma.

T-piece circuit

The T-piece circuit is a simple, large-bore, non-rebreathing circuit which is attached directly to an endotracheal or tracheostomy tube (Figure 9.7b). Humidified oxygen is delivered through one part of the T and expired gases leave through the other part. This device may be used as part of the weaning process when a patient has been ventilated previously by a mechanical ventilator (Bersten et al. 2009).

Assessment and recording tools

All patients should be assessed and monitored using a *track and trigger system* (e.g. National Early Warning Score – NEWS) (NICE 2007, RCP 2012). Observations for respiratory rate, pulse oximetry and oxygen saturation alongside oxygen delivery system, heart rate and blood pressure need to be recorded on observation charts (Box 9.3).

Arterial blood gas (ABG) analysis should be measured as soon as possible in all critically ill patients and situations involving hypoxaemic patients, and is part of the essential assessment in patients who may develop carbon dioxide retention (type 2 respiratory failure) (NICE 2007, O'Driscoll et al. 2008). ABG (see Chapter 10: Diagnostic tests) should be measured with the administered inspired oxygen concentration noted at the time of arterial blood sampling. This should be repeated in accordance with the patient's clinical response to treatment (O'Driscoll et al. 2008).

Pharmacological support

Oxygen cylinders and equipment may be ordered from the pharmacy whilst other medical equipment comes from external sources via stores and needs to be ordered before stocks run out to ensure ready availability in the event of an emergency. Nebulizers and broncholytic agents may improve respiratory status.

Domiciliary oxygen and portable oxygen

Some patients are so disabled by chronic respiratory disease that they require continual supplementary oxygen at home. Low-flow oxygen given over a period of time improves the prognosis of some patients (Benditt 2000, O'Driscoll et al. 2008).

Long-term oxygen may be prescribed for treatment of COPD, cystic fibrosis, interstitial lung disease, neuromuscular and

skeletal disorders, pulmonary hypertension and palliation in lung cancer. It may be provided in the form of cylinders. The problem with this is that the cylinders need changing frequently. Oxygen condensers (concentrators) are far more economical than cylinders. A condenser consists of a compressor powered by electricity. The condenser works by drawing in room air that is passed through a bacterial filter and a sieve bed. The sieve bed contains zeolite which has an affinity for nitrogen and when under pressure works by removing nitrogen and other gases, concentrating oxygen and delivering it through a meter at the front of the compressor (O'Driscoll et al. 2008).

The oxygen can be delivered to the patient by nasal cannulas or mask (Esmond 2001).

Specific patient preparations

Oxygen delivery to the patient should be explained, including what equipment is to be used (such as a mask or nasal cannula) and the importance of keeping the apparatus in place. The patient should know about the flammability of oxygen and the dangers of any naked flames/lit cigarettes in their immediate vicinity. The nurse should instruct the patient to notify him or her of increasing distress, air hunger, nausea, anxiety, dry nasal passages or 'sore throat' (due to drying) (O'Driscoll et al. 2008).

Procedure guideline 9.1 Oxygen therapy

Essential equipment

- Piped/wall oxygen and medical air
- Oxygen flow meter/regulator
- Oxygen cylinders for transport of patients
- Ambu-bag for emergencies
- Nasal cannulas
- Selection of oxygen masks
- Oxygen tubing, varying lengths and types
- Oxygen analysers

Optional equipment

- Non-invasive equipment in non-critical care areas (essential within critical care environments)
- High-flow O₂ and medical air mixers for use in HDU setting
- Humidification equipment
- Cold water bubble humidifiers

Medicinal Products

- Asthma inhalers or nebulizers
- Oxygen as prescribed for patient
- Nicotine patches to aid smoking cessation

Pre-procedure

Action	Rationale
1 Assess the patient's condition and level of oxygen therapy required, e.g. facemask, humidified oxygenation, nasal cannulas.	To ensure that the appropriate method for delivery of oxygen is chosen to suit the patient's condition (O'Driscoll et al. 2008, C).
2 Ensure an oxygen prescription is in place with clear target oxygen saturations for O ₂ therapy titration. See Box 9.2.	Medical oxygen is a drug. National guidelines and clinical governance require that the intentions of the clinician who initiates oxygen therapy should be communicated clearly to the person who actually administers oxygen to the patient and an accurate record must be kept of exactly what has been given to the patient (O'Driscoll et al. 2008, C).
3 Explain to the patient why they require oxygen therapy and the benefits and problems thereof.	To minimize apprehension and anxiety and improve understanding of treatment. E
4 Attach oxygen tubing to the port on the wall oxygen or cylinder (and not to the medical air port).	To ensure proper oxygen delivery and prevent hypoxia if connected to medical air port (NPSA 2007, C).

Procedure

5 Set oxygen flowmeter to required setting (L/min) and check oxygen is flowing through system by using fingertips.	To ensure system is working properly. E
6 <i>Either:</i> <i>Apply a nasal cannula</i> by gently placing the nasal prongs of the cannula into the patient's nostrils, draping the tubing over the patient's ears and sliding the fit connector up under the chin to hold the tubing securely in place. <i>Or:</i> <i>Apply an oxygen mask</i> by placing the mask over the patient's mouth and nose, then pull the elastic strap over the head and adjust the strap on both sides to secure the mask in a position that seals it against the face.	To ensure the mask or cannula is applied correctly to enable the patient to receive the oxygen. E To ensure patient comfort. E

Post-procedure

7 Check that the patient is comfortable.	To ensure patient comfort. E
8 Record that oxygen therapy has been commenced, time and flow rate.	To maintain accurate records (NMC 2010, C).
9 Provide continued reassurance to patient and opportunity to ask questions.	To minimize apprehension and anxiety and improve understanding of treatment. E

Problem-solving table 9.1 Prevention and resolution (Procedure guideline 9.1)

Problem	Cause	Prevention	Suggested action
Inability to maintain an airway.	Position of patient.	Provide pillows to support patient. Elevate head of bed. Demonstrate to patient orthopnoeic position.	Position patient preferably sitting up at an angle of greater than 45°.
	Airway secretions.	Provide sputum pot for expectoration. Saline nebulizers if prescribed to loosen secretions.	Encourage patient to cough and expectorate if able or remove secretions by suction if patient unable to do so.
Inability to maintain adequate oxygenation.	Inadequate oxygen delivery, patient's condition deteriorating. More breathless. Oxygen saturation decreased. Deteriorating blood gases.	Increased frequency and recording of cardiovascular observations and respiration rate. Attach pulse oximeter. Use of NEWS scoring.	Assess level of oxygen support required by assessing previous medical history and current respiratory assessment. Increase oxygen delivery using the lowest percentage of oxygen to achieve the individual goal for the patient.

(continued)

Problem-solving table 9.1 Prevention and resolution (Procedure guideline 9.1) (*continued*)

Problem	Cause	Prevention	Suggested action
Dry mouth.	Oxygen therapy can lead to a dry mouth.	Provide regular mouthcare or artificial saliva if prescribed.	Add humidification to the circuit (see Procedure guideline 9.2: Humidification for respiratory therapy). Give regular mouthcare.
Nasal cannula or mask discomfort.	Position or use of cannula and oxygen mask.	Use appropriate size mask.	Ensure correct placement and that the patient is comfortable. Cut off tip of cannulas that protrude into nares to a comfortable length.
Intolerance of oxygen therapy.	Fear and anxiety. Confusion. Hypoxia.	Explain need for therapy and benefit it will have. Allow patients to express their fears/concerns. Encourage relatives/carers to stay with patient.	Assess patient for change. Ensure continual reassurance given to patient. Ensure patient remains orientated to the environment and oxygen device. If intolerant of mask, nasal cannulas may be tolerated. If hypoxic, oxygen may need to be increased.
Inability to communicate.	Mask makes communication difficult; patient may not hear carer and nurse may not hear patient.	Provide patient with non-verbal means of communication, either pen and paper or symbol board.	Assist patient to move around bed area if not able to go far. Mobilize patient with portable oxygen cylinder if appropriate.
Inability to maintain personal hygiene.	Immobility. On bedrest. Mask restricting independence.	Provide patient with hygiene wipes or offer assistance if unable to meet own hygiene needs.	Provide reassurance for patient to remain independent where able. Allow them to carry out their own hygiene if able or help patient with hygiene if not.
Inability to maintain safe environment.	Detachment of oxygen from flowmeter. Kinked or looped oxygen tubing. Mask removed by patient.	Pulse oximeter with audible alarm.	Ensure oxygen attached to flowmeter. Check patient regularly. Ensure no kinks or loops arise. Ensure patient is attached to oxygen.

Post-procedural considerations

Immediate care

Explain the reasons for oxygen therapy and the benefits of keeping the device in place until further review. Allow opportunities to express discomfort. Document what percentage of oxygen was commenced and the patient's related observations, and continue to monitor the patient's respiratory status as frequently as necessary.

Ongoing care

For patients requiring oxygen therapy for more than 24 hours or when the patient reports discomfort due to dryness, humidification should be commenced to protect airway defences (Dysart et al. 2009, Ward and Park 2000) as well as for the general comfort of the patient.

Encouraging patients to sit out in chairs rather than lying or even sitting up in bed will help prevent atelectasis and aid removal of secretions. Ensuring that post-operative patients have effective pain relief will allow for early ambulation, as well as deep breathing and other basic exercises which will help prevent post-operative atelectasis or possible chest infections (Shelledy and Mikles 2002).

Accurate and frequent monitoring of vital signs and recording of observations as well as oxygen concentration and flow rates administered to the patient in conjunction with a track and trigger scoring system (e.g. NEWS) allow for early identification and referral of patients at risk of deterioration (NICE 2007, RCP 2012).

Weaning from oxygen therapy

Titrate or reduce oxygen therapy dose if the patient is clinically stable and the oxygen saturation has been in the upper zone of the target range for some time (usually 4–8 hours). Observe the patient 5 minutes after lowering the dose of oxygen therapy and document. Discontinue oxygen therapy once the patient is clinically stable on the lowest dose oxygen and the target saturations are maintained within the desired range on two consecutive

observations or as per written protocol of timed oxygen. Post-operative patients may require oxygen administration whilst on intravenous opiate, patient-controlled analgesia (BTS 2008).

Documentation

Baseline vital signs and oxygen flow rates or concentrations administered as well as the patient's response to therapy must be recorded on the patient's observation chart (NICE 2007). All patients on oxygen therapy should have an added score of 2 documented on NEWS scoring on the vital signs observation chart (RCP 2012).

Education of patient and relevant others

Patients should be educated regarding the necessity of keeping their oxygen masks on, and ambulatory patients must recommence oxygen with the help of nurses after mobilizing.

Before sending a patient home on oxygen, healthcare providers must be sure the patient and family members understand the dangers of smoking in an oxygen-enriched environment. An increased amount of oxygen in the environment increases the speed at which things burn once a fire starts. Oxygen can saturate clothing, fabric, hair, beards and anything in the area. Even flame-retardant clothing can burn when the oxygen content increases. It is important to keep all flames and heat sources away from oxygen containers and oxygen systems. Patients should be advised never to smoke or light a match while using oxygen or allow others in the same room to do so. Patients should also be advised not to smoke in bed. Every home should have at least one working smoke detector on every level and near all bedrooms. As many people on home oxygen therapy have limited mobility, home sprinkler systems can add an extra layer of protection (www.gov.uk/firekills). They also need to inform their home and car insurers that oxygen therapy will be used, as well as the local Fire Brigade. They should be reassured that a full written package of training on safe use and storage of equipment will be provided by the contractor supplying their home oxygen.

Complications

Carbon dioxide narcosis

Carbon dioxide is the chemical that most directly influences respiration by its effect on the efficiency of alveolar ventilation. The normal partial pressure of carbon dioxide in the blood is 4.0–6.0 kPa (30–45 mmHg). When this level rises, the pH of the CSF drops which in turn causes excitation of the central chemoreceptors, and hyperventilation occurs (Marieb et al. 2012).

In people who always retain carbon dioxide and are therefore usually hypercapnic because of chronic pulmonary disease such as chronic bronchitis, the chemoreceptors are no longer sensitive to a raised level of carbon dioxide. In these cases the falling PaO₂ becomes the principal respiratory stimulus (the hypoxic drive) (Marieb et al. 2012). Therefore, if a high level of supplementary oxygen was delivered to such patients in non-emergency situations, severe respiratory depression would ensue and ultimately unconsciousness and death. The Resuscitation Council UK and British Thoracic Society advise the administration of high-flow oxygen during an acute respiratory distress or arrest situation. Start with 15 litres of oxygen per minute and wean down to the flow rate required to maintain adequate peripheral saturations of 94–98% (O'Driscoll et al. 2008).

Oxygen toxicity

Pulmonary toxicity following prolonged higher percentages of oxygen therapy is recognized clinically, but there is still much to be learnt about the condition. The degree of injury is related to the length of time and percentage of oxygen to which the individual is exposed. The pattern is one of decreasing lung compliance as a result of a sequence of events, tracheal bronchial inflammation, haemorrhagic interstitial and intra-alveolar oedema, leading ultimately to fibrosis (Winslow 2013).

Where possible, long periods (i.e. 24 hours or more) of oxygen therapy above 50% should be avoided (Winslow 2013).

Retrolental fibroplasia

Retrolental fibroplasia is a disease affecting premature babies who weigh under 1200 g (about 28 weeks' gestation) if they are exposed to high concentrations of oxygen within the first 3–4 weeks of life. It appears that the oxygen stimulates immature blood vessels in the eye to vasoconstrict and obliterate, which results in neovascularization, accompanied by haemorrhage, fibrosis and then retinal detachment and blindness (Bersten et al. 2009, Pierce 1995).

Humidification

Definition

Humidity is the amount of water vapour present in a gas. The terms used to define humidity are absolute humidity, maximum capacity and relative humidity. *Absolute humidity* is the mass of water vapour that a given volume of gas can carry at a set temperature. When a gas is at its *maximum capacity*, it is said to be fully saturated. *Relative humidity* is the ratio of the absolute humidity to the maximum capacity. The warmer the gas, the more vapour it can hold but if the temperature of the gas falls, water held as vapour will condense out of the gas into the surrounding atmosphere (Khan and O'Driscoll 2004, O'Driscoll et al. 2008).

Anatomy and physiology

The respiratory tract is lined with ciliated epithelial cells that secrete mucus. Each cell has about 200 hair-like structures known as cilia, whose role is to remove unwanted mucus and secretions. Less than optimal humidification results in the reduction of adequate ciliary activity and can lead to squamous epithelial changes, dehydration with thickening of secretions, atelectasis and heat loss (Jenkins and Tortora 2013).

The provision of humidification and heat can improve patient tolerance of oxygen therapy and minimize symptoms of dryness.

It also reduces the metabolic cost of gas conditioning and, through adequate gas flow, improves lung and airway mechanics (Chanques et al. 2009, Lenglet et al. 2012).

Related theory

Normal room air has an approximate temperature of 22°C with a relative humidity of 50% and a water content of 10 mgH₂O. For effective gas exchange to occur in the lungs, the air would need to be at a temperature of 37°C with 100% humidity and a water content of 44 mgH₂O per litre by the time it reaches the bifurcation in the trachea, which is referred to as the isothermic point. When the temperature falls below 37°C and humidity falls below 100%, several changes take place in the airways. The mucus that collects in the airways thickens and movement of the cilia is reduced. If there is no improvement, the mucus will become thicker and immobile; the cilia will also lose their mobility so clearance of all secretions will stop and infection can set in (Marieb et al. 2012).

If there is a continuing lack of humidity further damage occurs. The cilia can break off, causing damage to the mucosal lining of the respiratory tract. The isothermic point of saturation moves from the bifurcation of the trachea to a lower point in the lungs, resulting in further damage which can lead to collapse of the alveoli, decrease in lung function and hypoxaemia (Jenkins and Tortora 2013, O'Driscoll et al. 2008).

Evidence-based approaches

Many devices can be used to supply humidification; the best of these will fulfil the following requirements.

- The inspired gas must be delivered to the trachea at a room temperature of 32–36°C with 100% humidity and should have a water content of 33–43 g/m³ (Bersten et al. 2009).
- The set temperature should remain constant; humidification and temperature should not be affected by large ranges of flow.
- The device should have a safety and alarm system to guard against overheating, overhydration and electric shocks.
- It is important that the appliance should not increase resistance or affect the compliance of respiration.
- It is essential that whichever device is selected, wide-bore tubing (elephant tubing) is used to allow efficient formation of water vapour (BTS 2008) (see Figure 9.7c).

Rationale

Inhalation of oxygen, which is a dry gas, used during respiratory therapy can cause evaporation of water from the respiratory tract and damage of the mucosal lining if humidification is not provided. In patients who are intubated or have a tracheostomy, the natural pathway of humidification is bypassed (Branson and Gentile 2010).

Indications

- Used for mechanical ventilation and non-invasive ventilation such as CPAP/non-invasive positive end-expiration (NIPEE).

Contraindications

- There are no contraindications to humidification, though the device chosen will depend upon type of oxygen therapy, tenacity of secretions and the patient's clinical condition (i.e. mechanical ventilation, self-ventilating at home, etc.).
- Humidification should not be used for patients requiring open system (mask) ventilation when 'droplet contact' isolation precautions are required.

Anticipated patient outcomes

The provision of adequate humidification of gases enabling clearance of secretions, a reduction in the tenacity of secretions and improved gas exchange. The patient's airway is to remain patent at all times.

Figure 9.8 Heat and moisture exchanger (HME).

Pre-procedural considerations

Equipment

Heat and moisture exchanger (HME)

During ventilatory humidification an HME performs the function of the nose and pharynx in conditioning the inspired air. It works passively by retaining heat and moisture from the expired air and returns it to the patient in the next inspired breath (Chiumello et al. 2004, Restrepo and Walsh 2012). HMEs may contain a bacterial filter and consist of spun, pleated, highly thermal conductive material (Figure 9.8). A type of HME known as an artificial or 'Swedish' nose (Figure 9.9) can be used in a self-ventilating patient with a tracheostomy who is being weaned from oxygen.

Figure 9.9 Swedish nose.

Figure 9.10 Cold water bubble humidifier.

It can also be used in ventilated patients, inserted between the patient's airway and the ventilator circuit.

Cold water bubble humidifier

This device (Figure 9.10) delivers partially humidified oxygen at about 50% relative humidity. Gas is either forced across or bubbled through water at room temperature. This method is not advised as it is inefficient (Bersten et al. 2009).

Water humidification chamber

With these devices, inspired gas is forced over, or through, a heated reservoir of water (water humidification chamber) (see Figure 9.7d). To achieve an adequate humidity for the patient, the water bath must reach a set temperature. The gas will then cool as it moves down the breathing circuit to the patient, and a relative humidity of 100% will be reached. Hot water bath humidifiers are therefore very efficient and useful for humidification for immobile patients, particularly if they are receiving mechanical ventilatory support. However, they have three main disadvantages.

- Danger of overheating and causing damage to the trachea.
- Their efficiency can alter with changes in gas flow rate, surface area and the water temperature.
- Condensation can form collections of contaminated water in the oxygen delivery tubes and can wash colonized biofilm from the inner lumen of the tracheal tube towards the patient (Mackenzie 2008).

Aerosol generators

These devices are not governed by temperature but provide microdroplets of water suspended in the gas (Bersten et al. 2009). The gas provided through aerosol devices can be very highly saturated with water. There are three main types of aerosol humidifier.

- Gas-drive nebulizer
- Mechanical (spinning disc) nebulizer
- Ultrasonic nebulizer

These devices are useful for the spontaneously breathing patient with chronic chest disease.

Procedure guideline 9.2 Humidification for respiratory therapy

Various humidifiers exist. Select the system most appropriate for the patient.

Essential equipment

- Water humidification chamber (see Figure 9.7d)
- Heating equipment
- Oxygen (elephant) tubing (see Figure 9.7c)
- Oxygen analyser (see Figure 9.7a)
- Sterile H₂O bottle or bag depending on type of humidifier used

Pre-procedure

Action	Rationale
1 Discuss with the patient's doctor the choice of system to be used.	To ensure the most appropriate device is selected to meet the patient's needs. E
2 Explain to the patient the reason for use of the humidifier and how it works.	To enable the patient to understand what is happening and to be able to tolerate the humidification. E

Procedure

3 Prepare the device to be used (although some circuits are ready prepared with humidifier). (a) Prepare humidifier and circuit. (b) Attach humidifier/wide-bore oxygen tubing; ensure minimal length of tubing, water trap and mask.	To ensure the circuit is in working condition and patent to oxygen flow. E Connecting all equipment to oxygen and mask and ensuring all connections are secure. E To reduce dead space from excess tubing. E
4 Once the circuit is set up, run the system to check it is functioning correctly and the circuit is intact and check oxygen delivered through the oxygen analyser.	To ensure that oxygen is being delivered through the circuit as set. E To ensure the system is humidifying the oxygen and that no leaks exist, which causes suboptimal oxygen delivery to the patient (BTS 2008, C ; Intersurgical 2009, C ; MDA 2000, C).
5 If the hot water system is in use, check it is running within recommended temperature range and attach to patient.	To ensure no damage to the patient's lungs if temperature above range. E
6 Check water is present in water source of system; do not allow to run dry.	To aid adequate delivery of humidity to the patient and prevent damage to the humidifier. E
7 Position the circuit tubing below the patient.	To ensure collection of humidity in the circuit is able to drain into the water trap or circuit rather than into the patient. E
8 Ask the patient if they find the humidification comfortable.	To ensure patient comfort. E

Post-procedure

9 Monitor the running of the system.	To ensure the system is functioning adequately and delivering humidity (MDA 2000, C).
10 Reassure the patient as they may find the system noisy and the excessive moisture in the circuit difficult to cope with.	To allow patient to adjust to the feel of the mask, preventing anxiety and panic at the initial increase of work of breathing (Moser and Chung 2003, E).
11 Assess the tenacity of secretions on a regular basis, and document all findings.	To assess how effective the choice of humidification device has been. E This will enable the same care to be continued or an alternative method to be evaluated. Documentation is imperative to the multidisciplinary approach to allow for ongoing best practice (Woodrow 2002, E).
12 Change the humidification and circuit on a weekly basis, and document.	To prevent contamination of equipment and minimize the risk of infection (Demers 2002, E).

Problem-solving table 9.2 Prevention and resolution (Procedure guideline 9.2)

Problem	Cause	Prevention	Suggested action
Potential blockage of humidifier.	Kinking of oxygen tubing or secretions in humidification filter.	Change filter 4–6 hourly or more frequently for patients with copious secretions. Administer 0.9% sodium chloride nebulizers if prescribed to loosen secretions. Check tubing not kinked underneath the patient.	Encourage patient to cough and expectorate if able or remove secretions by suction if patient unable to do so. Ensure tubing is not too long which would allow kinking.

Complications

Possible contamination of water in humidification if the tubing collects water and it is reintroduced into the humidification chamber. This chamber provides the perfect environment for contaminants to grow as it is moist and warm (Demers 2002).

High-flow oxygen therapy

Definition

High-flow oxygen therapy (HFOT) (Figure 9.11) is the provision of high-flow, heated and humidified oxygen therapy to the patient through a wide-bore nasal cannula, facemask, tracheostomy mask or tracheostomy tube (Vaughn and Granger 2004).

Evidence-based approaches

High-flow oxygen therapy allows the accurate delivery of oxygen therapy of up to 100% FiO₂ at a flow rate of up to 60 L/min (system dependent), previously unfeasible via conventional methods of oxygenation (15 L via a non-rebreathable facemask and 6 L via a nasal cannula) (O'Driscoll et al. 2008). Higher flow rates are of particular benefit for patients with hypoxaemic respiratory failure who have greater inspiratory flow requirements. HFOT can meet or exceed the patient's demand, minimizing the risk of air dilution and the inaccurate delivery of oxygen (Masclans and Roca 2012, Sztrymf et al. 2012). Invariably, oxygenation and work of breathing improve (Roca et al. 2010).

High-flow oxygen therapy emulates the temperature and humidity of a healthy adult lung (37°C and 44 mg/L H₂O), optimizing mucociliary clearance by preserving the function of the ciliated mucosa, reducing the risk of respiratory tract infections and ensuring good oxygenation and ventilation. HFOT also reduces dryness of the upper airway mucosa (Cuquemelle et al. 2012).

Although research on the effects of HFOT is limited, several studies have shown that high-flow nasal therapy helps to flush out the anatomical dead space, increasing the alveolar ventilation over minute ventilation. It also provides low levels of positive end-expiratory airway pressure which aid alveolar recruitment and reduce atelectasis formation (Dysart et al. 2009, Groves and Tobin 2007, Masclans and Roca 2012, Parke et al. 2007).

The nasal cannula allows the patient to communicate freely and does not interfere with daily activities such as speaking, eating and drinking, thereby increasing patient compliance (Roca et al. 2010, Tiruvoipati et al. 2010).

High-flow oxygen therapy can be used as a step between conventional oxygen therapy, non-invasive ventilation or mechanical ventilation, allowing the patient to receive level 2 care on the ward setting and possibly prevent admission to the intensive therapy unit (ITU) (Sztrymf et al. 2011). It can also help to wean patients off non-invasive or mechanical ventilation, facilitating earlier discharge from the ITU back to the ward (Antonicelli et al. 2011).

Figure 9.11 High-flow Optiflow circuit.

Indications

- Mild-to-moderate hypoxaemic respiratory failure.
- Difficulty clearing secretions.
- Respiratory wean.
- Symptomatic breathlessness (Hui et al. 2013, Ritchie et al. 2011, Sztrymf et al. 2011).

Contraindications

There are no documented absolute contraindications but relative contraindications may include:

- upper gastrointestinal or head and neck surgery and cancers
- obstructed nasopharynx
- haemoptysis or uncontrolled oral or nasal bleeding
- deranged clotting.

Procedure guideline 9.3 High-flow oxygen therapy

Essential equipment

- Oxygen supply
- Drip stand
- Air/O₂ blender
- Oxygen analyser (see Figure 9.7a)
- Heating equipment
- Water humidification chamber (see Figure 9.7d)
- Breathing circuit
- High-flow oxygen nasal cannula, mask or tracheostomy attachment
- HME/bacterial filter (see Figure 9.9)
- Bag of sterile water (see Figure 9.11)

Pre-procedure

Action	Rationale
1 Assess the patient using patient assessment, vital signs and ABG measurements to decide whether HFOT is indicated.	To determine if patient is hypoxaemic (O'Driscoll et al. 2008, C).
2 Explain the principles of HFOT to the patient and family and gain consent.	To increase patient knowledge, minimize anxiety, gain consent and aid patient compliance (NMC 2013, C).
3 Obtain and document patient's observations prior to commencing HFOT: (a) Respiratory rate (b) SpO ₂ (c) Heart rate (d) Blood pressure (e) Temperature (f) EWS/NEWS	To provide baseline observations prior to commencing oxygen therapy. E
4 Ensure patient is sitting upright and in a comfortable position.	To promote comfort and aid lung expansion and breathing (O'Driscoll et al. 2008, C).

Procedure

5 Set up HFOT as per manufacturer's instructions and attach sterile water bag to water humidification chamber (see Figure 9.11).	Adhering to manufacturer's guidelines ensures the safe and correct use of equipment. E
6 Turn on water humidifier and allow it to reach minimum temperature (37°C).	To warm the water in the chamber. E
7 Calibrate oxygen analyser (see Figure 9.7a) to room air (21%).	To ensure an accurate reading of the oxygen concentration which is to be delivered. E
8 Set desired flow rate and oxygen concentration.	To enable the delivery of blended air and oxygen at a high flow. E
9 Place the nasal cannula, facemask or tracheostomy attachment onto the patient and tighten the straps.	To ensure the fit is snug and comfortable. Uncomfortable devices will result in poor patient compliance. E
10 Monitor vital signs and EWS/NEWS for first 5 minutes after therapy is started.	To detect any deterioration in the patient's condition (O'Driscoll et al. 2008, C).
11 Document the indication for HFOT, the patient's vital signs, the target oxygen saturation and the set FiO ₂ and flow rate.	Aim for saturations of 95% for most acutely unwell patients, and 88–92% for those at risk of hypercapnic respiratory failure (O'Driscoll et al. 2008, C). To maintain accurate records (NMC 2010, C) and ensure continuity of care.

Post-procedure

12 Continue to monitor and document vital signs and EWS/NEWS at least 4 hourly or more frequently if unstable.	To monitor for signs of deterioration (O'Driscoll et al. 2008, C).
13 Escalate any problems regarding equipment or patient to an appropriate member of staff (e.g. senior nursing staff, critical care outreach team, medical staff or physiotherapists).	To ensure equipment is working properly. E To prevent patient deterioration (NICE 2007, C).
14 Monitor patient's response to HFOT and wean flow or oxygen as per senior nursing/medical staff advice.	To reduce oxygen as per patient's requirements (O'Driscoll et al. 2008, C).
15 Check equipment regularly (e.g. 4 hourly) to ensure the correct flow and oxygen concentration are being administered.	To ensure patient is not being over- or underoxygenated. E
16 Check tubing regularly to ensure it is free from trapped water. If found, lift tubing and drain water back into the water humidification chamber.	Trapped water will result in poor delivery of the oxygen therapy. E
17 Replace bag of sterile water approximately every 12 hours or as required so that the water humidification chamber does not dry out.	Drying out will cause an increase in the temperature of unhumidified air/oxygen being delivered which may damage the patient's airway. E Drying out of the water chamber may damage equipment. E

Problem-solving table 9.3 Prevention and resolution (Procedure guideline 9.3)

Problem	Cause	Prevention	Action
The oxygen analyser shows fluctuating oxygen concentrations.	The oxygen was turned on before the flow during the initial set-up. The tubing is logged with water.	Turn on the flow first, and then increase the oxygen to get the desired oxygen concentration. Check the tubing regularly.	Hold tubing upright to allow any logged water to flow back into the water chamber.
The patient is unable to tolerate the high flow of air/oxygen.		Explain the rationale for the high flow to the patient as this may aid compliance.	Reduce flow but continue to monitor vital signs, in particular SpO ₂ , respiratory rate and work of breathing.
The patient complains that the air/oxygen is too warm.		Explain to the patient that the air/oxygen will be warm, as this may aid compliance.	Change the humidifier setting from invasive mode to non-invasive mode but only if absolutely necessary as the invasive mode ensures optimal temperature and humidity.
The humidifier temperature alarms sounds.	The patient has removed the nasal cannula or mask and the HFOT system has been left on. The temperature/flow probes are not pushed into the circuit properly or have become disconnected. The bag of sterile water has run out.	Turn the HFOT system and humidifier off when not in use.	Check all fittings and connections. Replace the bag of sterile water.

Continuous positive airway pressure

Definition

Continuous positive airway pressure (CPAP) therapy is the maintenance of a positive airway pressure greater than ambient pressure throughout inspiration and expiration. It can be delivered through a facemask, nasal mask or mouthpiece, or through an endotracheal or tracheostomy tube (Bersten et al. 2009).

Related theory

Use of the CPAP circuit dates back to at least 1912, when Bunnell used a primitive circuit during thoracic surgery. The first recorded use in intensive care was by Poulton and Oxon in 1936. In the 1940s increased interest in CPAP was prompted by research into respiratory support in high-altitude flying. Further developments occurred in the 1950s and 1960s, and in 1976 Greenbaum et al. reported the use of CPAP with a facemask in adult respiratory distress syndrome. In 1972 Williamson and Modell successfully used CPAP for selected spontaneously breathing patients with acute respiratory failure. For treatment of acute pulmonary oedema, CPAP alone is very effective (Gorini et al. 2004, Gray et al. 2009, Nehyba 2007, Thille et al. 2011).

Non-invasive ventilation

Non-invasive ventilation (NIV) refers to mechanical ventilatory support applied without an artificial airway (endotracheal tube or tracheostomy). It can be delivered to the patient via nasal cannulas, facemask or helmet (Figure 9.12). The patient must be conscious and co-operative for this type of ventilation to be effective. NIV has the advantage of avoiding the need for tracheal intubation, thus reducing rates of mortality and morbidity. It can be used for patients who do not require immediate intubation or for palliative patients where invasive ventilation may not be deemed appropriate and is particularly useful in patients with chronic respiratory disease (De Silva 2009).

- In restrictive pulmonary disease, for example muscular dystrophy.
- In progressive neuromuscular disease, for example motor neurone disease.

Figure 9.12 CPAP mask and helmet.

- In obstructive pulmonary disease, for example COPD, bronchiectasis, cystic fibrosis.
- In nocturnal hypoventilation.
- In patients with acute exacerbation of chronic respiratory disease.
- In patients in whom endotracheal intubation and ventilation may not be considered appropriate or where difficulties may be anticipated in weaning a patient from a ventilator.

Non-invasive ventilators generally fall into two categories (Esmond 2001):

- pressure preset machines
- volume preset machines.

Mechanical ventilation

A mechanical ventilator is a device used to replace or assist breathing in order for satisfactory gas exchange to take place. The decision to ventilate a patient will be made after careful clinical examination, including assessment of respiratory mechanics, oxygenation and ventilation.

Ventilators are able to control tidal volume, respiratory rate, time of inspiration against time of expiration, inspired flow rate and inspired oxygen concentration (Bersten et al. 2009, Hinds and Watson 2008, Pierce 1995, West 2008).

Ventilators are divided into two main categories: negative pressure and positive pressure.

Negative pressure ventilators

These devices are now rarely used. They mimic normal breathing (negative pressure) and are known as iron lungs. The patient is enclosed in an airtight tank and a negative pressure is created by a separate pump which causes the alveolar pressure to fall within the lungs so a pressure gradient results, with air flowing into the lungs along the pressure gradient in order for ventilation to take place. An adaptation from the tank ventilator is the cuirass shell, which surrounds the thorax and abdomen and works on the same principle. The rare use of these devices would be in patients with chronic respiratory failure (neuromuscular disease, skeletal deformity or sleep-related respiratory problems).

Positive pressure ventilators

These devices provide a satisfactory gas exchange when inflating the lungs with a positive pressure via an endotracheal tube or tracheostomy.

Positive pressure ventilators have four main functions to perform during each respiratory cycle.

- Inflate the lungs.
- Cycle from inspiration to expiration.
- Allow expiration to take place.
- Cycle from expiration to inspiration.

They have a driving mechanism and can cycle from one phase of the respiratory cycle to another by a preset pressure, preset time or preset volume.

Varying modes of ventilation can be used.

- Volume controlled, e.g. synchronized intermittent mandatory ventilation (SIMV)
- Pressure controlled, e.g. bilevel positive airway pressure (BiPAP), SIMV
- Spontaneous/assisted ventilation, e.g. CPAP/bilevel NIV (CPAP ASB) (BTS 2008)

Hyperbaric respiratory therapy

Hyperbaric respiratory therapy is used mainly in the treatment of carbon monoxide poisoning, burns, gas gangrene, skin lesions, soft tissue injury, decompression sickness (the bends) and multiple sclerosis. The therapy is designed to give 100% oxygen at a range of pressures greater than atmospheric pressure. Oxygen is dissolved in the plasma, increasing the oxygen tension in the tissues (Bersten et al. 2009).

Evidence-based approaches

The aim of CPAP therapy is to improve gas exchange (oxygen and carbon dioxide) within the lungs and improve the work of breathing. CPAP is able to do this by:

- *increasing the functional residual capacity (FRC)*, which is the amount of gas left in the lungs at the end of normal expiration available for pulmonary gas exchange. In acute lung injury where gaseous exchange is severely inhibited, CPAP increases the FRC by reopening collapsed alveoli and improving ventilation and oxygenation (Hill et al. 2007)
- *improving the ventilation/perfusion ratio*: decreased intrapulmonary shunting with hypoxia could cause ventilation to the lungs to be reduced or blood flow to them impaired. Intrapulmonary shunting can then occur with underventilation of the lungs. CPAP helps to decrease the intrapulmonary shunting by improving the ventilation/perfusion mismatch (BTS 2008)
- *improved lung compliance (elasticity) of the lungs*: in respiratory failure the lungs become much stiffer and less compliant and breathing can become more difficult. Reduction in lung volume below a certain level results in airway collapse and underventilation. The increase in transpulmonary pressure required to overcome this can be achieved by CPAP (Hill 2006)
- *increasing lung volume (alveolar volume)* for gaseous exchange to take place. The factors above enable an increase in surface area of alveoli available for gas exchange. As a result, the work of breathing and the percentage of oxygen required may be reduced (Mistrali et al. 2013, Rose and Gerdtz 2009).

Rationale

Continuous positive airway pressure is the maintenance of a positive pressure throughout the whole respiratory cycle when breathing spontaneously. CPAP provides an additional therapy between conventional oxygen therapy and controlled ventilation. It helps prevent atelectasis, reduce the work of breathing and eliminate or reduce hypoxia whilst allowing the normalization of the FRC. Other benefits include the preservation of the ability to speak, cough, clear secretions and swallow whilst warming and humidifying inspired air via natural upper airway mechanics (BTS 2008, Hill et al. 2007, Pladek et al. 2007).

Indications

Continuous positive airway pressure is usually commenced to improve lung expansion. CPAP is also indicated in the presence of clinically significant pulmonary atelectasis when other forms of therapy, such as HFOT, incentive spirometry, chest physiotherapy and deep breathing exercises, have been unsuccessful.

- Acute respiratory failure
- Hypercapnic acute respiratory failure
- Acute exacerbation of COPD
- Post-extubation difficulty
- Weaning difficulties
- Post-surgical respiratory failure
- Thoracic wall deformities
- Cystic fibrosis
- Status asthmaticus
- Acute respiratory failure in obesity hypoventilation syndrome and obstructive sleep apnoea
- Chronic respiratory failure
- Chronic heart failure (Rose and Gerdtz 2009)
- Immunocompromised patients
- Neuromuscular disease (De Silva 2009)
- Patients 'not for intubation'
- Hypoxaemic acute respiratory failure (Ram et al. 2004)

Contraindications

- Recurrent pneumothoraces/untreated pneumothorax – may contribute to barotraumas
- An inability to protect their own airway
- Vomiting or excessive secretions and a high risk of aspirating
- Severe post-operative pulmonary air leak
- Central apnoea

- Epistaxis
- Any condition where an elevated intracranial pressure is undesirable or where reduction in cerebral blood flow is inappropriate (Kolbitsch et al. 2000)
- Any situation where there is already significant lung overdistension
- Unstable facial fractures, extensive facial surgery or lacerations and facial burns
- Laryngeal trauma, recent tracheal anastomosis
- Recent ear, nose and throat surgery
- Basilar skull fracture – at risk of pneumocephalus

NB: The last four contraindications listed are specific to mask CPAP and not necessarily relevant to helmet CPAP (Kolbitsch et al. 2000).

448

Methods of delivering CPAP

Continuous positive airway pressure can be delivered by nasal mask, facemask or helmet as illustrated in Figure 9.12.

Anticipated patient outcomes

- Ability to wean patient off CPAP mask and improvement of respiratory status with lower oxygen requirements.
- For lung expansion therapy, a minimum delivered tidal volume of at least one-third of the predicted inspiratory capacity (IC) ($1/3 \times 50 \text{ mL/kg}$) has been suggested. This corresponds to approximately 1200 mL in a 70 kg adult patient (Shelledy and Mikles 2002).
- An increase in peak flow.
- Cough more effective with treatment and secretion clearance enhanced as a consequence of deep breathing and coughing.
- Chest radiograph improved.
- Breath sounds improved (Sorenson and Shelledy 2003).

Legal and professional issues

Competencies

Close and thorough clinical assessment is of paramount importance when caring for a patient receiving CPAP or NIV. Physiological monitoring is not a substitute for clinical assessment and observation of the patient on the ventilator should be carried out regularly. Nursing staff caring for patients requiring CPAP ventilation would therefore need to be trained in advanced respiratory care or work in areas such as the high-dependency unit (HDU) or critical care unit (CCU) setting (Kinnear 2002).

Pre-procedural considerations

Care of patients with CPAP should be provided in HDU or CCU settings with cardiac and respiratory monitoring equipment. CPAP should be considered only with a co-operative patient who can control their airway and secretions with an adequate cough reflex. The patient should be able to co-ordinate breathing with the ventilator and breathe unaided for several minutes if CPAP is delivered via a ventilator (Sorenson and Shelledy 2003).

Equipment

- Flow generator with variable flow such as WhisperFlo. A means of generating a flow of pressurized breathable gas at variable rates and oxygen concentrations.
- CPAP mask (two-port type) or CPAP helmet with securing straps (see Figure 9.12).
- Bacterial-viral filter (*not* an HME) (Figure 9.13). Provides protection against various types of particles including bacteria, viruses and water droplets. The filter helps protect the patient, the equipment and the breathing circuit from contamination.
- Aerosol tubing.
- Oxygen analyser and T-piece (see Figure 9.7).
- CPAP positive end-expiratory pressure (PEEP) valve of prescribed level (Figure 9.14).

Figure 9.13 Bacterial-viral filter.

- Higher rated CPAP valve (+20 cmH₂O) (see Figure 9.14) and T-piece (if using WhisperFlo device).
- Water humidification chamber (heated wire) (see Figure 9.7d). Warms and humidifies inspired gas to core temperature and 100% relative humidity, which maximizes mucociliary clearance and prevents inflammatory reactions while sustaining airway patency and lung compliance (Williams et al. 1996.) (If humidifier is used a patient section and 1 litre bag of water for inhalation will be required.) In some departments a complete circuit is available with all of the disposable items provided in one kit.

Assessment and recording tools

While on CPAP, it is essential to monitor the patient's cardiovascular status, respiratory rate, capnography (EtCO₂), pulse oximetry and fluid balance at least hourly as well as regular ABG sampling.

Clinical features that should be assessed are:

- chest wall movement
- co-ordination of respiratory effort with the ventilator
- accessory muscle recruitment

Figure 9.14 CPAP valves.

- general assessment – patient sweating/clammy/dyspnoeic
- auscultation of the chest
- patient comfort
- neurological status – signs of confusion/tiredness.

The patient receiving NIV or CPAP should be fully monitored:

- heart rate and rhythm
- respiratory rate
- blood pressure
- oxygen saturation measured by pulse oximetry (SpO₂).

It has been reported that oxygen levels improve rapidly on NIV so it is important to measure SpO₂ continuously in the first 24 hours, aiming to keep it >95% with supplemental O₂ (Kinnear 2002, Sorenson and Shelledy 2003). All the above observations need to be documented on the observation chart or HDU observation chart as applicable.

Pharmacological support

Diuretics may be given if pulmonary oedema is present. In some extreme cases small doses of anxiolytics may be given to combat

the distress caused by CPAP therapy. This will require increased levels of monitoring to ensure patient safety (Allison 1991, Keen 2000, Lenique et al. 1997).

Non-pharmacological support

In some patients the presence of a relative, nurse or healthcare assistant may alleviate the distress caused by CPAP.

Specific patient preparation

Education

Continuous positive airway pressure can cause distress to patients, due especially to the tight-fitting mask, while the hood can seem claustrophobic. If possible, a clear and concise description of how the therapy works should be provided either verbally or via an information leaflet. As with any procedure, consent needs to be gained before treatment can commence. Allow time for the patient to express any concerns/fears they have regarding treatment. Acutely hypoxic patients may not comprehend the relevance of the therapy and so it should be explained to their relative/carer so they can reassure the patient (DH 2002, Moser and Chung 2003).

Procedure guideline 9.4 Continuous positive airway pressure

Essential equipment

- Drager bellows or similar high-flow oxygen delivery system (see Figure 9.7e)
- Compressed air supply
- CPAP helmet or mask
- CPAP circuit
- Humidification system (mask only) with temperature control
- Flowmeter
- Oxygen analyser
- Pulse oximetry
- Nasogastric tube
- Urinary catheter

Pre-procedure

Action	Rationale
1 Assess patient's conscious level.	To obtain a baseline and to be able to assess for change in condition (see Chapter 11: Observations). E
2 Explain the principles of CPAP to the patient and family and demonstrate the system to them. Observe and record the following. (a) Patient's respiratory function (b) Respiratory rate (c) Work of breathing (d) Colour, skin and mental status (e) Tissue oxygen saturation (SaO ₂)	To gain consent, minimize anxiety, increase knowledge and aid in patient compliance. E To obtain a baseline of respiratory function. E To observe for any change in respiratory function. E A reduction in level of consciousness or altered mental status may indicate hypoxaemia. E
3 Decide whether it is appropriate to insert an arterial cannula.	In order to monitor the acid/base balance. E
4 Observe and record the patient's cardiovascular function, including: (a) heart rate (b) blood pressure (c) temperature (d) central venous pressure (if patient has a central venous access device).	To obtain a baseline in order to assess any change in conditions (see Chapter 11: Observations). E
5 Assess fluid balance. (a) Input (b) Output (c) Accumulative balance (d) Overall fluid balance (e) Daily weight	To obtain a baseline of fluid balance. E To enable assessment of dehydration or fluid overload (Keen 2000, E).

(continued)

Procedure guideline 9.4 Continuous positive airway pressure (*continued*)**Action**

- 6 Assess patient's level of anxiety and compliance with treatment (the patient's ability to cope with the treatment).

Rationale

To enable an assessment to be made and an evaluation of the suitability of CPAP therapy. **E**

Procedure

- 7 Set up CPAP circuit. To prepare equipment for use. **E**
- 8 Ensure patient is in a comfortable position, sitting up in bed at a 45° angle or more or in a chair well supported by a pillow. To promote comfort and aid lung expansion and breathing (Fell and Boehm 1998, **E**).
- 9 Explain to patient how the helmet or mask is to be applied. To relieve anxiety and to reassure patient. **E**
To aid patient's compliance with CPAP. **E**
- 10 Apply helmet/mask gently, applying pressure as the patient adapts to the tight-fitting mask. Hold mask until patient is comfortable and settled. To relieve anxiety and to reassure patient. **E**
To aid patient's compliance with CPAP. **E**
- 11 Once the patient is settled with mask/helmet, apply the head strap or shoulder straps. Ensure mask/helmet and head strap are comfortable for the patient; alter position as required. To retain mask in place and aid patient comfort (Keilty and Bott 1992, **E**).
- 12 Ensure a good seal and that no leaks are present. To ensure a tight seal in order that the system functions optimally (Greenbaum et al. 1976, **E**).
- 13 Apply tissue protective dressing around vulnerable pressure points: nose, ears, back of head and neck. To alleviate pressure and prevent tissue breakdown. **E**

Post-procedure

- 14 Give further explanation to family/next of kin of how CPAP works and the importance of their presence and participation in communication. To relieve anxiety and support and reassure family and patient. **E**
- 15 Reassure the patient constantly. To relieve patient anxiety and promote co-operation. **E**
- 16 Discuss with doctor use of medication that might aid patient compliance with CPAP therapy and administer as necessary. Prophylactic administration of small doses of anxiolytic can aid compliance with CPAP therapy (Kinnear 2002, **E**).
- 17 Continue observation of vital signs and work of breathing. If patient is tiring, notify doctor. To prevent acute respiratory deterioration or to inform doctor in a timely manner in order to intubate the patient to avoid a respiratory arrest situation (NICE 2007, **C**).
- 18 Continue documenting NEWS score in order to flag up deterioration quickly. To prevent acute respiratory deterioration or to inform doctor in a timely manner in order to intubate the patient to avoid a respiratory arrest situation (NICE 2007, **C**; RCP 2012, **C**).

Problem-solving table 9.4 Prevention and resolution (Procedure guideline 9.4)

Problem	Cause	Prevention	Suggested action
Maintenance of airway.	Deteriorating respiratory function. Physical tiring.	Use of NEWS scoring to identify deterioration.	Regular monitoring of respiratory function including skin colour, breathing pattern, respiratory rate, oxygen saturation, blood gases. Discuss changes with medical or anaesthetic staff.
Inability to eat.	Gastric distension due to CPAP. Loss of appetite. Difficulty in eating; distress caused by respiratory status and CPAP. Nausea and vomiting.	Provide small but regular easily managed (soft) oral diet or supplement drinks.	Encourage diet and oral supplementary fluids. If unable to take orally, refer to dietician as an alternative method of feeding may be considered, for example enteral feeding via nasogastric or jejunal tube or intravenous feeding (PN). Administer antiemetic. Encourage and reassure patient.

Problem	Cause	Prevention	Suggested action
Aspiration, if unable to maintain own airway.	Inability to maintain own airway. Continuous pressure from CPAP system. Insufflation of air.	Seek SLT assessment. Keep NBM and insert nasogastric tube. Insert nasopharyngeal tube (Figure 9.15).	Observe and assess patient closely. After discussion with medical staff, a nasogastric tube may be inserted to reduce gastric distension.
Dry mouth.	CPAP system utilizes a very high oxygen flow which has a drying effect.	Provide adequate oral hydration.	Carry out regular mouthcare. Give patient regular sips of water, ice to suck or drinks as patient is able to take. Humidify, as in CPAP circuit.
Eyes (only applies to facemask CPAP): Dry Sore Conjunctival oedema	Mask: air leak. High-flow oxygen. Facial pressure from mask causing oedema.	Protect eyes from drying out. Use correct size of mask/helmet for patient.	Ensure mask/helmet is well sealed with no leaks. Apply pressure-relieving padding around mask. Apply regular eyecare (see Chapter 8: Patient comfort and end-of-life care). Adjust mask to facial contour. Alter and position mask as comfortably as possible. Position padding around the headstrap to relieve pressure.
Mask/helmet incorrectly sealed.	Incorrect size of mask or helmet.	Use appropriate size mask/helmet.	Alter mask/helmet position to correct and ensure comfort. Ensure mask/helmet is correct size. Alter position to ensure correct seal.
Non-compliance with CPAP equipment.	Anxiety.	Calm, informative communication.	Inform patient of any changes taking place. Communicate with the patient's family, keep them informed and involve them in care and communication with patient. Inform doctor of patient's anxiety level. Administer prescribed anxiolytic agent if required.
Helmet not inflating or patient finding it difficult to breathe with mask.	Disconnection of tubing. Not connected to piped oxygen.	Switch on all audible alarms on equipment. Clarify alarm parameters with medical/senior nursing staff. Keep bed space tidy and free from clutter. If possible, ensure bed space is close to/visible from nurse station.	Ensure nurse present with patient at all times. Observe patient and CPAP system closely to ensure equipment is working optimally and there is no failure of the system.
Inability to communicate effectively. Feelings of isolation.	Mask/helmet restriction.	Provide means of non-verbal communication. Ask relative/carer/HCA to stay with patient.	Reassure patient and ensure they are comfortable. Encourage patient to communicate and explain how they can use letterboard to do so. Reassure patient.

Post-procedural considerations

Immediate care

It is important to maintain a high level of monitoring while encouraging the patient to maintain good lung expansion by sitting upright and expectorating as required (Keen 2000). CPAP can cause the oral mucosa to dry out with prolonged use, leading to an increased risk of infection, so it is essential that regular mouthcare is provided. Regular ABG sampling can be used to assess the effectiveness of the treatment as well as guiding any changes required to either oxygen concentration or PEEP. As with all patients requiring an increased level of support, an accurate fluid balance chart should be maintained

to ensure that fluid overload does not occur (O'Driscoll et al. 2008).

Ongoing care

See Box 9.4.

Documentation

Document all the vital signs and monitoring as well as the patient's response to CPAP or NIV treatment.

Education of patient and relevant others

It is worth discussing with the patient and family/carer that intermittent use of CPAP is sometimes beneficial and that if it is required again, this does not necessarily indicate deterioration.

Figure 9.15 Nasopharyngeal airway and safety pin.

Box 9.4 Five things to make oxygen use safer in your hospital

- 1 **Check that the oxygen you are giving is prescribed.** Oxygen is a medicine and should always be prescribed. In an emergency, oxygen can be given immediately and documented later.
- 2 **Measure and record saturation levels.** Oxygen is a treatment for hypoxaemia, not breathlessness. Establish whether the patient is hypoxaemic and, if so, to what extent. Pulse oximetry is an essential tool in assessing the oxygen saturation of the blood and results should be recorded.
- 3 **Adjust the flow rate, if required, to achieve target saturation.** Maintain the target saturation range. The recommended initial target saturation range, unless stated otherwise, is 94–98%. If patients have chronic obstructive pulmonary disease (COPD) or other risk factors for hypercapnic respiratory failure, aim at a saturation of 88–92%.
- 4 **Don't confuse oxygen and medical compressed air.** Be aware of colour coding of flowmeters and make sure they are not obstructed by curtains or other equipment.
- 5 **Check the content of cylinders and calculate how long they will last.** This is especially important for cylinders on resuscitation trolleys and when transferring a patient (NPSA 2009).

Complications

With any circuit that includes the use of PEEP, there is the possibility of reduction in cardiac output. However, spontaneous ventilation decreases both the incidence and severity of this complication (Bersten et al. 2009). There is also a risk of vomiting and aspiration of gastric insufflation (blowing of air causing gastric distension), although this is minimized when used in awake patients or by the insertion of an oro/nasogastric tube (Schumaker et al. 1996). Patients requiring CPAP should ideally be in a HDU setting so a higher level of observations can be maintained (Box 9.5). Preventive pressure dressings should be considered in underweight patients or those with bony facial prominences, in addition to regular skin checks to ensure that the tight-fitting facemask required for CPAP is not compromising the skin integrity of vulnerable areas on the bridge of the nose and over the ears (Keen 2000).

Box 9.5 Continual monitoring of patients requiring continuous positive airway pressure ventilation

- Oxygen flow setting, concentration administered, PEEP used
- Pulse rate and rhythm from ECG if available
- Sputum production: quantity, colour, consistency
- Skin colour
- Blood pressure
- Intracranial pressure for patients who have neurological deficit
- Respiratory rate
- Patient subjective response to therapy: pain, discomfort, dyspnoea
- Neurological status and level of consciousness
- Breath sounds
- O₂ saturation
- Chest X-ray

ECG, electrocardiogram; PEEP, positive end-expiratory pressure.

Chest drains

Definition

A chest drain is a length of tubing, made of clear, rigid yet pliable plastic, which may have a radiopaque strip incorporated into it that enables X-ray detection. It has a proximal and distal end. The proximal end is inserted into the pleura and has a number of holes, which facilitate drainage. The distal end is connected to the drainage system (Marieb et al. 2012) (Figure 9.16).

Anatomy and physiology

Each lung is surrounded by a double membrane called the pleura. The outer membrane is the parietal pleura; this is attached to the thoracic (chest) wall and contains nerve receptors which detect

Figure 9.16 A chest drain and underwater seal bottle are used to drain a left pleural effusion.

pain. The inner membrane is the visceral pleura and this adheres to the lung, covering the lung fissures, hilar bronchi and vessels (Figure 9.17). The pleurae are thin, serous and porous, which allows for movement of interstitial fluid across these membranes (Berne 2004, Guyton and Hall 2006, Marieb et al. 2012, Tortora and Derrickson 2011).

Pleural space

A space exists between the parietal and visceral pleura commonly known as the pleural space, cavity or potential space. Approximately 3–5 mL of serous fluid produced by the pleurae fills this space, enabling the pleurae to move in unison with the chest wall on inspiration. In addition, the serous fluid enables the membranes to be held closely together by surface tension forces. A careful balance is required to control the amount of fluid present in the pleural space. This balance is maintained by the oncotic pressure across the pleurae and lymphatic drainage. Approximately 1–2 litres of fluid move across the pleural space each day (Tortora and Derrickson 2011, Urden et al. 2006).

The natural recoil tendency of the lungs during breathing causes them to try and collapse, so a negative pressure is required on the outside of the lungs to keep them expanded. This is provided by the pleurae. During respiration, the intrapleural pressure will vary. Before inspiration, the pressure within the pleural space is equal to $-5 \text{ cmH}_2\text{O}$. During inspiration, there is a decrease in the intrapleural pressure due to the diaphragm being drawn down and outward with expansion of the chest. The pressure falls to $-7.5 \text{ cmH}_2\text{O}$, and this results in air being drawn in for gaseous exchange (Marieb et al. 2012). During expiration, the lung returns to its pre-inspiratory state by elastic recoil, with collapse of the chest wall and diaphragm and the exhalation of gas, resulting in a subsequent rise in the intrapleural pressure to $-4 \text{ cmH}_2\text{O}$. If there is loss of the normal negative pressure, partial or total lung collapse can occur, which can then lead to a reduction in the capacity of the lung available for effective gaseous exchange (Berne 2004, Guyton and Hall 2006, Marieb et al. 2012, Tortora and Derrickson 2011).

Related theory

Chest drains are inserted to drain air (pneumothorax) or fluid (haemothorax, pleural effusion or empyema) from the lungs and the management of the chest drain depends on the reason for insertion. As a rule, chest drains inserted for pneumothorax should never be clamped. Chest drains inserted for a pleural effusion need intermittent clamping to control the amount of fluid

Box 9.6 Signs and symptoms of pleural effusions

Dyspnoea

- Dyspnoea is the most common clinical symptom at presentation.
- It indicates a large effusion (usually not $<500 \text{ mL}$).
- It is reported to occur in 50% of patients with malignant pleural effusions.
- However, other factors (e.g. underlying lung disease, cardiac dysfunction and anaemia) also may contribute to the development of dyspnoea.

Chest pain

- Chest pain may be mild or severe; it typically is described as sharp or stabbing, is exacerbated with deep inspiration, and is pleuritic.
- Pain may be localized to the chest wall or referred to the ipsilateral shoulder or upper abdomen (frequently seen with malignant mesothelioma), usually because of diaphragmatic involvement.
- It often diminishes in intensity as the pleural effusion increases in size.
- Chest pain signifies pleural irritation, which can aid in the diagnosis of the cause of the effusion, since most transudative effusions do not cause direct pleural irritation (Maskell and Butland 2003).

Other signs and symptoms (associated more closely with the underlying disease process)

- Increasing lower extremity oedema, orthopnoea and paroxysmal nocturnal dyspnoea all may occur with congestive heart failure.
- Night sweats, fever, haemoptysis and weight loss may occur with tuberculosis.
- An acute febrile episode, purulent sputum production and pleuritic chest pain may occur in patients with an effusion associated with aerobic bacterial pneumonia (Maskell and Butland 2003).

drained off in one attempt to prevent re-expansion pulmonary oedema, coughing and chest discomfort and haemodynamic instability (Laws et al. 2003, Roberts et al. 2010). Patients may present with various signs and symptoms of pleural effusions (Box 9.6) and of pneumothorax (Box 9.7).

Box 9.7 Signs and symptoms of pneumothorax

- Predominant symptom is acute pleuritic chest pain, restlessness, anxiety.
- Dyspnoea results from pulmonary compression.
- Symptoms are proportional to the size of the pneumothorax.
- Also depend on the degree of pulmonary reserve.
- Physical signs include:
 - tachypnoea
 - absent or diminished breath sounds on affected side
 - subcutaneous emphysema
 - decreased tactile and vocal fremitus.
- In a tension pneumothorax:
 - the patient is hypotensive with acute respiratory distress
 - the trachea may be shifted away from the affected side, causing asymmetrical chest expansion
 - there is hyper-resonance (tympany) to percussion on affected side
 - neck veins may be engorged
 - there is progressive cyanosis.
- Diagnosis can be confirmed with a chest X-ray (Bowman 2009).

Pleural effusion

This is defined as an excessive amount of fluid in the pleural space (Kumar and Clark 2009). The fluid can be composed of malignant cells or result from an accumulation of lymph in the pleural space (chylothorax) (Kozer and Adams 2005). An effusion occurs as a result of trauma, carcinoma, heart failure, hypoproteinaemia or pneumonia. Pleural effusions occur when an imbalance in pressure allows the flow of fluid into the pleural space to exceed its absorption (Broadus and Light 2010, Chernecky and Shelton 2001). Drainage of large pleural effusions should be controlled by periodically clamping the drain. Draining too much fluid off the lungs may cause re-expansion pulmonary oedema. The amount of fluid evacuated by pleural aspiration will be guided by patient symptoms (cough, chest discomfort) and should be limited to 1.5 litres on a single occasion. If the patient's blood pressure drops suddenly or if the patient experiences painful coughing then the nurse would need to clamp the drain, escalate to medical or senior nursing staff member, continue frequent observations and consider intravenous fluid challenge to prevent further loss of volume resulting in subsequent hypotension (Feller-Kopman et al. 2006, Laws et al. 2003, Roberts et al. 2010).

Pleural effusions are classified into transudates and exudates. A *transudative pleural effusion* occurs when the balance of hydrostatic forces influencing the formation and absorption of pleural fluid is altered to favour pleural fluid accumulation. The permeability of the capillaries to proteins is normal (Broadus and Light 2010, Maskell and Butland 2003). In contrast, an *exudative pleural effusion* develops when the pleural surface and/or the local capillary permeability are altered (Broadus and Light 2010, Maskell and Butland 2003).

There are many causes of transudates and exudates as illustrated in Box 9.8 and Box 9.9.

Pneumothorax

This can be defined as air in the pleural cavity (Kumar and Clark 2009). When the integrity of either pleural layer is breached, air can enter the pleural cavity, causing the lung to collapse down towards the hilum (Henry et al. 2003, Simpson et al. 2012). Many procedures performed in an intensive care or emergency setting can result in an iatrogenic pneumothorax and tension pneumothorax. Examples of these procedures include incorrect chest tube insertion, mechanical ventilation therapy, central venous catheterization, cardiopulmonary resuscitation, hyperbaric oxygen therapy, needle, transbronchial or transthoracic lung biopsy, liver biopsy or surgery, and neck surgery (Bowman 2009).

Spontaneous pneumothorax

Spontaneous pneumothorax is a collection of air or gas in the chest that causes the lung to collapse (NLM 2010). Spontaneous pneumothorax can occur as a result of trauma, surgery, central venous catheter insertion, during positive pressure ventilation, and in those individuals with lung conditions, for example asthma, chronic bronchitis, tuberculosis, pneumonia or carcinoma of the lung due to the mechanical and physiological

Box 9.9 Causes of exudative pleural effusion

- **Malignant disorders:** metastatic disease to the pleura or lungs, primary lung cancer, mesothelioma, Kaposi's sarcoma, lymphoma, leukaemia
- **Infectious diseases:** bacterial, fungal, parasitic and viral infections; infection with atypical organisms such as *Mycoplasma*, *Rickettsia*, *Chlamydia*, *Legionella*
- **Gastrointestinal diseases and conditions:** pancreatic disease, Whipple's disease, intra-abdominal abscess, oesophageal perforation, abdominal surgery, diaphragmatic hernia
- **Collagen vascular diseases:** rheumatoid arthritis, systemic lupus erythematosus, benign asbestosis effusion
- **Meigs' syndrome:** benign solid ovarian neoplasm associated with ascites and pleural effusion
- **Drug-induced primary pleural disease:** nitrofurantoin, amiodarone, procabazine, methotrexate, bleomycin, metronidazole
- **Injury after cardiac surgery** (Dressler's syndrome): injury reported after cardiac surgery, pacemaker implantation, myocardial infarction, blunt chest trauma, angioplasty (Maskell and Butland 2003).

processes of these conditions (NLM 2010, Simpson et al. 2012). If left untreated, a spontaneous pneumothorax can become a tension pneumothorax.

Tension pneumothorax

A tension pneumothorax is a complete collapse of the lung. It occurs when air enters but does not leave the space around the lung (pleural space). It is a life-threatening emergency that requires immediate treatment (NLM 2010, Simpson et al. 2012).

Haemothorax

Haemothorax is a collection of blood in the space between the chest wall and the lung (the pleural cavity), usually the result of chest injury, trauma to the heart, lungs or major vessels or in a patient who has bled on anticoagulant therapy (NLM 2010).

Haemopneumothorax

Haemothorax may also be associated with pneumothorax. Depending on the amount of blood or air in the pleural cavity, a collapsed lung can lead to respiratory and haemodynamic failure (NLM 2010).

Empyema

This is defined as pus in the pleural space. Its main causes include rupture of an abscess of the lung, following pneumonia, pulmonary tuberculosis, or an infection following thoracic surgery (Kumar and Clark 2009).

Chylothorax

Chylothorax is a milky white fluid from a pleural space, usually resulting from disruption of the thoracic duct or its tributaries. This fluid contains a high level of triglyceride (>110 mg/dL), an essential feature for its diagnosis. More than 50% of chylothorax is due to malignancy, and lymphoma accounts for 75%, followed by lung carcinoma (Maskell and Butland 2003). Neoplastic disease causes 13–40% of all pleural effusions. Pleural effusion develops in nearly half of all patients with metastatic cancer. The most common tumours that cause malignant pleural effusions are adenocarcinoma and other carcinomas of the lung, breast cancer, lymphoma and leukaemia. These malignancies, combined, account for approximately 75% of all malignant pleural effusions. Other relatively common malignancies associated with pleural effusion are ovarian carcinoma,

Box 9.8 Transudative pleural effusion

Can be caused by:

- congestive heart failure (most common transudative effusion)
- hepatic cirrhosis with and without ascites
- nephrotic syndrome
- peritoneal dialysis/continuous ambulatory peritoneal dialysis
- hypoproteinaemia (e.g. severe starvation)
- superior vena cava obstruction (Maskell and Butland 2003).

stomach cancer and sarcomas (including melanoma) (Maskell and Butland 2003).

Evidence-based approaches

Chest drains may be used in patients with collapsed lungs, malignancies, chest trauma or after surgery. Inserting chest drains is a common procedure, but not without risk. The procedure can be carried out in general wards provided adequate monitoring is available, in a clean area appropriate for such procedures (Havelock et al. 2010). Most are planned, but some may need to be done as emergencies. When chest drains are not inserted properly, the procedure may result in the puncture of major organs such as heart, lungs, liver and spleen (NPSA 2008). The National Patient Safety Agency (NPSA) highlighted the risk associated with chest drain insertion to all healthcare professionals in its report of May 2008. The major causes for injury or harm with insertion of chest drains as highlighted by the NPSA and the Medicines and Healthcare Products Regulatory Authority (MHRA) are:

- lack of supervision of junior doctors and lack of experience of clinicians inserting chest drains
- failure to follow manufacturer's instructions
- the site of insertion and poor positioning
- excessive insertion of dilator
- anatomical anomalies and the patient's clinical condition
- inadequate imaging
- lack of knowledge of existing clinical guidelines (NPSA 2008).

Purse-string sutures should not be used for large-bore drains as they pull a linear wound into a tight circular shape which causes pain for the patient and leaves an unsightly scar, so mattress sutures (Figure 9.18) should be used to secure large-bore chest drains (Laws et al. 2003, O'Driscoll et al. 2008).

Rationale

Any abnormal collection of fluid or air in the pleural space can compress the lung, causing it to collapse either partially or fully, which can seriously compromise ventilation and the mechanics of breathing (Allibone 2003, MacDuff et al. 2010). Chest or intrapleural drainage is a method used to remove the collection of air, fluid, pus or blood from the pleural space in order to restore normal lung expansion and function (Hyde et al. 1997, MacDuff et al. 2010, McMahon-Parkes 1997). The type of drainage equipment generally depends on the purpose of chest drain insertion.

A pneumothorax should always have an underwater seal bottle attached to it as bubbling in the bottle is an indication of air still in the pleural cavity. If bubbling reduces and then stops, it may indicate that the lung is reinflated. Mostly pleural effusions may

be attached to ambulatory chest drainage bags with Heimlich flutter valves which aid early patient mobilization (Havelock et al. 2010, Laws et al. 2003, MacDuff et al. 2010).

Indications

- Pneumothorax:
 - in any ventilated patient
 - tension pneumothorax after initial needle relief
 - persistent or recurrent pneumothorax after simple aspiration
 - large secondary spontaneous pneumothorax in patients over 50 years.
- Malignant pleural effusion.
- Empyema and complicated parapneumonic pleural effusion.
- Traumatic haemopneumothorax.
- Post-operative, for example thoracotomy, oesophagectomy, cardiac surgery (Laws et al. 2003, O'Driscoll et al. 2008).
- Drainage of pleural effusions.
- Drainage of chyle (lipids drained by the lymphatic system) (Adam and Osborne 2005, Maskell and Butland 2003).

Contraindications

- Lung densely adhered to chest wall throughout in a hemithorax is an absolute contraindication.
- Differential diagnosis between pneumothorax and bullous lung disease needs to be investigated.
- Drainage of post-pneumonectomy space only after consultation with cardiothoracic surgeon.
- Abnormal blood clotting screen or low platelet count; it is good practice to correct any coagulopathy or thrombocytopenia prior to chest drain insertion.
- Warfarin should be stopped and time allowed for its effects to resolve (Laws et al. 2003, O'Driscoll et al. 2008).

Principles of care

- To maintain sterility of the chest drainage system and avoid introduction of bacteria into the intrapleural space.
- To keep the system patent.
- To keep the system upright and airtight (Kirkwood 2002).
- To monitor the patient's vital signs, pain score and amount of drainage and report any changes in breathing or vital signs.

Methods of chest drain insertion

The NPSA (2008) strongly advises the use of ultrasound guidance when inserting a chest drain for fluid removal to prevent injury to adjacent organs. Wherever possible, the drain should be inserted under direct ultrasound guidance, preferably in the radiology department. If not possible, portable ultrasound equipment must be used at the patient's bedside during insertion. Practitioners must be competent in the use of the equipment and should be supervised if not experienced.

Legal and professional issues

The current recommendations of the NPSA and BTS (Havelock et al. 2010, Laws et al. 2003, O'Driscoll et al. 2008) are that:

- chest drains are only inserted by staff with relevant competencies and adequate supervision
- ultrasound guidance is strongly advised when inserting a drain for fluid
- clinical guidelines are followed and staff made aware of the risks
- a lead is identified for training of all staff involved in chest drain insertion
- written evidence of consent is obtained from patients before the procedure, wherever possible
- local incident data relating to chest drains are reviewed and staff encouraged to report further incidents (NPSA 2008).

Figure 9.18 Mattress sutures.

Consent

Prior to commencing chest tube insertion, the procedure should be explained fully to the patient and consent recorded in accordance with national guidelines. The General Medical Council (GMC) guidelines for consent state that it is the responsibility of the doctor carrying out a procedure, or an appropriately trained individual with sufficient knowledge of a procedure, to explain its nature and the risks associated with it (Laws et al. 2003). Written evidence of consent is obtained from patients before the procedure, wherever possible, and documented in the patient's notes.

Competencies

456

The NPSA alert (2008) highlights the need for training for medical or nursing staff who insert chest drains. Nursing staff need to ensure they are familiar with chest drain management by attending training in their individual hospitals and keeping up to date with NPSA and MHRA alerts and national guidelines for chest drain management. Consultants and senior nursing staff are responsible for ensuring that the BTS guideline is implemented in their individual departments. It is the individual responsibility of all medical and nursing personnel to ensure that they work in line with BTS guidelines (O'Driscoll et al. 2008).

Pre-procedural considerations

Equipment

Drain size

The size of tube used is dependent on the reason for drainage. As no large randomized trials comparing small- and large-bore tubes have been performed, the optimum size of drainage catheter remains controversial (Laws et al. 2003, O'Driscoll et al. 2008).

In the past, the use of a large-bore drain (Figure 9.19) was recommended to prevent the blockage of chest drains, particularly by thick malignant or infected fluid (Hyde et al. 1997). However, currently the majority of physicians prefer to use smaller bore catheters (Figure 9.20) (10–14 French [Fr]) and some smaller studies have shown that these are often as effective as larger bore tubes (Clements et al. 1998, Patz 1998). Small-bore drains are more comfortable and better tolerated by the patient (Laws et al. 2003, O'Driscoll et al. 2008).

Drainage systems

Pre-packed drainage systems are now available for drainage of pneumothoraces, haemothoraces or pleural effusions. The bottle has a screwtop with two ports. One port has the underwater

Figure 9.19 Trocar drainage tube.

Figure 9.20 Seldinger drain.

length of tubing attached. The second port has a shorter length of tubing attached which acts as the venting end and is exposed to air or could be attached to a suction unit. Venting prevents the build-up of pressure in the chest drainage system, which in turn aids evacuation of air or fluid from the lungs (McMahon-Parkes 1997) (Figure 9.21).

The underwater seal occurs when there is adequate sterile water in the bottle, usually 500 mL. The distal end of the chest drain is then attached to the underwater seal port of the chest drain bottle and immersed 2.5 cm below the level of the water. Incoming air bubbles through the water, which acts as a one-way valve and prevents the backflow of air into the intrapleural space (McMahon-Parkes 1997).

For more complicated pneumothoraces or haemothoraces, a plastic multichamber system incorporates the one-bottle system into one unit. There are three chambers: the first is for drainage, the second chamber is the underwater seal and the third chamber is the vacuum or suction control. When this system is set up, water is placed in the water seal chamber to the indicated mark,

Figure 9.21 One-bottle system.

Figure 9.22 Underwater chest drainage system. (a) Venting/suction port. (b) Port to patient. (c) Water level.

and also placed in the suction control chamber to the required level (Pierce 1995) (Figure 9.22).

Assessment and recording tools

Some hospitals have chest drain-specific charts in order to document swinging or fluctuating, bubbling, draining and suction settings on a half-hourly or less frequent basis (Laws et al. 2003).

Pharmacological support

On insertion of a chest drain, tissue damage occurs and this activates nerve fibres surrounding the insertion site (Gray 2000, Hilton 2004). While the drain is in place, the nerve fibres or tissue cannot heal. Therefore, the patient will experience pain throughout the insertion procedure and after the drain has been inserted (O'Driscoll et al. 2008, Tomlinson and Treasure 1997). Inadequate pain control can cause the patient to breathe ineffectively and the patient may try to avoid coughing, resulting in complications such as chest infections (Gray 2000). Risk can be reduced by chest physiotherapy from a physiotherapist (Gray 2000). In a study by Luketich et al. (1998), 50% of patients experienced pain levels of 9–10 on a scale of 0–10, with 10 being most pain imaginable. Therefore, prior to inserting an intrapleural drain, unless contraindicated, premedication such as an opioid should be administered as prescribed (Laws et al. 2003, O'Driscoll et al. 2008). Benzodiazepines should only be administered if additional skilled staff are available to ensure proper airway control and vital signs monitoring (O'Driscoll et al. 2008). A comprehensive plan for pain control involving the patient and healthcare professionals should be produced. Pain

Figure 9.23 Triangle of safety. Source: Laws et al. (2003). Reproduced with permission from BMJ Publishing Group, Ltd.

management should cover all stages of the intrapleural drainage process (Gray 2000):

- insertion
- management of the chest drain during the drainage process
- removal of the chest drain.

Current protocols for the management of pain include patient-controlled analgesia, paravertebral blocks, non-steroidal anti-inflammatory drugs or transcutaneous electrical nerve stimulation (Allibone 2005).

Specific patient preparation

The patient's vital signs must be recorded prior to the procedure (Laws et al. 2003). Before insertion of a chest drain, the patient should have a chest X-ray reviewed by the practitioner. The chest X-ray will confirm the site of the pneumothorax or effusion to be drained.

Patients who are receiving anticoagulation therapy or who have platelet abnormalities should have appropriate haematological investigations (international normalized ratio [INR] or activated partial thromboplastin ratio [APTR]) to ascertain whether correction is required prior to insertion of the drain (Havelock et al. 2010, Tang et al. 2002). If the INR or APTR is too high, or platelets subnormal, bleeding could occur if left untreated.

Chest drains are usually inserted in an area which is known as the 'triangle of safety' (Figure 9.23). This is the triangle bordered by the anterior border of the latissimus dorsi, the lateral border of the pectoralis major muscle, a line superior to the horizontal level of the nipple, and an apex below the axilla (Laws et al. 2003, O'Driscoll et al. 2008). Once the drain has been placed in any position within the 'triangle of safety', re-expansion of the lung occurs. However, in cases of intrapleural adhesions or localized collection of pus or fluids, the practitioner will need to position the tip of the drain to assist drainage (Hyde et al. 1997, O'Driscoll et al. 2008, Tang et al. 2002).

Education

Nurses working with patients requiring chest drainage need to continually keep up to date with new guidelines related to chest drain management and ensure that junior staff are aware of updates and new techniques for insertion (Laws et al. 2003, O'Driscoll et al. 2008, NPSA 2008).

Procedure guideline 9.5 Chest drain: insertion

Essential equipment

- Sterile gloves and gown
- Sterile chest drain pack, containing gallipot, disposable towel, forceps
- Skin antiseptic solution, for example iodine or chlorhexidine gluconate 0.5% in 70% alcohol
- Sterile drapes
- Gauze swabs
- A selection of syringes (10 mL × 2) and needles (21–25 gauge)
- Scalpel and blade
- Suture (e.g. Mersilk 2.0)
- Instrument for blunt dissection (e.g. curved clamp)
- Guidewire with dilators in most Seldinger drain packs (see Figure 9.20)
- Chest tube, for example Seldinger drain or large-bore trocar chest drain (see Figure 9.19, Figure 9.20)

- Connecting tubing
- Closed drainage system (including sterile water 1 litre if underwater seal bottle is being used):
 - Chest drain bottle and tubing (see Figure 9.22)
 - Ambulatory chest drain bag with Heimlich flutter valve (Figure 9.24)
- Occlusive dressing
- Chest drain clamps × 2

Optional equipment

- Thoracic low vacuum suction pump if required (high-volume, low-pressure suction adaptor) (Figure 9.25)

Medicinal Products

- Local anaesthetic such as lidocaine 1% (up to 3 mg/kg) is usually infiltrated. Higher doses may result in toxic levels (Laws et al. 2003, O'Driscoll et al. 2008)

Pre-procedure

Action

- 1 Cleanse hands with alcohol handrub. Hands to be cleansed before and after each patient contact.
- 2 Explain and discuss the procedure with the patient. Ensure the operator has gained written consent if patient is conscious and able to do so.
- 3 Administer analgesia prior to procedure, after discussion with the prescriber about the type and route of administration. The analgesia should be given at least half an hour before the procedure.
- 4 Administer sedation on prescriber's instruction, only if considered appropriate, for example for an anxious patient; ensure staff skilled in airway management are available prior to administering benzodiazepines.
- 5 Cleanse hands with alcohol handrub.
- 6 Prepare trolley, placing equipment on bottom shelf. Take to patient's bedside.
- 7 Prime the underwater seal system with sufficient sterile water to cover the drainage tube. Cleanse hands with alcohol handrub.
- 8 Assist operator in setting up sterile procedure pack.
- 9 Check the correct side of chest for drain insertion on chest X-ray.
- 10 Position patient in preparation for the procedure. The patient may be positioned flat on the bed with the arm on the affected side placed behind their head away from the chest wall or abducted to 90°. If patient is able to sit upright, they can be positioned resting over a table supported by a pillow.

Rationale

- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To ensure the patient understands why and how the procedure is to be performed and gives their valid consent (O'Driscoll et al. 2008, **C**; Laws et al. 2003, **C**; NMC 2013, **C**).
- To minimize any pain during the procedure and to ensure the patient is pain free and able to co-operate (Laws et al. 2003, **C**).
- To relieve anxiety and allow the patient to relax and co-operate, and to enable the procedure to proceed. **E**
- To prevent loss of airway due to administration of sedation such as benzodiazepines and opiates which may cause respiratory depression (O'Driscoll et al. 2008, **C**).
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To ensure all equipment is available. **E**
- This prevents backflow of air or fluid into the pleural space, and marks the initial water level to allow measurement of subsequent drainage (Adam and Osborne 2005, **E**).
- To minimize risk of infection and to have equipment ready. **E**
- To ensure drainage of correct side by checking the chest X-ray (O'Connor and Morgan 2005, **E**).
- To facilitate insertion of the intrapleural drain. To aid patient comfort (Hyde et al. 1997, **E**).
- To prevent injury to adjacent organs (Laws et al. 2003, **C**).

Procedure

- 11 Observe the patient throughout procedure, with attention to respiratory status including colour, respiratory rate, respiratory pattern, equal movement of chest and peripheral tissue oxygen saturations.
Observe patient for any change to the cardiovascular system by alterations in heart rate or blood pressure.
- 12 Communicate with the patient during the procedure and explain what is happening at each stage.

- To look for any change in the patient's condition and report to the doctor, to ensure appropriate intervention, for example oxygen therapy (Laws et al. 2003, **C**).
- To look for any change in the patient's condition and report to the doctor, to ensure appropriate intervention (Allibone 2003, **E**).
- By communicating throughout, the patient feels involved and informed (Laws et al. 2003, **C**).

The following steps would be performed by the practitioner inserting the drain.

- | | |
|---|---|
| 13 The practitioner will wash their hands with an antiseptic detergent and apply sterile gloves and a gown. Strict aseptic technique is to be adhered to. | To minimize risk of infection (Fraise and Bradley 2009, E). |
| 14 The area for planned insertion of the drain will be cleaned with chlorhexidine gluconate 0.5% in alcohol and allowed to air dry. | To minimize risk of infection (Fraise and Bradley 2009, E). |
| 15 Local anaesthetic, e.g. lignocaine 1%, will be injected into the skin and deeper tissue (intercostal muscle and parietal pleura) along proposed insertion site. | To minimize the feeling of pain on drain insertion (Gray 2000, P). Lignocaine 1% is preferred to 2% as the volume given is considered to be more important than the dose to aid spread of effective anaesthetic area (Havelock et al. 2010, E). |
| 16 Wait 2–3 min for local anaesthetic to take effect. | To ensure local anaesthetic has been effective. E |
| 17 An incision is then made with a scalpel to enable the chest drain to be inserted. | To aid and ease the movement of the drain into the correct position. E |
| 18 For smaller bore drains, a dilator is passed gently over the guidewire using a slight twisting action (Havelock et al. 2010). For large-bore chest drains, a finger or Spencer Wells clamp may then be manoeuvred through to the parietal pleura to guide the drain into place, between the parietal and visceral pleurae in the pleural space (Miller and Harvey 1993). The dilator should not be inserted further than 1 cm beyond the depth of the skin to the pleural space. | To aid the drain into the correct position. E
Exploration with a finger is felt to be unnecessary for the elective medical insertion of medium or small-sized chest tubes and is only used for surgically or trauma inserted large-bore drains using blunt dissection (Laws et al. 2003, C).
Drains should never be inserted using substantial force (Havelock et al. 2010, C). If excessive force is used to dilate there is a risk of perforating a vital organ (Havelock et al. 2010, C). |
| 19 The drain is then clamped using two clamps, or three-way tap for Seldinger drains, until connected to the drainage system. | To prevent further lung collapse and entry of air (Laws et al. 2003, C). The three-way taps in kits for chest drains have a wider internal diameter to aid drainage of pleural fluid. E |
| 20 Connect the distal end of the drain to the drainage system and ensure that it is well supported and secured. | To allow for inflation of the lung or drainage of fluid, to ensure there is no movement of drain and that it remains in the correct position (Allibone 2003, E). |
| 21 The proximal end of the drain is secured and sutured in place with an anchoring suture and for a large-bore drain, a mattress suture should be inserted (Havelock et al. 2010). Unclamp chest drains. | To secure drain in position. Purse-string stitches should no longer be used as they cause pain and unsightly scarring (Laws et al. 2003, C). |
| 22 Clean the site and apply a dressing of gauze, then an occlusive dressing over the gauze. | To ensure site is well covered and sealed (Laws et al. 2003, C).
To reduce risk of infection (Fraise and Bradley 2009, E). |

Post-procedure

- | | |
|--|---|
| 23 Send patient for chest X-ray. | To ensure correct position of the drain and that the lung has reinflated (Havelock et al. 2010, C ; Laws et al. 2003, C). |
| 24 Check the drain is well secured. | To prevent movement or accidental disconnection of drain (Havelock et al. 2010, C ; Laws et al. 2003, C). |
| 25 Monitor if there is bubbling/swinging of water in the bottle/tubing or drainage fluid and check there are no leaks around the site or any loose connections within the drainage system. Bubbling is usually present with a pneumothorax, but should not be present with a pleural effusion. | To ensure there is no occlusion or leak which will prevent re-expansion of the lung or drainage of the fluid (Havelock et al. 2010, C ; Laws et al. 2003, C). Bubbling indicates an air leak either in the pleural space or with the drainage equipment and should be investigated if not expected (i.e. chest drain inserted for a pneumothorax) (Havelock et al. 2010, C). |
| 26 Record any bubbling, swinging and drainage on observation and fluid balance charts. | To keep an accurate record of type of drainage on fluid balance chart (Laws et al. 2003, C ; NMC 2010, C). |
| 27 Ensure patient comfort following the procedure. Return the patient to an elevated position sitting in bed, well supported by pillows, and give further analgesia if required. | To ensure patient comfort in order to aid recovery and breathing (Allibone 2003, E). |
| 28 Dispose of waste appropriately. | To reduce risk of sharps injury and cross-infection (DH 2005, C ; Fraise and Bradley 2009, E). |
| 29 Cleanse hands with alcohol handrub. | Hands to be cleansed before and after each patient contact (Fraise and Bradley 2009, E). |

Figure 9.24 Ambulatory chest drainage bag with Heimlich flutter valve. (a) Tube connection to patient. (b) Air vent (green). (c) 50 mL syringe filled with air.

Figure 9.25 High-volume, low-pressure suction unit (thoracic suction adaptor).

Figure 9.26 Chest drain on suction.

Procedure guideline 9.6 Chest drainage: suction*Essential equipment*

- Thoracic high-volume and low-pressure suction unit (different to normal wall suction units on wards) (see Figure 9.25)
- 1–2 metres of suction tubing
- Suction canister with filter (Figure 9.26)

Pre-procedure

Action	Rationale
1 Cleanse hands with alcohol handrub.	To minimize the risk of infection (Fraise and Bradley 2009, E).
2 Explain the procedure to the patient and communicate with the patient during the application of suction and explain what is happening at each stage.	To keep the patient fully informed. To enable the patient to feel reassured (Laws et al. 2003, C).
3 Discuss analgesia management with the patient. Give analgesia to the patient as prescribed.	To ensure patient comfort (Gray 2000, P).

Procedure

4 Prepare the suction unit, which should be thoracic low-volume suction (bedside suction units are high volume and therefore not suitable), for use with single chamber underwater seal drain bottles and check equipment is working properly and suction can be maintained to the medical team's prescribed pressure.	To maintain safety, ensuring the suction is set at low pressure (Laws et al. 2003, C).
5 Ensure suction equipment tubing is connected firstly to an intermediate 'vac sac' suction canister and then further tubing connected to underwater drain bottle suction port.	This is to prevent any bubbles or froth entering the thoracic suction equipment filter, which would wet the filter and block the suction equipment. This would cause a blocked drain and is the equivalent of clamping a bubbling drain and could lead to a tension pneumothorax (MHRA 2010, C).
6 Connect venting or suction port (see Figure 9.26) to the suction unit, as directed by the medical team. Adjust the suction to required level prescribed, usually 1–2 kPa or 10–20 cmH ₂ O (Adam and Osborne 2005, Havelock et al. 2010) or to a level that is tolerable for the patient.	To ensure patient comfort and to ensure suction is applied. E Higher volumes of suction may injure lung tissue (Kirkwood 2002, E). Patients experience pain if suction levels are too high, therefore suction should be reduced gradually to a level that the patient can tolerate (Havelock et al. 2010, C).
7 Position patient to aid comfort, ensuring the patient is pain free and relaxed.	To aid breathing for lung expansion. To aid patient comfort (Gray 2000, E).
8 Monitor chest drainage and record amount.	To maintain patient safety by observing level of suction and amount of fluid drained (Allibone 2003, E).
9 Ask patient to inform staff if they need to mobilize and ensure suction is disconnected from patient and reconnected when patient is back in bed.	To prevent pneumothorax, as air cannot escape from the bottle. E

Procedure guideline 9.7 Chest drain: priming ambulatory chest drain bag*Essential equipment*

- Ambulatory chest drainage bag
- 50 mL syringe

Procedure

Action	Rationale
1 To prime the bag, use the 50 mL syringe to inject air through the drainage tube by inserting the syringe nozzle into the drainage tube (see Figure 9.24).	The ambulatory bag <i>must</i> be primed prior to use to ensure that the Heimlich flutter valve is working (Choi et al. 2007, E).
2 Air will pass through the flutter valve which can be confirmed visually by observing the valve 'leaves' open when air moves through and then close spontaneously and the bag inflating slightly.	To ensure that the Heimlich flutter valve is working. It acts as a one-way valve preventing air from entering the chest cavity when the drain is emptied (Graham et al. 1992, R1).

Procedure guideline 9.8 Chest drain: changing the bottle*Essential equipment*

- Cleaning solution, for example chlorhexidine in 70% alcohol
- Non-sterile gloves
- Tape
- Sterile chest drain bottle
- 1 litre sterile water bottle
- Chest drain non-toothed clamps × 2
- Procedure pack

*Pre-procedure***Action****Rationale**

- 1 Cleanse hands with alcohol handrub.

Hands to be cleansed before and after each patient contact (Fraise and Bradley 2009, **C**).

- 2 Explain and discuss the procedure with the patient.

To ensure the patient is well prepared, and to ensure their co-operation and consent (Laws et al. 2003, **C**; NMC 2013, **C**).

- 3 Cleanse hands with alcohol rub and fill new chest drain bottle to water fill line or until drainage tube is submerged in water.

To prevent infection and to prevent reflux of air or fluid into the lungs, and to create a water seal (Kirkwood 2002, **E**).

Procedure

- 4 Undo the taping around the tubing which secures chest drain to chest drain bottle tubing.

In order to disconnect the chest drain tube from the chest drain bottle tube (Kirkwood 2002, **E**).

- 5 Clamp the tubing close to the chest wall with two clamps for the shortest time needed to change the bottles.

To prevent air entering the chest cavity and causing a pneumothorax (Laws et al. 2003, **C**). Clamping the drain for long periods of time may increase the risk of pneumothorax (Laws et al. 2003, **C**).

- 6 Observe patient's breathing and respiratory status during the procedure.

To identify any respiratory deterioration early and report any abnormalities to medical team (Allibone 2005, **E**).

- 7 Clean tubing at the connection and remove full bottle and tubing and connect new bottle and tubing to clamped chest tube.

To prevent infection entering system during disconnection and connection of tubing (Fraise and Bradley 2009, **E**).

- 8 Ensure a secure connection, unclamp and tape using H-shaped securing tape (Figure 9.27).

To prevent bottle from falling over or disconnection causing air to re-enter the pleural cavity (Allibone 2005, **E**).

- 9 Ensure drain bottle is secure by attaching it to bed or put on a stand on the floor.

To prevent it being knocked over. **E**

- 10 Cleanse hands with alcohol handrub.

Hands to be cleansed before and after each patient contact (Fraise and Bradley 2009, **E**).

- 11 Document new bottle on fluid balance chart and in nursing documentation.

To keep accurate record of amounts drained (Allibone 2005, **E**; Laws et al. 2003, **C**; NMC 2010, **C**).

- 12 Observe patient for any changes in respiratory status as per previous instructions.

To identify any respiratory deterioration early and report any abnormalities to the medical team (Allibone 2005, **E**).

Figure 9.27 H-shaped securing tape.

Procedure guideline 9.9 Chest drain: removal

Two nurses/assistants are required to facilitate safe removal of a chest drain. One is required to tie the suture and seal the site, and the other to remove the drain.

Essential equipment

- Sterile dressings pack containing gallipot, gauze, sterile towel
- Cleaning solution, for example 0.9% sodium chloride
- Non-sterile gloves
- Stitch cutter
- Sterile occlusive dressing, e.g. paraffin gauze
- Tape

Pre-procedure

Action	Rationale
1 Cleanse hands with alcohol handrub.	Hands to be cleansed before and after each patient contact (Fraise and Bradley 2009, E).
2 Prepare patient for removal of the drain. Explain and discuss each step of the procedure with the patient.	To ensure the patient is well prepared, and to ensure their co-operation and consent (Laws et al. 2003, C ; NMC 2013, C).
3 Encourage patient to practise breathing exercises, as these are required to help with the procedure. The patient should be instructed to take two deep breaths in and out and on the third breath to hold the breath in and perform the Valsalva manoeuvre. It is on this breath that the drain will be removed, that is, at the end of inspiration (Adam and Osborne 2005).	To prepare the patient and encourage co-operation. E To allow the patient to practise the breathing exercises. E To prevent the entry of air that can occur due to a negative intrathoracic pressure (Allibone 2005, E ; Tomlinson and Treasure 1997, E).
4 In order to reduce the complication of recurrent pneumothorax, the Valsalva manoeuvre can be used. This requires patients to hold their breath and to bear down or try to breathe out against a closed glottis (Allibone 2005).	This increases the intrathoracic pressure, which reduces the possibility of air re-entering the pleural space through the drain site (Allibone 2005, E ; Laws et al. 2003, C ; Havelock et al. 2010, C).
5 Administer analgesia prior to procedure after discussion with prescriber about the type and route of administration. The analgesia should be given at least half an hour before the procedure.	To minimize any pain during the procedure and to ensure the patient is pain free and able to co-operate (Gray 2000, P ; Havelock et al. 2010, C).
6 Discontinue suction if in use and disconnect from venting/suction port.	To prevent a tension pneumothorax (Laws et al. 2003, C).
7 Cleanse hands with alcohol handrub.	Hands need to be cleansed before and after each patient contact (Fraise and Bradley 2009, E).
8 Prepare trolley for procedure.	To ensure everything is ready to perform the procedure. E
9 Assist or set up the sterile procedure pack, and apply apron.	To minimize risk of infection and to have equipment ready (Fraise and Bradley 2009, E).

Procedure

10 Position patient comfortably.	To aid patient comfort. E
11 Clamping of chest drain prior to removal is not necessary.	Unnecessary clamping increases risk of pneumothorax (Adam and Osborne 2005; Havelock et al. 2010, C ; Laws et al. 2003 C).
12 Place protective pad underneath the patient and drain.	To absorb any ooze from the drain. To reduce risk of contamination of the patient and bed clothing. E
13 Cleanse hands with alcohol handrub before touching the drain or dressing.	To reduce risk of infection (Fraise and Bradley 2009, E).
14 Remove dressing from around drain site, examine sutures present: (a) tube retaining suture (anchor suture) and (b) mattress suture; expose the ends of these sutures.	To prepare for drain removal and check what type of suture is present so that the suture can be used to form an airtight seal when the drain is removed (Adam and Osborne 2005, E).
15 Both assistants for the procedure must wash their hands with an antiseptic solution, and apply gloves.	To reduce risk of infection (Fraise and Bradley 2009, E).
16 First nurse/assistant prepares mattress suture and loosens ends ready to tie the suture when the drain is removed.	To prepare for drain removal. E
17 Second nurse/assistant prepares and cuts the anchor suture and ensures the drain is mobile and ready to remove.	To prepare for drain removal. E

(continued)

Procedure guideline 9.9 Chest drain: removal (continued)

Action	Rationale
18 Second nurse/assistant asks the patient to start deep breathing exercises: to take three deep breaths then hold their breath on the third one and bear down (Valsalva manoeuvre) while the drain is pulled out steadily and smoothly.	To aid in drain removal. Deep breathing exercises can help to prevent a tension pneumothorax. During full inspiration and Valsalva manoeuvre, the intrathoracic pressure is increased, thus preventing air flowing into the intrathoracic cavity. If a drain is removed too quickly or without due care, a pneumothorax can occur due to rupture of the pleura (Havelock et al. 2010, C ; Laws et al. 2003, C).
19 First nurse/assistant will then tie the mattress suture securely to the skin.	To form an airtight seal and prevent air entry and formation of a pneumothorax (Havelock et al. 2010, C ; Laws et al. 2003, C).
Post-procedure	
20 Ask the patient to breathe normally after tube is removed.	To assess if there is any air escaping from suture site. E
21 Clean around site with 0.9% sodium chloride and apply an occlusive dressing, such as gauze soaked in flexible collodion or petroleum gauze under waterproof strapping.	To clean site, form an airtight seal and prevent air entry. E To prevent an air leak if drain puncture site is not closed properly (Adam and Osborne 2005, E).
22 Ensure that the patient is sitting upright, and support with pillows.	To ensure patient comfort and aid respiration (Allibone 2005, E).
23 Dispose of waste appropriately.	To ensure safety and reduce risk of infection (DH 2005, C ; Fraise and Bradley 2009, E).
24 Document removal on fluid chart and in nursing notes.	To provide a point of reference for any queries (NMC 2010, C).
25 A chest X-ray should be performed approximately 2 hours post removal unless acute deterioration.	To check that a pneumothorax has not recurred (O'Connor and Morgan 2005, R5).
26 Both the patient and the drain site should be monitored closely (Allibone 2005). Inform doctor of any changes in patient's breathing, tachycardia or other vital signs.	To observe for signs of respiratory distress secondary to reaccumulation of fluid/air in pleural cavity (Allibone 2005, E ; Havelock et al. 2010, C).
27 Record vital signs on observation charts including respiration rate and oxygen saturation levels.	An increased respiration rate or increase in oxygen requirements or drop in saturation may indicate a problem with the chest drainage system (Havelock et al. 2010, C).
28 Cleanse hands with alcohol handrub.	Hands need to be cleansed before and after each patient contact (Fraise and Bradley 2009, E).

Problem-solving table 9.5 Prevention and resolution (Procedure guidelines 9.5, 9.6, 9.7, 9.8 and 9.9)

Problem	Cause	Prevention	Suggested action
Lack of drainage.	Kinking, looping or pressure on the tubing may cause reflux of fluid into the intrapleural space or may impede drainage, causing blocking of the intrapleural drain.	Ensure tubing is tailored for patient. If patient is able to, involve them in the care of the drain, such as ensuring tubing is not kinked when sitting out in the chair or moving in the bed.	Check the system and straighten tubing as required. Secure the tubing to prevent a recurrence of the problem.
Fluid in drain not swinging.	Drain occluded due to position or occlusion.	Ensure drain is secured and regularly check site for kinking of tubing.	Check no loops or kinks present in tubing. Lift drain, not higher than the patient's chest, to see if the obstruction will clear. Seek medical advice as the drain may need replacing.
Fluid in drain not bubbling as expected to.	Drain occluded or not correctly positioned.	Check tubing regularly.	Check no loops or kinks in the tubing. Lift tubing to see if it will clear.
Continuous bubbling in chest drain bottle.	Air leak in system.	Check bottle for bubbling and swinging and check integrity of bottle regularly. Ensure all connections are secure.	Check system for loose connections in tubing or around drainage unit. If no leak present in the drainage tubing, the leak may be present in the lung. Inform doctor. Prepare chest drain insertion pack.

Problem	Cause	Prevention	Suggested action
Leakage from drain site.	Bleeding or infection.	Check site regularly during the day.	Remove the dressing and observe the site. Inform doctor, take swab. Clean and redress site. Discuss with medical team regarding prescription of antibiotic therapy.
Drainage from around drain site.	As a result of the insertion procedure. Incomplete closure with sutures. Infected insertion site.	Ensure aseptic technique when dealing with wound. Keep wound clean and dry, check puncture site regularly.	Observe drain site, amount and type of drainage. Inform doctor. Take swab from site. Prepare suture pack to be available if required. Discuss with medical team regarding prescription of antibiotic therapy.
Accidental disconnection of the drainage tubing from the intrapleural drain.	Connections not secure.	Tape the connections together by using 'H' dressing which allows nurse to visualize connection site.	Apply a clamp to the drain immediately in order to avoid air entering the pleural space. Re-establish the connection as soon as possible in order to re-establish drainage. Ask patient to cough gently to aid air removal. If necessary, use a clean, sterile drainage tube; tubing may have been contaminated when it became disconnected. Report to the doctor, who may wish to X-ray. Record the incident in the relevant records. The patient may have been upset by the incident and will need reassurance.
Intrapleural drain falls out.	Drain not secure.	Check suture site and dressings daily, ensure anchor stitch is still intact. Apply omental tag dressing to prevent accidental fall-out.	Pull the mattress suture immediately to close the wound. Cover the wound with an occlusive sterile dressing. Check the patient's vital signs. Inform a doctor. The objective is to minimize the amount of air entering the pleural space. The drain will probably need reinserting. Prepare chest drain insertion pack. Reassure the patient with appropriate explanations.
Poor arm movement.	Restriction of arm movement due to position of drain.	Explain the need for arm exercises and involve physiotherapy team in mobilizing.	Encourage movement of limb to keep mobile. Adjust analgesia as required.
Pain.	Drain pulling at site.	Use omental tag and other dressings to ensure drain does not pull at site.	Try repositioning tubing, so that it is not dragging or irritating skin. Give analgesia as prescribed.
Restricted mobility of patient.	Due to position of drain and attachment to the drainage unit. Due to pain at site of insertion.	Work in liaison with physiotherapist. Encourage patient to move in bed and change position.	Explore with the patient the movement that is possible and aid them where help is required. Offer patient regular analgesia as prescribed and record pain score. Encourage mobility, aid patient to sit in chair.

Post-procedural considerations

Immediate care

The nurse should check the patient's vital signs including respiratory rate, temperature, oxygen saturation, heart rate, blood pressure and, if appropriate, arterial blood gases and pain score (NICE 2007). The nurse should observe the patient closely for changes in breathing rate or pattern or drop in blood pressure if a large pleural effusion has been drained, as it might drain quite quickly and could cause a significant drop in blood pressure (O'Driscoll et al. 2008). The drains and connections should be checked to ensure that they are secure and the drain tubing is

not kinked. The bottle should always be below the chest drain entry site and monitored for bubbling in the case of a pneumothorax (which indicates air still present in the pleura) and swinging (which indicates the drain is patent). If the patient has a pleural effusion, the amount of fluid drained should be monitored and should be no more than 1500 mL/h at a time, as it may induce re-expansion pulmonary oedema (O'Driscoll et al. 2008). The rate of drainage should be slowed down if the patient experiences pain, starts coughing or if their blood pressure drops, by clamping the drain intermittently (Laws et al. 2003, O'Driscoll et al. 2008). The drain should be unclamped if the patient becomes short of breath or experiences dyspnoea, and the doctors and critical care

outreach team should be informed of any changes in the patient's condition. A bubbling drain should never be clamped (Laws et al. 2003), even for a transfer, and the nurse must be satisfied that the patient is safe for transfer to the X-ray department with the chest drain placed below the chest insertion site (Havelock et al. 2010, Laws et al. 2003).

Securing the drain

The British Thoracic Society (Havelock et al. 2010, Laws et al. 2003) advises that purse-string stitches should not be used as they cause pain by changing a linear wound into a circular one and leave an unsightly scar. Only large- and medium-bore drains require suturing; small-gauge chest tubes do not usually require suturing other than an anchoring suture to prevent the drain falling out. The suture material should be strong and non-absorbable to prevent breaking, such as silk (Havelock et al. 2010, Laws et al. 2003). Ensure the drain is secured to the skin to prevent pulling out of sutures with an appropriate self-adhesive securement device such as a Statlock (Moureau and Iannucci 2003) or omental tag (Havelock et al. 2010, Laws et al. 2003).

Dressing the insertion site

A simple dry dressing (low-linting gauze) should be applied around the drain and secured with adhesive tape during drainage and after removal of drain (Tang et al. 2002). Heavy strapping should be avoided as it can restrict chest movement. Dressings during the drainage procedure should be kept clean and dry and not removed until the drain is ready for removal (Havelock et al. 2010, Laws et al. 2003).

Ongoing care

Maintenance of drainage systems

When the drain is attached to the drainage bottle bubbling or swinging should be observed; this indicates that air is being evacuated from the pleural space. As the lung reinflates, the bubbling should decrease. If bubbling continues, a leak may be present in the patient's lung. Causes of air leaks include:

- air in chest from a pneumothorax
- an eyelet from chest tube outside the chest wall
- blocked drain may cause an air leak at puncture site
- inadequate drain size
- poor tube connections
- poor seal around the entry site to the lung (Kirkwood 2002).

The presence of an air leak should be assessed. Bubbling can occur in the underwater seal compartment. If bubbling occurs when the patient coughs, this would usually indicate that the leak is only minor. However, continuous bubbling would indicate a serious air leak in the system. The drain and tube should be inspected thoroughly down to the level of the underwater seal to eliminate any external problems such as loose tubing connections or poor seal around the drain at the insertion site. A chest X-ray should also be ordered to establish the position of the drain. Air leaks should be treated with caution and prompt action is required (such as referral to a specialist respiratory physician).

Tubing should be tailored to suit the patient's needs, allowing room to manoeuvre but preventing coiling and looping (Avery 2000, Hyde et al. 1997, Kirkwood 2002, O'Driscoll et al. 2008). Loops, coiling and kinks in the tubing can cause build-up of the pleural effusion, impaired gas exchange and infection as well as impeding drainage (Kirkwood 2002, O'Driscoll et al. 2008) so regular inspection of tubing should be carried out.

There is debate about recommendations on taping the connection between the chest drainage bottle and drainage tubes (Avery 2000, Godden and Hiley 1998), as the nurse may not be able to see if the connections have parted beneath the tape (Adam and Osborne 2005); however, without any additional method of security, such

as tape, there is a risk of the drainage tubing becoming disconnected (Allibone 2005, O'Driscoll et al. 2008). Using an 'H'-shaped securing tape either side of the joined tubing connections is often undertaken in clinical practice (see Figure 9.27).

An omental tag of tape can be used which allows the tube to lie a little away from the chest wall to prevent tube kinking and tension at the insertion site (Havelock et al. 2010, Laws et al. 2003).

Report any pyrexia and monitor site for signs of infection. Continue with monitoring of vital signs, drainage type and amount. Offer patient regular analgesia as prescribed and keep accurate pain score documentation.

Suction and its use

The addition of suction to the drainage system increases the negative pressure, enhancing lung re-expansion. A high-volume, low-pressure suction unit should be applied to a single chamber chest drain bottle (Havelock et al. 2010, Hyde et al. 1997, Tang et al. 2002), using pressure in the range of 10–20 cmH₂O (1–2 kPa). The suction pressure should only be increased if the patient's pain is controlled and if the patient tolerates the increase.

Once suction has been discontinued, the tubing to the underwater seal should be disconnected from the venting port, otherwise this could cause positive pressure and may precipitate a tension pneumothorax (Havelock et al. 2010, Tang et al. 2002). The suction unit should be cleaned by wiping it with a damp cloth and a mild disinfectant solution. Most suction units are fitted with a disposable air filter capsule, between the vacuum connector and the filter capsule mount. The filter prevents cross-infection and should be changed after each patient. Direct connection between the chest drain bottle and the wall-mounted, high-flow, low-vacuum regulator without an intermediate jar or canister can lead to patient injury, loss of effective suction and contamination of the hospital vacuum system and infection hazard. Therefore an intermediate canister must be attached between the suction unit and chest drain bottle to prevent froth entering the filter of the suction system (MHRA 2010) (see Figure 9.26). Ambulatory chest drainage bags cannot be attached to suction. Advanced multichamber chest drain bottles have built-in suction control and require high-flow suction adaptors to facilitate suction levels. Manufacturer's instructions must be followed.

Stripping/milking of chest drains

Milking and stripping of chest tubes to keep tubing patent increases the negative pressure in the intrathoracic cavity to –100 to –400 cmH₂O and so milking or stripping of chest tubes on a routine basis should be avoided as it may harm the tissue in the intrathoracic cavity (Kirkwood 2002). If a chest drain becomes occluded or blocked, the tubing needs to be replaced rather than milking or stripping (Avery 2000).

Clamping of chest drains

The British Thoracic Society guidelines (Havelock et al. 2010, Laws et al. 2003, Miller and Harvey 1993) discourage clamping of chest drains as this can prevent air leaving the pleural space. This in turn can cause a pneumothorax which could progress to a life-threatening tension pneumothorax. A bubbling chest drain should never be clamped. There is also no need to clamp tubing when mobilizing or transporting patients to other departments as this may also cause a tension pneumothorax (Havelock et al. 2010, Henry et al. 2003, Hyde et al. 1997). When changing the bottle system, it is necessary to clamp the drain for the shortest period of time possible and, during this process, the patient should be under close observation for any signs of deterioration in breathing (Brandt et al. 1994).

In cases of pneumothorax, the chest drain, which usually shows bubbling in the chest drain bottle, should not be clamped at the time of its removal (Laws et al. 2003). The only time a bubbling chest drain should be momentarily clamped is in the event of disconnection, if there is damage to the drainage bottle, to locate a leak in the drainage system or to control the amount

of drainage for a pleural effusion (Allibone 2005, Avery 2000, Henry et al. 2003, Laws et al. 2003). A clamped drain to control drainage of pleural fluid should be closely supervised by nursing staff who are familiar with the management of chest drains and nurses should unclamp the chest drain and escalate to a doctor or senior nursing staff immediately in the event of any clinical deterioration (Havelock et al. 2010). Drainage of a large pleural effusion should be controlled by clamping the drain to prevent the potential complication of re-expansion pulmonary oedema. A maximum of 1500 mL should be drained in the first hour after insertion of the drain. Subsequent drainage should be managed by intermittent clamping depending on the patient developing symptoms of cough or chest discomfort (Havelock et al. 2010).

Chest drain removal

If a patient has had a pneumothorax, the chest drain should not be clamped at the time of its removal (Havelock et al. 2010, Laws et al. 2003). In a study comparing removal in inspiration or expiration with a Valsalva manoeuvre, there was no difference in the immediate or short-term rate of pneumothorax (Bell et al. 2001).

The chest drain should be removed with a brisk firm movement while an assistant ties the mattress suture to close the wound (Havelock et al. 2010, Laws et al. 2003). The Valsalva manoeuvre (asking the patient to hold their breath while trying to exhale against a closed glottis, or bear down) increases the intrathoracic pressure which prevents air from entering the thoracic cavity on removal of the drain (Avery 2000, Havelock et al. 2010, McMahon-Parkes 1997).

The decision to remove a drain is usually made by a medical practitioner based on the following criteria.

- Absence of an air leak into the chest drain bottle, usually noted when the patient exhales forcibly or coughs. When a patient is ventilated with positive pressure this will coincide with the expiration.
- Re-expansion of lung following previous discontinuation of any suction when there should be no air leak or drainage.
- The volume of fluid draining into the chest drain is minimal. Guidelines on what is minimal vary but less than 200 mL/day (Havelock et al. 2010).
- There is no evidence of respiratory compromise or failure.
- There is no coagulation deficit or increased risk of bleeding (check latest coagulation results prior to removal).
- In many cases radiological evidence of the absence of air or fluid accumulation will be required before removal.

Documentation

Document clearly in the patient's notes and keep an accurate record of type and amount of drainage on relevant nursing observation or fluid balance charts. Document whether the drain is swinging or bubbling or draining and if suction is used and the level of suction used. Document if the drain is clamped to manage the amount of fluid drained for pleural effusion and ensure vital signs are documented at the same time as clamping to ensure early management of any problems. Record vital signs and pain score half hourly directly post insertion for 2 hours, then progress to 2 hourly for another 2 hours then daily continue at least 4 hourly vital signs and pain monitoring.

Education of patient and relevant others

If the patient is able to, encourage them to take care that the chest drain bottle does not fall over and the tubing is not kinked or pulling (Havelock et al. 2010). Also teach the patient to ensure that the drain is not lifted above the insertion site and to continue to mobilize if possible; suggest mobility exercises to prevent sore and stiff shoulders. If the patient is not able to assist then ensure that nursing staff continue frequent monitoring of drain and tubing and insertion site and assist the patient in arm movements.

Complications

- Incorrect placement (extrapleural, intrapulmonary, subdiaphragmatic) or drain dislodgement.
- Puncturing of adjacent organs: lung, stomach, spleen, liver, heart and great vessels.
- Pulmonary laceration (haemorrhage, fistula).
- Pneumothorax.
- Bleeding from:
 - local incision, intercostal vessels
 - lung
 - internal mammary artery (with anterior placement)
 - great vessels (rare).
- Infection: empyema.
- Mechanical (kinking, luminal obstruction) which may cause a pneumothorax.
- Surgical emphysema.
- Re-expansion pulmonary oedema, if large amounts of fluid are drained from a pleural effusion over a short period of time (Havelock et al. 2010, Laws et al. 2003).

467

Tracheostomy and laryngectomy care

Definition

A tracheostomy is the surgical creation of an opening (stoma) in the anterior wall of the trachea to facilitate ventilation; this opening is usually maintained by the use of a tracheostomy tube (Figure 9.28a). The opening is commonly made at the level of the second or third cartilaginous ring (McGrath et al. 2012). When a total laryngectomy (the surgical removal of the larynx) is performed, a permanent stoma is formed by stitching the end of the trachea to the skin of the neck (McGrath et al. 2012).

Anatomy and physiology

Figure 9.28a shows the anatomy of the neck. The larynx, situated at the top of the trachea, houses the vocal cords and is the point of transition between the upper and lower airways (Epstein 2009). It is made up of nine cartilage segments, the largest of which is called the thyroid cartilage. Inferior to this is the cricoid cartilage which attaches to the large cylindrical tube/elastic structure known as the trachea. This is usually approximately 11 cm long and is made up of rigid cartilage anteriorly and a posterior membranous portion (Epstein 2009). The trachea then divides at the carina to form the right and left mainstem bronchi of the lungs.

Related theory

The exact location of the stoma will be determined on an individual basis according to the patient's neck and rationale for tracheostomy. Low stomas (i.e. beyond the third tracheal ring) increase the risk of bleeding from the brachiocephalic trunk, and a tracheostomy that is too close to the cricoid has an increased risk of subglottic stenosis, a condition that is difficult to treat (De Leyn et al. 2007).

Evidence-based approaches

Rationale

Indications for a tracheostomy

- The patient has an obstructed upper airway, for example by a foreign object or oedema of the soft tissues.
- The patient is likely to need prolonged artificial ventilation – the tracheostomy reduces the risk of tissue damage and work of breathing by shortening the dead space, therefore promoting the weaning process from artificial ventilation.

Figure 9.28 (a) Anatomy of the head and neck. (b) Temporary tracheostomy. (c) Permanent tracheostomy.

- The patient is unable to independently maintain their airway, i.e. those with reduced consciousness levels may be unable to maintain a patent airway or protect from aspiration.
- The patient's bronchial secretions cannot be cleared due to poor cough effort and the patient is therefore at risk of aspiration.
- The patient is undergoing upper airway surgery.
- The patient has undergone a laryngectomy – the stoma will be permanent (McGrath et al. 2012).

Contraindications

The only absolute contraindications for tracheostomy are severe localized sepsis/skin infection, uncontrollable coagulopathy (ICS 2008) or prior major neck surgery which completely obscures the anatomy (De Leyn et al. 2007).

Types of tracheostomy

A *temporary tracheostomy* usually refers to a stoma formed as an elective procedure at the time of major surgery (such as a total glossectomy) (Prior and Russell 2004) (see Figure 9.28b), although percutaneous techniques, performed by the bedside in intensive care units, are becoming commonplace (ICS 2008).

A *permanent tracheostomy* is the creation of a tracheostomy usually following a total laryngectomy (Prior and Russell 2004) (see Figure 9.28c). The larynx is removed and the trachea is sutured in position to form a permanent stoma, known as a laryngectomy stoma (Clotworthy 2006a). The patient will breathe through this stoma for the remainder of their life. As a result, there is no connection between the nasal passages and the trachea (Edgton-Winn and Wright 2005).

Percutaneous tracheostomy

The percutaneous method most commonly used is known as percutaneous dilational tracheostomy (PDT) (De Leyn et al. 2007), enabling the pretracheal tissues to be incised under local anaesthesia. A sheath is inserted into the trachea between the cricoid and the first tracheal ring or between the first and second rings. The trachea is progressively dilated with a series of conical dilators, which are slipped over a guidewire, ready for a tracheostomy tube to be inserted. Now frequently performed in the critical care setting as an early intervention post initiation of mechanical ventilation, the procedure takes less time and requires fewer resources, such as theatres and surgeons, resulting in fewer costs, than a surgical tracheostomy (Patel and Matta 2004). Another potential benefit of percutaneous tracheostomy is more rapid stomal closure and smaller scar formation once the tracheostomy tube has been removed (Patel and Matta 2004).

Surgical tracheostomy

Elective surgical tracheostomy is ideally performed in the operating theatre under general anaesthetic, although it can be performed under local anaesthetic (De Leyn et al. 2007). A horizontal incision is made halfway between the sternal notch and the cricoid cartilage (Price 2004). The strap muscles are divided and the thyroid isthmus is retracted/divided, enabling the trachea to be exposed and the tracheal cartilages to be counted. The tracheostomy should be sited over the second and third or third and fourth tracheal cartilages (Price 2004).

Legal and professional issues

Competencies

The most common problems associated with tracheostomy, in both general wards and critical care, are related to obstruction or displacement (ICS 2008). All hospitals or community settings should have a procedure for managing such situations and all staff involved in the care of the patient must be both aware of the procedure and appropriately trained in either managing the situation or supporting additional staff. At all times, if there is any doubt about the appropriate care that needs to be given, or the management of a situation, call for more senior or emergency help, according to local policy, as soon as possible.

Having emergency equipment readily available is paramount at all times for all types of altered airways (see 'Pre-procedural considerations' for equipment required). All staff caring for the patient should also know the type of tube in place at any one time; this and details of all care provided should be clearly documented.

Managing difficult situations with a tracheostomy is stressful for both the patient and staff, so prevention is always better than cure. All procedures should be undertaken only after approved training, supervised practice and competency assessment, and carried out in accordance with local policies and protocols.

Risk management

The standards within each hospital should be based upon evidence and recommendations from the following sources.

- Intensive Care Society
- St George's Hospital Tracheostomy Guidelines
- National Tracheostomy Safety Project
- Difficult Airway Society
- Fourth National Audit Project (NAP 4)

Pre-procedural considerations

Equipment

The following should always be at the bedside, during transfers or accessible if the patient is self-caring or ambulant.

- Operational oxygen with tracheostomy mask and non-rebreathe mask available.
- Operational suction, checked each shift, with a selection of suction catheters present, including Yankauer suction catheters.
- Sterile water (Serra 2000) can be used to help clear suction tubing of secretions after suctioning has been performed.
- Non-powdered latex-free gloves, aprons and eye protection (Day et al. 2002).
- Two spare cuffed tracheostomy tubes, one the same size as the patient is wearing, the other a size smaller, in case of an emergency tracheostomy tube change (Serra 2000, Tamburri 2000).
- One 10 mL syringe to inflate cuff.
- Tracheal dilators (ICS 2008) (Figure 9.29).
- Spare soft neck ties or tape.
- Suture cutter and lubricating gel.
- Cuff pressure manometer (Serra 2000) (Figure 9.30).
- Readily available resuscitation equipment (ICS 2008) including bag valve mask.
- Tracheostomy tube holder and dressing.
- Catheter mount and tracheostomy disconnection wedge.

It can be useful to have the above equipment in a small 'tracheostomy box' that can remain by the patient's bedside or move with the patient during transfer.

When caring for the patient who has undergone a total laryngectomy, the equipment listed above should always be by the bedside, and in addition the following equipment is recommended.

- Tilley's forceps: these are angled forceps that can be used to remove crusts or plugs of mucus from in and around the stoma.
- Pen torch (or access to a light source).
- Micropore or Elastoplast tape for those patients with a tracheo-oesophageal puncture, to ensure that the catheter keeping the puncture patent is secured firmly with tape or a suture.

Similar to the 'tracheostomy box', it may be useful to have a 'laryngectomy box' readily available by the bedside and for transfers.

Figure 9.29 Tracheal dilator.

Figure 9.30 Cuff pressure manometer.

Tracheostomy tubes

Tracheostomy tubes are made of either metal or plastic, and therefore vary considerably in rigidity, durability and kink resistance (ICS 2008). Most tubes manufactured now are dual-cannula tracheostomies and are inherently safer and most commonly preferred, particularly for use in acute settings. The outer tube maintains the patency of the airway while the inner tube, which fits snugly inside the outer tube, can be removed for cleaning without disturbing the stoma site. The major advantage of an inner cannula is that it allows immediate relief of life-threatening airway obstruction in the event of blockage of a tracheostomy tube with clots or tenacious secretions. Disposable inner tubes are now available; these single-use items are quicker to use (McGrath et al. 2012) and minimize cross-infection as no cleaning is required.

The majority of tracheostomy tubes are manufactured from plastics of varying types, some of which become softer at body temperature (e.g. polyvinyl chloride construction). Some also have a high-volume, low-pressure cuff which distributes the pressure evenly on the tracheal wall and aims to minimize the risk of tracheal ulceration, necrosis and/or stenosis at the cuff site (ICS 2008, Russell 2004). The cuff when inflated provides a seal between the tube and tracheal wall, enabling effective ventilation and protection of the lower respiratory tract against aspiration (Russell 2004).

Most tubes are sized according to their internal diameter in millimetres, varying also in their length and shape. The size and style of the tube chosen will depend upon the size of the trachea

Figure 9.31 Portex cuffed tube.

and the needs of the individual patient (Bond et al. 2003, Lewarski 2005, Serra 2000). It is essential that all staff caring for a patient with a tracheostomy know the type of tube in place at any one time, and that this information is readily available and clearly documented in the patient's notes (ICS 2008).

A selection of tube types and commonly seen tubes is described below.

Cuffed tracheostomy tubes

Portex Blue Line and Portex Blue Line Ultra cuffed tracheostomy tubes

These are single-use tracheostomy tubes constructed of siliconized polyvinyl chloride with an introducer and inflatable cuff of 'high-volume/low-pressure' design (Figure 9.31). They are softer and more pliable and are often used when percutaneous tracheostomy is performed in the critical care setting. The cuff pressure should be monitored regularly. Once the stoma is well-formed, after about 7–10 days, and depending on the patient's specific weaning needs, the Portex tube may be replaced by a more suitable, sturdier tube such as a Shiley tube (Hess 2005).

Shiley cuffed tracheostomy tube

This is a plastic tube with an introducer and one inner tube (Figure 9.32a). The inner tube has the universal 15 mm extension at its upper aspect to facilitate connection to other equipment.

Figure 9.32 (a) Shiley cuffed tube. (b) Shiley plain tube. (c) Shiley plain fenestrated tube. (d) Shiley cuffed fenestrated tube.

The outer tube has an inflatable cuff to give an airtight seal and facilitate ventilation and prevention of aspiration. Shiley tubes are often used in the immediate post-operative phase, that is, at 24–72 hours. As with all cuffed tracheostomies, the internal cuff pressure should not exceed 25 cmH₂O (ICS 2008) and should be monitored on a regular basis. The cuff should be deflated to remove the tube (to prevent mucosal damage and allow the tube to be removed safely) when the patient is eating and drinking, or when a speaking valve or decannulation plug is *in situ* (ICS 2008). Failure to deflate the cuff when a speaking valve or plug is in place will result in complete occlusion of the patient's airway.

Cuffless tracheostomy tubes

Shiley cuffless tracheostomy tube

This is a plastic tube with an introducer and two inner tubes (see Figure 9.32b). One inner tube has an extension known as a 15 mm hub or adaptor at its upper aspect. The majority of tracheostomy tubes used in the hospital setting have the universally sized 15 mm hub to allow attachment to speaking valves and other equipment (Russell 2004). The other tube has no 15 mm hub extension and is less obtrusive and suitable for those patients not requiring attachment to other equipment (Russell 2004).

A cuffless Shiley tube is usually used for the following reasons.

- To keep the tracheostomy tract patent if the patient is going to have further surgery.
- In place of a metal tracheostomy tube if the patient is going to have radiotherapy to the neck area (Prior and Russell 2004). Keeping the metal tube *in situ* during radiotherapy can cause reactions due to interference of the metal with the radiotherapy beam and leads to an increased dose being given to the underlying stoma and surrounding skin (Prior and Russell 2004).
- For a laryngectomy patient who has a benign or malignant stenosis of the trachea and requires a longer tube than the regular length laryngectomy tube to keep the stenosis patent.

Fenestrated tracheostomy tubes

Shiley fenestrated cuffless tube

The Shiley fenestrated cuffless tube (see Figure 9.32c) is a plastic tube with an introducer and three inner tubes. One inner tube has no hub jutting out, is less obtrusive and is suitable for those patients not requiring attachment to other equipment (Russell 2004). The other two inner tubes have the universal 15 mm extension at the upper aspect to facilitate connection to other apparatus, and one of these (with a green coloured hub) also has a fenestration midway down the tube (the clear or white hubbed inner has no fenestrations down the side and sits flush with the outer tube). This is to encourage the passage of air and secretions into the oral and nasal passages. It is useful when attempting to encourage a return to normal function following long-term use of a temporary tracheostomy, for example enabling the patient to communicate verbally. Fenestrated tubes are not recommended for use following percutaneous tracheostomy or when patients are requiring mechanical ventilation due to a risk of surgical emphysema (ICS 2008).

A fenestrated tube is the most suitable for phonation and weaning. A cap (known as a decannulation plug – see Figure 9.38) is placed onto the tube, occluding the artificial airway. This enables air flow through as well as around the tracheostomy tube, allowing the patient to breathe via the oral and nasal passages again. The cap can be left *in situ* for certain periods of time until the patient can tolerate the tube occluded continuously for an uninterrupted period of time. The Intensive Care Society (ICS 2008) states that this period of time should be a *minimum of 4 hours* uninterrupted, though common practice is 24 hours in ward environments. Once this has occurred, removal of the entire tube, known as decannulation, can be considered (Harkin 2004, Serra 2000). The decannulation procedure should ideally take place in

Figure 9.33 Kapitex Tracheotwist cuffed fenestrated tube.

the morning, during normal working hours, to ensure that a specialist assessment can be sought if the patient requires tracheostomy tube reinsertion (Harkin 2004).

Shiley fenestrated cuffed tube

This tube is very similar to the cuffless fenestrated tube although it has an outer cuff to facilitate ventilation and protect against aspiration, and only two inner tubes (see Figure 9.32d). Both inner tubes have the universal 15 mm extension at the upper aspect to facilitate connection to other apparatus, and one of these (with a green coloured hub) also has a fenestration midway down the tube. The outer tube also has a fenestration in the middle of the cannula, again to encourage a return to normal function. The fenestrated tube can also be occluded with a cap, to assess the patient's oral and nasal airway, first ensuring that the *cuff has been completely deflated* and that the fenestrated inner tube is *in situ*. This tube is particularly useful for weaning patients who require both periods of cuff inflation (to protect the airway) and cuff deflation (to enable a speaking valve to be used) (Russell 2004).

Specialist function tubes

Kapitex Tracheotwist fenestrated tube

This is a plastic tube with an introducer and two inner tubes (Figure 9.33). One of these inner tubes has an extension at its upper end to facilitate connection to other apparatus. The other inner tube has a fenestration midway down the tube, while the outer tube also has a fenestration consisting of a series of small holes. This helps to reduce the risk of granulation tissue growing through the fenestration. The neck plate or flange moves in a vertical and horizontal direction, enabling the plate to move as the patient moves. An inner tube with integrated speaking valve can be ordered separately.

Portex Blue Line Ultra 'Suctionaid' (Figure 9.34) and Tracheotwist 306 tracheostomy tubes

These are specialist tracheostomy tubes that have a facility for aspiration of subglottic secretions. They are mostly used for the prevention of ventilator-associated pneumonia (VAP) in critically ill patients, although they are now also indicated for patients with conditions such as bulbar palsy who are unable to effectively clear secretions accumulating above the tracheostomy tube. Suction should not be applied continuously due to the risk of laryngeal injury (ICS 2008).

Metal tubes

Jackson silver tracheostomy tube

This is a silver tube with an introducer and inner tube (Figure 9.35a). The inner tube is locked in position by a small

Figure 9.34 Portex Blue-Line Suctionaid tracheostomy tube.

catch on the outer tube and may be removed and cleaned as necessary without disturbing the outer tube.

Negus silver tracheostomy tube

This is a silver tracheostomy tube with an introducer and a choice of inner tubes, with and without speaking valves (Figure 9.35b). The outer tube does not have a safety catch so the inner tube can at times be coughed out inadvertently.

Additional tracheostomy supplies

Speaking valves

These are plastic devices with two-way valves that fit onto the 15 mm hub of the fenestrated inner tube. Distinction should be made between open and closed position valves.

- The open position speaking valve (e.g. Rusch valve) (Figure 9.36) is open by default and closes with positive pressure (expiration) which diverts air through the upper airways past the vocal cords, thus allowing production of a voice.
- The closed position speaking valve (e.g. Passy Muir valve) (Figure 9.37) is closed by default and requires negative

pressure (i.e. the patient's inspiratory effort) to open. Once expiration starts, it closes, causing air to be diverted as described above. This type of valve can be used in ventilator circuits, always with cuff deflation, for patients who are mechanically ventilated.

If a non-fenestrated cuffed tube is in place, the cuff should always be deflated before a speaking valve is fitted as the patient will not be able to exhale (Clotworthy 2006b). Ordinarily, practitioners will also consider changing a non-fenestrated tube for a fenestrated tube (double lumen, with fenestrated inner tube). This will allow air to be diverted through the fenestrations of the tube in addition to air already diverted around the tube to the upper airways. If a non-fenestrated tube is in place, depending on the size of the tracheostomy tube and the diameter of the patient's trachea, sufficient air may not be diverted past the cuff. This will result in pressure building up because the patient will not be able to breathe out and the valve will not be tolerated. In this case a complete outer tube change to a fenestrated tube will be necessary.

However, anecdotal evidence from practice (often in critical care environments) would suggest that in some instances, cuff deflation alone (without changing a non-fenestrated tube for a fenestrated tube) may be sufficient to allow air diversion past the cuff through the upper airways as described above. It is important that each individual case is considered carefully and that practitioners weigh up the potential discomfort and distress a complete tracheostomy tube change may cause against the potential risks of fitting a speaking valve on a non-fenestrated tube. It is therefore imperative that, when a speaking valve is used for the first time, the patient is carefully monitored for any signs of respiratory distress. If the patient experiences difficulty in breathing, an inability to vocalize or they begin to sound wheezy or stridulous, the speaking valve should be removed immediately and the patient reassessed (ICS 2008).

Decannulation plug

This is a small plastic plug which fits into the outer fenestrated tube (Figure 9.38). It is used to encourage patients to divert air around the tube and into the nose and mouth before removal of the tracheostomy tube as described previously. Alternatively, a small plastic plug (Kapitex) or a blind hub (Shiley) can be fitted into or over the inner fenestrated tube. This is particularly useful for patients who are still producing tenacious secretions as the

Figure 9.35 (a) Jackson silver tube. (b) Negus silver tube.

Figure 9.36 Rusch speaking valve.

plug or hub can be removed to enable the inner tube to be cleaned (Harkin 2004).

Laryngectomy tubes

Patients who have undergone a total laryngectomy may require a cuffed tracheostomy tube for the first 24–48 hours. The tube stents the often oedematous stoma and the inflated cuff prevents blood-stained secretions from entering the lungs. During the immediate post-operative phase, the decision on whether a tube is required and which type is made by the surgeon (Clotworthy 2006a). For those patients with no tube in place, the nurse must be extremely vigilant, assessing the bare stoma frequently to ensure that it is not at risk of stenosis. A stenosed stoma will restrict the patient's breathing, hinder the removal of secretions and prevent the insertion of a cuffed tube in an emergency situation. Stoma size should be sufficiently large, ideally 20–25 mm in diameter (Rhys Evans et al. 2003), in order to insert a size 6 or above Shiley tracheostomy tube or equivalent. In the longer term, many patients no longer require a tube of any type.

Colledge silver laryngectomy tube

This is a silver laryngectomy tube with an introducer (Figure 9.39a). It is often used to dilate a laryngectomy stoma which

Figure 9.38 Decannulation plug.

has stenosed. These tubes can be cleaned, autoclaved and reused.

Shiley laryngectomy tube

This is a plastic tube with an introducer and inner tube (Figure 9.39b). The inner tube has the universal 15 mm hub enabling attachment to other equipment. It is shorter in length than a tracheostomy tube, thereby conforming to the slightly shorter trachea in the patient who has undergone a total laryngectomy. The inner tube may be removed and cleaned frequently without disturbing the outer tube. It is sometimes worn post-operatively while the stoma is healing to help facilitate a 'neater' shaped stoma.

Shaw silver laryngectomy tube

This is a silver laryngectomy tube with an introducer and an inner tube beyond both lower and upper aspects of the outer tube. Thus pressure dressings may be secured without occluding the stoma. The silver catch on the outer tube keeps the inner tube in position (Figure 9.39c).

Stoma button

This is a soft silastic 'button' (Figure 9.39d). It may be used in place of a laryngectomy tube. It is very light and comfortable to wear and can be used in conjunction with a Blom–Singer speaking valve. In order to facilitate the use of the Blom–Singer speaking valve, a diamond shape is cut out of the silastic (see Chapter 4: Communication for specific information on surgical voice restoration).

Silastic laryngectomy tube

This is a slightly opaque silastic tube which is longer in length in comparison to the stoma button. It is available in 36 and 55 mm lengths and in a variety of different sizes (Figure 9.39e). It is most suitable for patients who experience a degree of stenosis further down the trachea (see Chapter 4: Communication for further information).

Specific patient preparation

Care of the patient with a tracheostomy requires a multidisciplinary approach. Patients may have issues with pain and discomfort, swallowing, speech, mobility and general care. Speech and language therapists will play a pivotal role in the assessment and management of the patient's impaired swallowing and speech. Specialized physiotherapists are skilled in mobilization rehabilitation (see Chapter 6: Moving and positioning), humidification techniques and general care for tracheostomies. Patients may have difficulty with an altered body image and need psychological support not only from the team closely involved in their care but also potentially from a formal psychological support team. Other key support teams include rehabilitation teams (for rehabilitation, relaxation and occupational therapy), critical care outreach teams (particularly for newly formed stomas in the ward environment and/or the deteriorating patient with airway difficulties), anaesthetists in the event of an airway emergency, discharge co-ordinators and community teams for patients with airways who are going home.

Humidification

Humidification may be required initially while a new stoma adapts to the outside environment. It can be provided for patients requiring low-rate (1–5 L/min) oxygen therapy by using a disposable nebulizer set with sterile 0.9% sodium chloride (approximately 5 mL), attached to the oxygen supply and setting the gas rate for the liquid to form into humidification droplets. The nebulizer is administered using a specific tracheostomy mask (Figure 9.40) rather than via the nose and mouth, as is usual practice. Local policy will determine frequency which may need to be every 4–6 hours or more frequently in patients with more tenacious secretions. 0.9% sodium chloride nebulizers can also be given using air instead of oxygen if the patient is not on oxygen therapy. Patients requiring continual high concentrations of oxygen ($\geq 28\%$) require humidification via a heated circuit where possible or a cold water Venturi humidified system at all other times (see Figure 9.6, Figure 9.10). Patients no longer requiring oxygen therapy can receive humidification in the form of a HME and a patient with a laryngectomy stoma can effectively humidify using laryngeal stoma protectors that combine protection along with humidification, for example Laryngofoam, Buchanan bib, Romet (McGrath et al. 2012).

Humidification of a tracheostomy is important to prevent drying of the airway which impairs mucus and cilia function, resulting in thickened airway secretions. Devices such as HME filters or a Trachphone (Figure 9.41), which also has an integral speaking valve and oxygen port, may be used for tracheostomy patients (McGrath et al. 2012).

Education

Patient education is paramount to providing quality care. In the initial post-operative/post-procedural phase, this may be purely to

Figure 9.40 Tracheostomy mask.

aid comfort and relaxation, explaining and stressing the rationale and importance of suctioning, positioning and how to strengthen cough. This will involve a multidisciplinary approach with all members of the team educating, supporting and providing comfort throughout all interventions.

For patients with long-term tracheostomy needs, early education is vital. Supporting an individual with a tracheostomy of any type requires an understanding of the impact the tracheostomy

Figure 9.41 Trachphone.

tube has on the patient's airway and knowing how to manage potential complications (Serra 2000). In order to support and teach the patient and/or their carer, staff must confirm whether the tube serves as the primary airway (i.e. a permanent stoma) or if the patient has a functioning upper airway (Bowers and Scase 2007, McGrath et al. 2012).

Patient education will come from various sources but primarily the clinical nurse specialists, nursing staff, physiotherapists and community nursing teams will play pivotal roles. Education will be both practical (i.e. through demonstration with their own tracheostomy, possibly utilizing mirrors) or through the use of posters and pictures. Practical tracheal suctioning on a specialized mannequin and examining the tracheostomy tubes can also be beneficial (McGrath et al. 2012).

Tracheostomy: dressing change

Evidence-based approaches

A tracheostomy is a surgical opening into the trachea and hence a potential route of infection, so the area should be kept clean. Tracheostomies can also cause damage to the surrounding

tissues through pressure and the presence of irritant secretions (McGrath et al. 2012), necessitating regular inspection and appropriate care of the area to prevent tissue damage and wound breakdown. Changing the dressing will ensure that the surrounding skin remains clean, dry and free from irritation and infection (Edgton-Winn & Wright 2005).

Rationale

Indications

In some patients, dressing may not be indicated as it creates an ideal environment for bacterial colonization (Higgins 2009). Secretions from the stoma can also cause excoriation around the site. The decision to dress a tracheostomy should be based on clinical need, although a thorough assessment of the stoma is indicated for all patients with altered airways (i.e. tracheostomy or laryngectomy). The dressing around the tracheostomy tube can be renewed without removing the tube, which should be done twice a day or more frequently if necessary (Serra 2000).

Contraindications

Occasionally a surgical team may request that the original dressing remain intact for a period of time, usually 24–48 hours. There may be an increased risk of bleeding associated with the stoma formation and in this instance the dressing should not be changed until consultation with the surgeon has occurred.

Principles of care

Changing the tracheostomy dressing always requires two people (McGrath et al. 2012): one to secure the tracheostomy and the other to assess and dress the stoma site. When assessing the wound, if infection is suspected, that is, the area is reddened, excoriated, painful, discoloured or exudate is present, a microbiology swab should be sent for culture (Higgins 2009, ICS 2008, McGrath et al. 2012).

The stoma should be cleaned thoroughly with 0.9% sodium chloride and an appropriate dressing applied where indicated. This should be a foam dressing, usually manufactured with a cross-shaped incision to fit around the tracheostomy tube (McGrath et al. 2012). For those patients with secretions that tend to accumulate around the stoma, a specialized barrier product can be used to prevent the skin becoming red and excoriated (Hampton 1998).

Stoma sutures (secured to the flange of the tracheostomy tube) are removed on day 7 (day 7–10 if the tracheostomy has been inserted using a percutaneous technique). If the patient has previously received external beam radiotherapy to the neck, stoma sutures are removed on day 10.

Procedure guideline 9.10 Tracheostomy: dressing change

This procedure requires two nurses: one to hold the tracheostomy in place and the other to change the dressing.

Essential equipment

- Sterile dressing pack
- Tracheostomy dressing or keyhole dressing
- Cleaning solution, such as 0.9% sodium chloride
- Tracheostomy securing tapes
- Bactericidal alcohol handrub

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Screen the bed or cubicle.

Medicinal Products

- Review a possible need for analgesia

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

To ensure the patient's privacy. **E**

(continued)

Procedure guideline 9.10 Tracheostomy: dressing change (continued)		
Action	Rationale	
3 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and prepare the dressing tray or trolley.	To minimize the risk of infection (Fraise and Bradley 2009, E).	
4 Perform the procedure using aseptic technique, i.e. apply apron and gloves.	To minimize the risk of infection. E	
Procedure		
5 Remove the soiled dressing from around the tube, clean around the stoma with 0.9% sodium chloride using low-linting gauze.	To reduce the risk of dressing fragments entering the altered airway (Russell 2005, E) and to remove secretions and any crusts.	
6 Replace with a tracheostomy dressing or a comfortable foam-backed keyhole dressing (Action figure 6).	To ensure the patient's comfort. E To avoid pressure from the tube (Scase 2004, E).	
7 Renew tracheostomy tapes, checking that 1–2 fingers can be placed between the tapes and neck.	To secure the tube. E To ensure that the tapes are not too tight (Scase 2004, E ; Woodrow 2002, E) or too loose, thus decreasing the chance of necrosis caused by excessive pressure from the tapes (Serra 2000, E).	
Post-procedure		
8 Monitor patient closely for changes in respiratory rate and pattern of breathing, pulse, dyspnoea.	Any procedure to the tracheostomy if not managed correctly may lead to possible dislodgement of tube or secretions, leading to respiratory deterioration or distress. E	
		
Action Figure 6 Sterile tracheostomy keyhole dressing.		

Tracheostomy: suctioning

Evidence-based approaches

Rationale

An effective cough requires closure of the glottis, then reopening of the glottis once an adequate intrathoracic pressure is achieved. When a tracheostomy is *in situ*, the mechanism of closing the glottis is compromised, so the patient's ability to remove secretions is reduced as they are unable to generate the high flows required for coughing. In addition to this, the natural mechanisms of warming and humidifying the gases are lost, altering the consistency of secretions. Secretions become thick and dry, inhibiting mucociliary transport (Higgins 2009), leading to a potential blocking of the tracheostomy tube. Tracheal suction is an essential component of managing secretions, maintaining respiratory function and a patent airway.

Indications

The use of routine suctioning should be avoided and careful assessment of the patient's respiratory function should be carried out instead. Inspection, auscultation, percussion and palpation will help to determine the following (Hough 2001, Pryor and Prasad 2008).

- The patient's ability to clear their own secretions.
- Location of any secretions.

- Whether these secretions could be reached by the catheter.
- How detrimental these secretions might be for the patient.

The presence of prominent audible secretions, visible secretions, decreased oxygenation or diminished breath sounds during the assessment would indicate a need for suction (Ireton 2007).

Contraindications

Tracheal suction is an essential component of care for all patients with artificial airways. Most contraindications are relative to the patient's risk of developing adverse reactions or worsening clinical condition as a result of the procedure. Hence choosing to not suction in order to avoid a potential side-effect may sometimes be more harmful to the patient.

However, despite its necessity, suction may be painful and distressing to the patient and can also be complicated by hypoxaemia, bradycardia and cardiovascular compromise (particularly in patients with autonomic dysfunction such as spinal injuries), alveolar collapse, tracheal mucosal damage, bleeding and the introduction of infection (Higgins 2009, ICS 2008).

Principles of care

Infection risk

Universal precautions must be used at all times when suctioning; this includes wearing aprons, gloves and eye protection.

Figure 9.42 Components of a closed-circuit catheter. The control valve locks the vacuum on or off. The catheter is protected inside an airtight sleeve. A T-piece connects the device to the tracheal tube. The irrigation port allows saline instillation for irrigating the patient's airway or for cleaning the catheter.

Both the caregiver and patient are at risk of infection when suctioning is performed and, in order to minimize this, examination gloves should be worn and an aseptic technique should be used, decontaminating hands with an alcohol handrub before and after the suction procedure (DH 2005). Suction catheters (see Figure 9.59) are for single use only and should be disposed of after each suction.

Suction should be performed using aseptic techniques, with the patient upright and in a neutral head alignment.

Method of suctioning

Shallow suctioning, where the catheter is inserted to a pre-measured depth not beyond the distal end of the tracheostomy tube, is preferred to deep suctioning, in which the suction catheter is inserted until resistance is met. Deep suctioning should be avoided as it is associated with increased risks of mucosal damage, inflammation (De Leyn et al. 2007) and bleeding, subsequently increasing the risk of airway occlusion. Always suction with the inner tube *in situ* and change to a non-fenestrated inner tube before the procedure. The instillation of 0.9% sodium chloride to 'aid' suctioning is not recommended (Celik and Kanan 2006, ICS 2008). Suction should always be performed with the inner tube *in situ*, and if necessary changed to a non-fenestrated inner tube. The suction catheter should have a diameter no greater than half the internal diameter of the tracheostomy tube; for example, suction catheter size = $2 \times (\text{tracheostomy size} - 2)$ (see Figure 9.59).

The lowest possible vacuum should be applied to minimize atelectasis. Pre-oxygenation may be necessary in those with high O_2 requirements. The catheter should be inserted approximately 10–15 cm, depending on the length of the tracheostomy tube, before applying suction and slowly withdrawing the catheter. Suction should be applied for a maximum of 10 seconds. The application of 0.9% sodium chloride to 'loosen' or 'aid' suctioning is not recommended (ICS 2011, McGrath et al. 2012).

Any difficulty in passing the suction catheter should lead to the consideration that the tube is blocked or misplaced and requires immediate attention (ICS 2011).

Anticipated patient outcomes

Suctioning can cause distress, is uncomfortable and is associated with airway changes and cardiovascular instability, and should therefore only be performed when indicated and not at fixed intervals. Frequency should be determined on an individual patient basis and suctioning should aim to clear airway secretions when the patient is not able to, ensuring airway patency and patient safety at all times.

Equipment

Suction catheter size and suction pressure

Choosing the correct suction catheter size depends on the size of the tracheostomy tube. As a guide, the diameter of the suction catheter should not exceed one-half of the internal diameter of the tracheostomy tube (Griggs 1998, Hough 2001).

The following formula can be used to determine the correct size catheter.

$$\text{Suction catheter size (Fg)} = 2 \times (\text{size of tracheostomy tube} - 2)$$

$$\text{For example: } 8.00 \text{ mm ID tube: } 2 \times (8 - 2) = 12 \text{ Fg (ICS 2008)}$$

The incorrect choice of catheter, poor technique and the use of an excessively high suction pressure may all lead to mucosal trauma. The lowest possible vacuum pressure should be used, ≤ 100 – 120 mmHg (13–16 kPa) to minimize atelectasis (ICS 2008) and mucosal damage.

Pre-procedural considerations

Within a critical care setting, a closed-circuit suction system is an alternative method to the open suction system for patients being mechanically ventilated. This closed system has the catheter sealed in a protective plastic sleeve, which is connected permanently into a standard ventilator circuit, thus preventing the catheter becoming contaminated (Figure 9.42). This also reduces the number of times the patient is disconnected from the ventilator, avoiding further hypoxia and cross-infection. Patients who are immunosuppressed, actively infectious patients or those who require high levels of PEEP may in particular benefit from a closed unit (Billau 2004).

Procedure guideline 9.11 Tracheostomy: suctioning a patient**Essential equipment**

- Suction source (wall or portable), collection container and tubing, changed every 24 hours to prevent growth of bacteria (Billau 2004)
- Disposable plastic apron
- Eye protection, for example goggles
- Bactericidal alcohol handrub
- Sterile suction catheters (assorted sizes according to tube size)
- A selection of non-sterile, powder-free, clean boxed gloves
- Sterile bottled water (labelled 'suction' with opening date), changed every 24 hours to prevent the growth of bacteria (Billau 2004)

Pre-procedure**Action****Rationale**

478

- 1 If secretions are tenacious, consider using, as prescribed, 2 hourly or more frequently 0.9% sterile sodium chloride nebulizers or other mucolytic agents such as nebulized acetylcysteine.
Rationale: Suctioning may not be as effective if the secretions become too tenacious or dry. Anecdotal evidence through practice suggests that frequent 0.9% sterile sodium chloride or acetylcysteine nebulizers may assist in loosening dry and thick secretions. **E**
- 2 Explain procedure to patient and ensure upright position if possible. If the patient is able to perform their own suction, self-suction should be taught. This is not appropriate in critical care settings.
Rationale: To obtain the patient's co-operation and to help them relax. **E**
The procedure is unpleasant and can be frightening for the patient (Billau 2004, **E**). Reassurance is vital. **E**
Self-control of the patient's suction is preferable with long-term stomas, if the patient is able to manage it. **E**
- 3 If a patient has a fenestrated outer tube, ensure that a plain inner tube is *in situ*, rather than a fenestrated inner tube (Russell 2005).
Rationale: Suction via a fenestrated inner tube allows a catheter to pass through the fenestration and cause trauma to the tracheal wall (Billau 2004, **E**).

Procedure

- 4 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and put on a disposable plastic apron, disposable gloves and eye protection.
Rationale: To minimize the risk of cross-infection. **E**
Gloves minimize the risk of infection transfer to the catheter or from the sputum to the nurse's hands (Fraise and Bradley 2009, **E**). Some patients may accidentally cough directly ahead at the nurse; standing to one side with tissues at the patient's tracheostomy minimizes this risk. **E**
- 5 If patient is oxygen dependent, hyperoxygenate for a period of 3 minutes.
Rationale: To minimize the risk of acute hypoxia (Billau 2004, **E**).
- 6 Ensure that the suction pressure is set to the appropriate level.
Rationale: Recommended suction pressure is ≤ 100 – 120 mmHg (13–16 kPa) to minimize atelectasis (ICS 2008, **C**).
- 7 Select the correct size catheter. As a guide, the diameter of the suction catheter should not exceed one-half of the internal diameter of the tracheostomy tube (Griggs 1998, Hough 2001). The following formula can be used to determine the correct size catheter:
Suction catheter size (Fg) = $2 \times (\text{size of tracheostomy tube} - 2)$
For example: 8.00 mm ID tube: $2 \times (8 - 2) = 12$ Fg (ICS 2008).
Rationale: This ensures that hypoxia does not occur while suctioning: the larger the volume, the greater the bore of the tube. **E**
Incorrect choice of catheter size can cause mucosal damage. **E**
A tube with too small a diameter may not be able to remove thick secretions. **E**
- 8 Open the end of the suction catheter pack and use the pack to attach the catheter to the suction tubing. Keep the rest of the catheter in the sterile packet. Use an aseptic technique throughout.
Rationale: To reduce the risk of transferring infection from hands to the catheter and to keep the catheter as clean as possible. **E**
- 9 An additional clean, disposable glove can be used on the dominant hand at this stage.
Rationale: To facilitate easy disposal of the suction catheter after suction. **E**
- 10 Remove the catheter from the sleeve and introduce the catheter to about one-third of its length or approximately 10–15 cm (ICS 2008) or until the patient coughs. If resistance is felt, withdraw catheter approximately 1 cm before applying suction by placing the thumb over the suction port control and slowly withdraw the remainder of the catheter (McGrath et al. 2012).
Rationale: Gentleness is essential; damage to the tracheal mucosa can lead to trauma and respiratory infection. **E**
The catheter should go no further than the carina to prevent trauma (McGrath et al. 2012, **E**).
The catheter is inserted with the suction off to reduce the risk of trauma (McGrath et al. 2012, **E**).

11 Do not suction the patient for more than 10 seconds (ICS 2008).	Prolonged suctioning may result in acute hypoxia, cardiac arrhythmias (Day et al. 2002, E), mucosal trauma, infection and the patient experiencing a feeling of choking.
12 Wrap catheter around dominant hand, then pull back glove over soiled catheter, thus containing catheter in glove, then discard.	Catheters are used only once to reduce the risk of introducing infection. E
13 If the patient is oxygen dependent, reapply oxygen immediately.	To prevent hypoxia. E
14 Rinse the suction tubing by dipping its end into the sterile water bottle and applying suction until the solution has rinsed the tubing through.	To loosen secretions that have adhered to the inside of the tube. E
15 If the patient requires further suction, repeat the above actions using new gloves and a new catheter. Allow the patient sufficient time to recover between each suction, particularly if oxygen saturation is low or if patient coughs several times during the procedure. The patient should be observed throughout the procedure.	To ensure general condition is stable (Billau 2004, E).
16 Repeat the suction until the airway is clear. No more than three suction passes should be made during any one suction episode (Day 2000, Glass and Grap 1995) unless in emergency such as tube occlusion (Nelson 1999).	To minimize the risk of hypoxaemia (Day 2000, E).
Post-procedure	
17 Where appropriate, reconnect the patient to oxygen within 10 seconds post suctioning.	To minimize the risk of hypoxaemia (Day 2000, E).
18 Observe patient's respiratory rate and pattern, oxygen saturations, heart rate and work of breathing closely over the following 15 minutes. Observe for signs of bleeding.	Suctioning can be complicated by hypoxaemia, bradycardia, tracheal mucosal damage and bleeding (ICS 2008, C).

Complications

Hypoxia

The act of suctioning reduces vital lung volume from the lungs and upper airways. Each suctioning procedure should last no longer than 10 seconds to decrease the risk of trauma, hypoxia and other side-effects (ICS 2008). Ventilator disconnection or removal of the oxygen supply will also add to the risk of hypoxia prior to suctioning. Within a critical care setting, this risk can be avoided by hyperoxygenating the lungs with 100% oxygen, either manually or via a ventilator (Glass and Grap 1995, Hough 2001), which should be considered for all patients with high oxygen requirements.

Cardiac arrhythmias

Arrhythmias may be brought about by the onset of hypoxaemia or a vagal reflex instigated by tracheal stimulation by the catheter (MacIntyre and Branson 2009).

Raised intracranial pressure

This may occur if the suction catheter causes excessive tracheal stimulation and results in coughing and an increase in the patient's intrathoracic pressure, both of which compromise cerebral venous drainage (Pryor and Prasad 2008).

Tracheostomy: changing the inner cannula

Evidence-based approaches

Rationale

Tracheostomy tubes with an inner cannula are inherently safer and are now usual practice. Changing the inner cannula regularly

allows for visual inspection of secretions, aiding the decision about humidification requirements and reducing the risk of airway occlusion.

Indications

- If a tracheostomy has an inner cannula, it should be regularly removed and inspected for patency.

Contraindications

- Inner cannulas should only be used with the tracheostomy they are designed for.
- Care must be taken when inspecting and/or changing an inner cannula. Pre-oxygenation and/or suction may be necessary prior to the procedure so patient stability must be considered.

Principles of care

The inner cannula should be removed, inspected and when necessary changed at regular intervals, the frequency of inspection being determined by the volume and tenacity of the patient's secretions (ICS 2008). Any nurse starting a shift should perform a baseline assessment of the airway tube and inner cannula to check on the type and amount of secretions and the need for humidification (Rhys Evans et al. 2003). Disposable inner cannulas should be cleaned according to the manufacturer's instructions.

Procedure guideline 9.12 Tracheostomy: inner cannula change**Essential equipment**

- Sterile dressing pack
- Cleaning solution, such as 0.9% sodium chloride
- Disposable plastic apron, powder-free gloves and eye protection
- Bactericidal alcohol handrub
- Inner cannula of the same size as the tracheostomy tube that is *in situ*

Pre-procedure**Action****Rationale**

- | | |
|---|--|
| 1 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Ensure the emergency trolley is readily available if required. Inform staff which procedure will be taking place in case help is required. | In event of difficulty replacing airway. E
To ensure that all staff are aware that airway is to be changed so in the event of difficulties, staff are available to assist. E |
| 3 Preoxygenate the patient if known to desaturate by increasing the oxygen delivered according to the patient's need to ensure oxygen saturations greater than 95%. | As oxygen mask will be removed for the changing and cleaning or disposing of the inner cannula, the patient will be without additional oxygen for a short period of time and may desaturate (ICS 2008, C). |
| 4 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and prepare a dressing trolley. | To minimize the risk of infection (Fraise and Bradley 2009, E). |
| 5 Screen the patient's bed. | To ensure the patient's privacy. E |

Procedure

- | | |
|---|---|
| 6 Perform the procedure using clean technique. | To minimize the risk of contamination. E |
| 7 Assist the patient to sit in a semi-recumbent position (Clotworthy 2006c) with the neck extended. | To ensure the patient's comfort and to maintain a patent airway. Extending the neck will make removal and insertion of the tube easier (Clotworthy 2006c, C). |
| 8 Remove the dressing pack from its outer wrappings. | To reduce the risk of cross-infection (Fraise and Bradley 2009, E). |
| 9 Put on a disposable plastic apron and eye protection, for example goggles. | Some patients may accidentally cough directly ahead at the nurse; standing to one side and wearing a disposable apron and eye protection will minimize transfer of secretions on to the nurse. E |
| 10 Clean hands with bactericidal alcohol handrub. | To minimize the risk of infection (Fraise and Bradley 2009, E). |
| 11 Put on clean disposable plastic gloves. | Gloves minimize the risk of infection from the sputum to the nurse's hands (Fraise and Bradley 2009, E). |
| 12 Remove the inner cannula and, if disposable, dispose in clinical waste bag. If non-disposable, clean cannula with sterile 0.9% sodium chloride and dry thoroughly. Do not leave the inner cannula to soak. | To minimize the risk of infection (Fraise and Bradley 2009, E). Soaking tubes could result in absorption of the solution into the material, causing irritation to the trachea (ICS 2008, C) as well as bacterial colonization in stagnant cleaning solution (McGrath et al. 2012, C). |
| 13 Place the new inner tube in position and ensure it is secured in a 'locked' position. | To re-establish airway and prevent cannula from dislodging. E |
| 14 Ensure that the patient is comfortable. | To ensure patient comfort. E |
| 15 Clear away the trolley and equipment. | To remove equipment appropriately. E |

Post-procedure

- | | |
|--|--|
| 16 Observe patient's respiratory rate and pattern, oxygen saturations, heart rate and work of breathing closely over the following 15 minutes. Observe for signs of bleeding. | Changing a tube is potentially hazardous (ICS 2008, C) and may cause respiratory distress in patients. The insertion of a new tube may cause new bleeding of surrounding tissues. E |
| 17 Document the time when you changed the inner cannula and the type of secretions the patient has, and the size of the tracheostomy tube. Thicker secretions or old blood will require more frequent changes to prevent occlusion of the inner cannula. | To ensure all staff are aware of the tube size and type (NMC 2010, C). To ensure all staff are aware of the need for and frequency of inner cannula changes. |

Tracheostomy: tube change

Definition

Tracheostomy tube changing is the removal of the old tracheostomy tube and replacing with a new device. This procedure is required for various reasons, downsizing, changing from non-fenestrated to fenestrated tubes, or for weaning or infection prevention purposes. It is the most critical event after formation of the tracheostomy as there is risk of possible loss of the airway (Johnson et al. 2010, McGrath et al. 2012). The exact period of time to wait before the first post-operative change varies, because time is needed to allow a tract between the skin and the trachea to develop. Therefore around 5 days is usually acceptable (Johnson et al. 2010).

The first tracheostomy tube change

This must be performed by a doctor/practitioner who is not only competent in tracheostomy tube placement, but also has advanced airway management and intubation skills. Except in emergencies, the first change should not be performed within 72 hours following a surgical tracheostomy or before 5 days (and ideally 7–10 days) after a percutaneous tracheostomy (Johnson et al. 2010). This procedure requires the presence of a second practitioner who is trained in tracheostomy care and who is prepared to summon help if required. The procedure must be recorded in the patient's records (ICS 2011).

Subsequent tube changes

- These should be performed as frequently as clinically indicated, and in accordance with the manufacturer's recommendations.
- They must only be performed by personnel trained in tracheostomy tube changes.

- They require the presence of a second practitioner who is trained in tracheostomy care to a minimum level of first responder skills.
- All change must be recorded in the patient's records (ICS 2011).

Evidence-based approaches

Rationale

Indications

- Minimizing risk of post-operative infection and granulation tissue formation around the tube.
- Verifying the formation of a stable tract to allow nursing staff to perform changes.
- Changing from a non-fenestrated to a fenestrated tracheostomy tube to facilitate weaning and communication with tracheostomy speaking valve.
- Downsizing the tracheostomy tube if the patient is clinically improving (MacIntyre and Branson 2009).

Contraindications

- Changing a tracheostomy tube too soon after formation (generally <5 days); this increases likelihood of entry into a false passage as the tract may not have healed adequately.
- Poor visualization of tracheostomy tract and inadequate lighting, exposure and lack of emergency equipment.
- Performer inexperience without availability of staff versed in airway management.
- Patients with extremely high ventilator settings, which increase the risk of decannulation.
- Patient non-co-operation without ancillary support (Johnson et al. 2010).

Procedure guideline 9.13 Tracheostomy: tube change

Essential equipment

- Sterile dressing pack
- Tracheostomy foam-based dressing or keyhole dressing
- Tracheostomy securing tapes or ties
- Cleaning solution, such as 0.9% sodium chloride
- Barrier cream
- Lubricating gel
- Disposable plastic apron, powder-free gloves and eye protection
- Bactericidal alcohol handrub
- New tracheostomy tube for insertion

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Ensure the emergency trolley is readily available. Inform staff what procedure will be taking place in case help is required.	In event of difficulty replacing airway. E To ensure that all staff are aware that airway is to be changed so in the event of difficulties, staff are available to assist. E
3 Recheck suction and oxygen supply, ensure spare tubes, dilators and all emergency equipment are readily available.	To ensure patient safety in the event of inability to secure airway with new tube. E
4 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and prepare a dressing trolley.	To minimize the risk of infection (Fraise and Bradley 2009, E).
5 Screen the patient's bed.	To ensure the patient's privacy. E

(continued)

Procedure guideline 9.13 Tracheostomy: tube change (continued)**Procedure****Action****Rationale**

- | | |
|---|---|
| 6 Perform the procedure using clean technique. Always perform the procedure in hospital with a second, appropriately trained person available. | To minimize the risk of contamination. E
To ensure patient safety at all times (ICS 2011, C ; McGrath et al. 2012, C). |
| 7 Assist the patient to sit in a semi-recumbent position (Clotworthy 2006c) with the neck extended. | To ensure the patient's comfort and to maintain a patent airway. Extending the neck will make removal and insertion of the tube easier (Clotworthy 2006c, C). |
| 8 Remove the dressing pack from its outer wrappings and open the tracheostomy dressing. | To reduce the risk of cross-infection (Fraise and Bradley 2009, E). |
| 9 Put on a disposable plastic apron and eye protection, for example goggles. | Some patients may accidentally cough directly ahead at the nurse; standing to one side and wearing a disposable apron and eye protection will minimize transfer of secretions on to the nurse. E |
| 10 Clean hands with bactericidal alcohol handrub. | To minimize the risk of infection (Fraise and Bradley 2009, E). |
| 11 Put on clean disposable plastic gloves. | Gloves minimize the risk of infection from the sputum to the nurse's hands (Fraise and Bradley 2009, E). |
| 12 If the new tracheostomy is cuffed, check the cuff by inflating it with air (according to manufacturer's instructions) then fully deflate the cuff. | To check for air leaks and spontaneous deflation (Clotworthy 2006c, C). |
| 13 Insert the introducer or obturator of the new tube, checking that it can be easily removed. | To become familiar with removing the introducer or obturator prior to insertion (Clotworthy 2006c, C). |
| 14 Lubricate the new tube sparingly with a lubricating jelly and place on the sterile dressing surface. | To facilitate insertion and maintain sterility. E |
| 15 Thread the new tapes or ties through the slit on one of the flanges by untying one side of the old ties. | To ensure the ties are ready to secure as soon as the tube is inserted. Most ties now are made of Velcro and are comfortable to wear and easy to adjust. E |
| 16 If the old tube is cuffed, slowly deflate the cuff, suctioning patient if required. | Pooled secretions above the cuff may enter the lungs when the cuff is deflated (Clotworthy 2006c, C). |
| 17 Gently remove the soiled tube from the patient's neck while asking the patient to breathe out. | Conscious expiration relaxes the patient and reduces the risk of coughing. Coughing can result in unwanted closure of the tracheostomy. E |
| 18 Quickly clean around the stoma with 0.9% sodium chloride and dry gently. Apply barrier cream with topical swabs (an aqueous cream may be used if the patient is having the site irradiated). | Provide care efficiently so as not to prolong the time the patient is without a formal airway and/or oxygen. To remove superficial organisms and crusts. Skin around the stoma is at risk of breakdown due to the constant presence of moisture in this area (Serra 2000, E). The skin surrounding the site should be kept clean and dry to prevent bacterial growth (Spruce et al. 2012, E). Meticulous skin care is therefore essential in order to prevent infection. Creams containing metallic compounds must not be used on irradiated skin as metal will worsen any skin reaction (Prior and Russell 2004, E). |
| 19 Insert a clean tube with introducer in place, using an 'up and over' action. | Introduction of the tube is less traumatic if directed along the contour of the trachea. E |
| 20 Remove the introducer immediately. | The patient cannot breathe while the introducer is in place. E |
| 21 Place the inner tube in position. | The inner tube can be changed as necessary when the outer tube is in position, thus minimizing the risk of trauma to trachea and stoma. E
The quantity of secretions present will determine the frequency with which the inner tube is changed. E |
| 22 Secure the second tape on the other side of the tracheostomy flange. Ensure the tapes are secure with a space from skin to tie of 1–2 fingers only. | To secure the tube while at the same time ensuring that it will not cause discomfort to the patient. E |
| 23 Remove gloves and ask the patient to breathe out onto the palm of your hand. | Flow of air will be felt if the tube is in the correct position. E |
| 24 Put on clean disposable plastic gloves. | To minimize the risk of infection from the sputum to the nurse's hands (Fraise and Bradley 2009, E). |

25 Put the tracheostomy dressing around the tube.	Dressings can be used as an effective barrier to prevent bacteria from entering the site (Spruce et al. 2012, E).
26 Ensure that the patient is comfortable.	The procedure can be traumatic for some patients, resulting in coughing and even discomfort. It is important for the nurse to stay with the patient until coughing has resolved, provide reassurance and administer analgesia where appropriate. E
27 Remove gloves, apron etc. Clear away the trolley and equipment.	To ensure removal of equipment. E
28 Dispose of all single-use tracheostomy tubes immediately in contaminated waste. For long-term reusable tubes, clean the soiled tube with sterile water or in line with the manufacturer's recommendations. If the tube is very soiled then use sodium bicarbonate to remove debris. The tube must be rinsed thoroughly and stored dry at the patient's bedside. Plastic tubes should not be soaked in solutions.	Most new tracheostomy tubes are single use with disposable equipment to prevent infection. To remove debris that may occlude the tube and/or become a source of infection. E Soaking tubes could result in the absorption of the solution into the material, causing irritation to the trachea (Bjorling et al. 2007, E).
Post-procedure	
29 Observe patient's respiratory rate and pattern, oxygen saturations, heart rate and work of breathing closely over the following 15 minutes. Observe for signs of bleeding.	Changing a tube is potentially hazardous (ICS 2008, C) and may cause respiratory distress in patients. The insertion of a new tube may cause new bleeding of surrounding tissues. E
30 Document the new tube size and type and any problems observed during the change.	To ensure all staff are aware of the tube size and type (NMC 2010, C).

Problem-solving table 9.6 Prevention and resolution (Procedure guidelines 9.10, 9.11, 9.12 and 9.13)

Problem	Cause	Prevention	Suggested action
Profuse tracheal secretions.	Local reaction to tracheostomy tube.	Maintain euvolaemia with adequate and not excessive hydration. Hyoscine can be considered by clinicians to aid in the reduction of excessive secretions following the immediate post-operative phase when excessive secretions are common.	Suction frequently, for example every 1–2 hours, or on clinical need.
Lumen of tracheostomy tube occluded.	Tenacious mucus in tube.	Frequent suction as required and regular inner tube changes. Humidify airways. Encourage coughing to clear secretions from within the tube.	Change the inner tube. Use 0.9% sodium chloride nebulizers, HMEs and suction. Continue to change the inner tube regularly, for example 1–3 hourly.
	Dried blood and mucus in the tube, especially in the post-operative period.	As above.	Provide humidification (see Procedure guideline 9.2: Humidification for respiratory therapy). Humidification, administering air if there is no need for oxygen.
Tracheostomy tube dislodged accidentally.	Tapes/ties not secured adequately. Tracheostomy tube not secured adequately by staff during moving and handling of patient.	Ensure tapes secure at all times with 1–2 finger spaces maximum between skin and tapes/ties. Educate patient and staff about safe mobilization of patients with tracheostomy.	Insert spare tube. This should be clean and ready at the bedside (Serra 2000). <i>Note:</i> tracheal dilators must be kept at the bedside of patients with tracheostomies (Serra 2000).
Unable to insert clean tracheostomy tube during tube change.	Unpredicted shape or angle of stoma.	Emergency equipment with spare tubes, lubricant, tracheostomy dilators should always be readily available before tube change. Always perform procedure with a second person when in hospital setting. Only perform if skilled and trained in performing a tube change. Know and understand local policy for emergency management before undertaking the procedure.	Remain calm since an outward appearance of distress may cause the patient to panic and lose confidence. Lubricate the tube well and attempt to reinsert at various angles. If unsuccessful, attempt to insert a smaller-size tracheostomy tube. If this is impossible, keep the tracheostomy tract open using tracheal dilators and inform the doctor.

(continued)

Problem-solving table 9.6 Prevention and resolution (Procedure guidelines 9.10, 9.11, 9.12 and 9.13) (*continued*)

Problem	Cause	Prevention	Suggested action
	Tracheal stenosis due to patient coughing, patient being very anxious or because the tube has been left out too long.		Insert a smaller-size tracheostomy tube. If insertion still proves difficult, do not leave the patient but ask for a tube to be brought to the bed. Keep the tracheostomy patent with tracheal dilators if stenosis is pronounced until the tube is reinserted.
Tracheal bleeding following or during change of the tube.	Trauma due to suction or to the tube being changed. Presence of tumour. Granulation tissue forming in fenestration of tube.	Ensure emergency equipment including artery forceps available before procedure.	Change the tube as planned if bleeding is minimal. For profuse bleeding, insert a cuffed tube and inflate the cuff (Clotworthy 2006c). Inform the doctor. Perform tracheal suction to remove the blood from the trachea.
Infection.	Nature of surgery and condition of patient often predispose to infection.	Ensure dressings are changed when soiled and universal infection precautions are adhered to.	Encourage the patient to cough up secretions and/or suction regularly. Change the tube and clean the stoma area frequently, for example 4 hourly. Protect permanent stomas with a bib or gauze. Following result of sputum specimen, commence appropriate antibiotics as needed.

Post-procedural considerations

Documentation

All interventions and care given should be clearly documented in the patient's notes once performed. It is essential that all staff caring for a patient with a tracheostomy know the type of tube in place at any one time, and that this information is readily available and clearly documented in the patient's notes (ICS 2008). As discussed, the use of care plans and bundles may aid in standardizing documentation of patients with a tracheostomy, though this should comply with local policy at all times.

Complications

The main complications associated with tracheostomies are blockage, dislodgement of tracheostomy tube and bleeding at tracheostomy site or inside trachea due to suction injury or coagulopathy, usually presenting with respiratory difficulty. A systematic approach should be adopted and the situation given urgent attention (Box 9.10). When all types of tracheostomies are considered, the likelihood that an airway stoma encountered in an emergency situation is a laryngectomy is between 1 in 20 and 1 in 30. A patient with a tracheostomy is more likely to come to harm by not having oxygen applied to the face if confusion surrounds the nature of the stoma; the default emergency action is therefore to apply oxygen to the face and the stoma for all neck breathers when there is any doubt as to the nature of a stoma. Any oxygen applied to the upper airway can be removed in the case of a laryngectomy once this has been confirmed to be the case. Ventilation via laryngectomy stomas can be achieved using paediatric facemasks or laryngeal masks applied to the anterior neck (RCUK 2012).

The National Tracheostomy Safety Project has published distinct guidelines for management of emergencies for patients with either a tracheostomy (Figure 9.43) or laryngectomy (Figure 9.44), with both carrying a clear message emphasizing the need for oxygenation of the patient and the need to call for help early. It also designed 'the green algorithm' for emergency tracheostomy management with a patent upper airway (RCUK 2012).

Box 9.10 Tracheostomy emergency

- DONT PANIC!
- Call for help – senior medical and nursing staff.
- Reassure patient.
- Assess patency of airway and breathing – is the patient breathing via the nose or mouth? Check oxygen saturations.
- If the airway is not patent it must be cleared immediately ONLY by those with appropriate airway and tracheostomy management experience.
- Multiple attempts to reinsert the tracheostomy should not be made.
- If in doubt, remove the tracheostomy tube and allow the patient to breathe through the mouth/nose (cover the stoma site).
- Apply oxygen masks over both sites of air entry.

Cardiopulmonary resuscitation

Definition

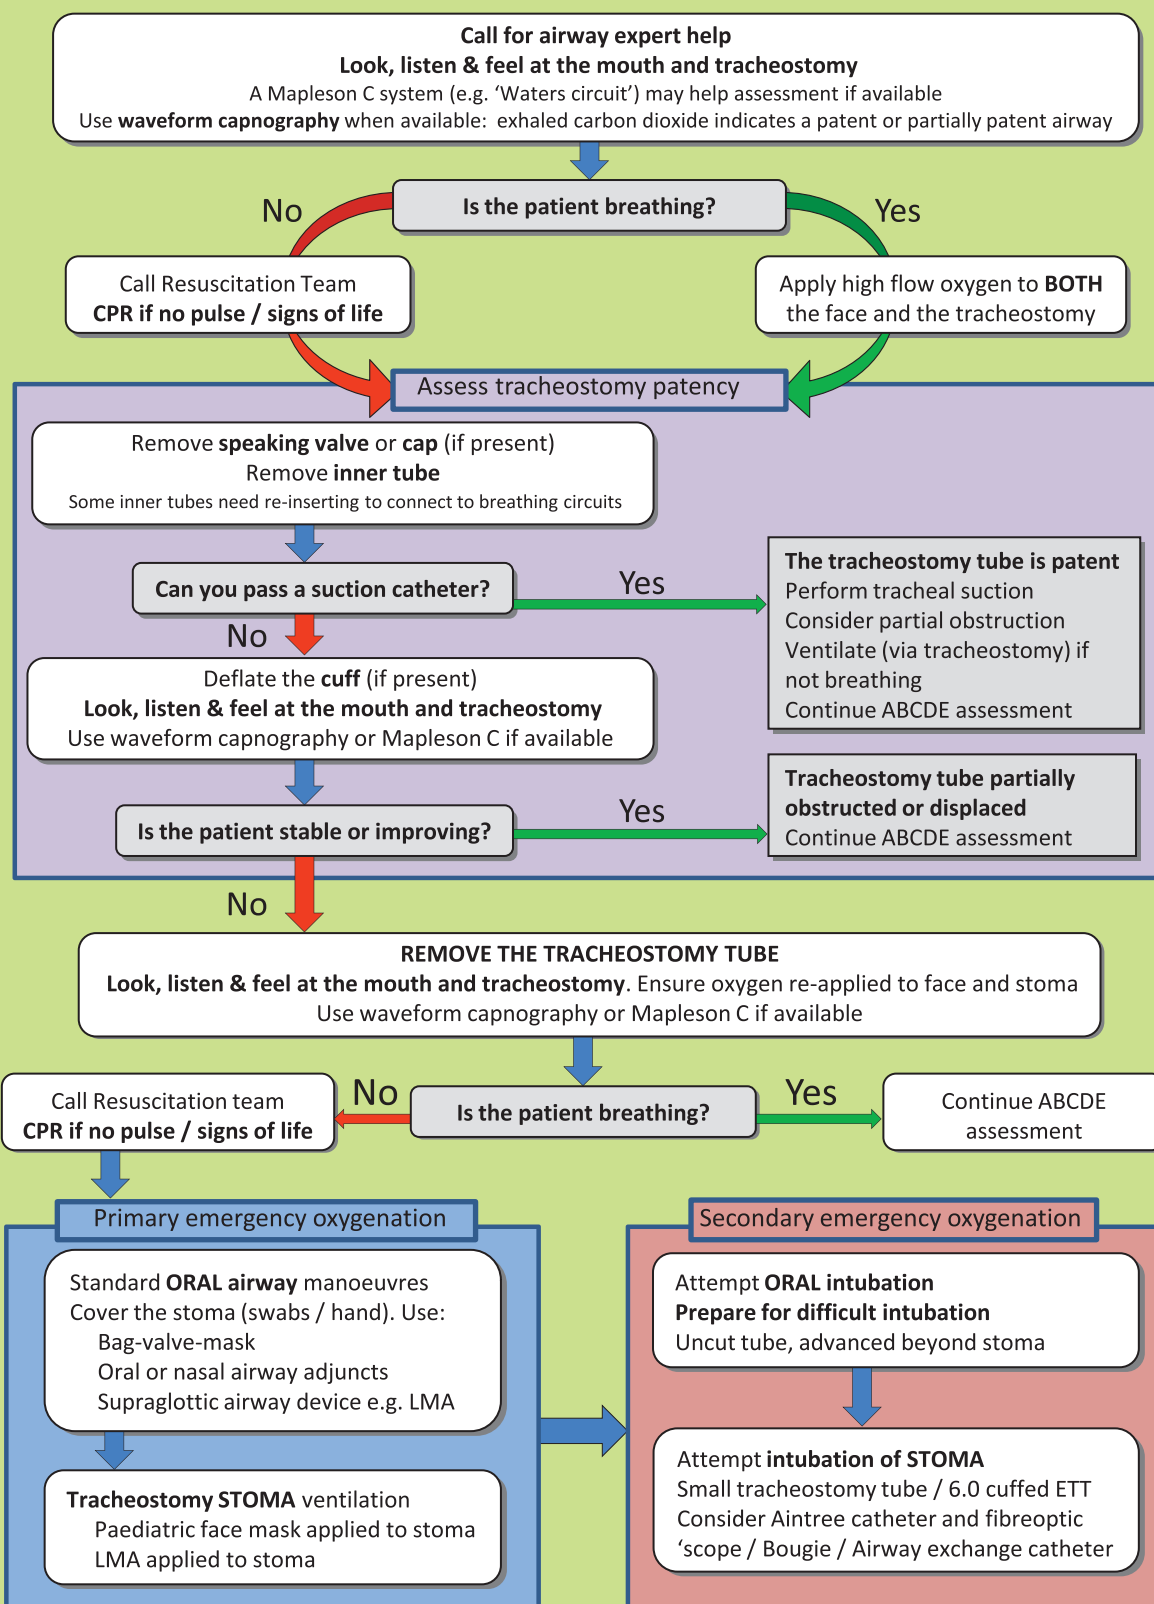

Cardiopulmonary resuscitation is an emergency procedure such as cardiac compressions and ventilation, which are performed in an effort to manually preserve cardiac output and oxygenation to ensure intact brain function until further measures are taken to return spontaneous blood circulation and breathing in a person in cardiac arrest (RCUK 2010a, 2010b).

Anatomy and physiology

The heart

The heart is made up of four chambers: two upper atria and two lower ventricles (see Figure 11.5). The right atrium receives deoxygenated blood via the venous circulation. From the right atrium, blood flows into the right ventricle which pumps it into

Emergency tracheostomy management - Patent upper airway

the lungs via the pulmonary arteries. Carbon dioxide is released and oxygen is absorbed. This blood is oxygenated and returns to the heart via the pulmonary veins that empty into the left atrium. The blood then passes into the left ventricle which pumps it into the aorta and arterial circulation (Waugh and Grant 2010).

The atrioventricular septum completely separates the right and left sides of the heart. From shortly after birth, the two sides of the heart never directly communicate. Blood travels from right side to left side via the lungs only. However, the chambers themselves work together. The two atria contract simultaneously and the two ventricles contract simultaneously (Waugh and Grant 2010).

To prevent backflow of blood, the heart has valves. The atrioventricular (AV) valves are between the atria and ventricles. The right AV valve between the right atrium and right ventricle is also called the tricuspid valve because it consists of three cusps. The left AV valve between the left atrium and ventricle is called the bicuspid as it has two cusps. Both arteries that emerge from the heart have a valve to prevent blood from flowing back into the heart – the semi-lunar (SL) valves. The pulmonary SL valve lies where the pulmonary trunk leaves the right ventricle and the aortic SL valve is situated at the opening between the aorta and left ventricle. The valves open and close in response to pressure changes as the heart contracts and relaxes (Jenkins and Tortora 2013, Moran 2010).

Cardiac conduction system

This pathway is made up of the:

- sinoatrial (SA) node
- AV node
- bundle of His
- left and right bundle branches
- Purkinje fibres.

The SA node is the natural pacemaker of the heart. It releases electrical stimuli at a regular rate, which will vary depending on whether the body is at rest or in action. As each stimulus passes through the myocardial cells of the atria, it creates a wave of contraction which spreads rapidly through both atria (Jenkins and Tortora 2013).

The rapidity of atrial contraction is such that around 100 million myocardial cells contract in less than one-third of a second; this is so fast it appears instantaneous.

When the electrical stimulus from the SA node reaches the AV node, it is delayed briefly so that the contracting atria have enough time to pump all the blood into the ventricles. Once the atria are empty of blood, the valves between the atria and ventricles close. At this point the atria begin to refill and the electrical stimulus passes through the AV node, through the bundle of His, along the left and right bundle branches and the Purkinje fibres. In this way all the cells in the ventricles receive an electrical stimulus causing them to contract (Becker 2007).

Around 400 million myocardial cells that make up the ventricles contract in less than one-third of a second. As the ventricles contract, the right ventricle pumps blood to the lungs where carbon dioxide is released and oxygen is absorbed, whilst the left ventricle pumps blood into the aorta from where it passes into the coronary and arterial circulation.

At this point the ventricles are empty, the atria are full and the valves between them are closed. The SA node is about to release another electrical stimulus and the process is about to repeat itself. However, there is a third section to this process. The SA node and AV node contain only one stimulus. Therefore every time the nodes release a stimulus, they must recharge before they can do it again (Jenkins and Tortora 2013).

In the heart, the SA node recharges whilst the atria are refilling, and the AV node recharges when the ventricles are refilling. This means there is no need for a pause in heart function. Again, this process takes less than one-third of a second. (The times given for

the three different stages are based on a heart rate of 60 beats per minute, or 1 beat per second.)

The term used for the release of an electrical stimulus is 'depolarization' and the term for recharging is 'repolarization'.

So, the three stages of a single heart beat are:

- atrial depolarization
- ventricular depolarization
- atrial and ventricular repolarization (Jenkins and Tortora 2013, Moran 2010).

Related theory

Cardiac arrest implies a sudden interruption of cardiac output. It may be reversible with appropriate treatment (Handley 2004, RCUK 2010a, 2010b). The patient will collapse, lose consciousness, stop breathing and will be pulseless (Jevon 2001, Paradis 2007).

The four arrhythmias that cause cardiac arrest are:

- asystole
- ventricular fibrillation (VF)
- pulseless ventricular tachycardia (VT)
- pulseless electrical activity (PEA).

For the purposes of resuscitation guidelines, these rhythms are divided into two groups by their treatment:

- VF and pulseless VT, which require defibrillation
- non-VF/VT, which do not require defibrillation (RCUK 2010b).

Resuscitation is the emergency treatment of any condition in which the brain fails to receive enough oxygen.

Potentially reversible causes of a cardiopulmonary arrest

During cardiac arrest, potential causes or aggravating factors for which specific treatment exists should be considered. For ease of memory, there are eight common causes of arrest, four of which begin with the letter H and four with the letter T.

- Hypoxia
- Hypovolaemia
- Hypo-/hyperkalaemia/metabolic
- Hypothermia
- Thrombosis – coronary or pulmonary
- Tamponade – cardiac
- Toxins
- Tension pneumothorax (RCUK 2010a, 2010b)

Hypoxia

There are many reasons why a patient may become severely hypoxic, the most common being the following.

- Acute respiratory failure (O'Driscoll et al. 2008)
- Airway difficulties (RCUK 2012)
- Acute lung injury (O'Driscoll et al. 2008)
- Severe anaemia
- Neuromuscular disorders

For healthy cell metabolism, the body requires a constant supply of oxygen. When this is interrupted for more than 3 minutes in most situations (except when there is severe hypothermia), cell death occurs, followed by lactic acidosis and very rapidly a cardiorespiratory arrest. The risk of hypoxia is minimized by ensuring that the patient's lungs are ventilated adequately with 100% oxygen (RCUK 2010b).

Hypovolaemia

Hypovolaemia in adults that results in PEA is usually due to severe blood loss. While it is not the nurse's role to make a

medical diagnosis, they may be aware of significant factors in the history of a patient that may have led to PEA.

The most common causes of severe blood loss are:

- trauma
- surgical procedure
- gastrointestinal mucosa erosion
- oesophageal varices
- peripheral vessel erosion (by tumour usually)
- clotting abnormality.

Note: Blood loss, although usually overt, can be covert such as a gastrointestinal bleed which may only become apparent when the patient collapses.

488

The treatment for hypovolaemia is identifying and stopping the source of fluid or blood loss, and replacing the circulating volume with the appropriate fluid. Fluid resuscitation is normally started with a crystalloid, for example 0.9% sodium chloride, and/or colloid, for example Gelofusine (depending on local protocols); there is no evidence that colloids are more effective than crystalloids. Blood is likely to be required rapidly if the blood loss exceeds 1500–2000 mL in an adult (Perel et al. 2007, RCUK 2010b).

Hypo-/hyperkalaemia and other metabolic disorders

Because potassium is so closely linked with muscle and nerve excitation, any imbalance will affect both the nervous conduction and the muscular working of the heart. Therefore a severe rise or fall in potassium can cause arrest arrhythmias. The causes of hypokalaemia are:

- gastrointestinal fluid losses
- urinary fluid loss
- drugs that affect cellular potassium, for example antifungal agents such as amphotericin.

The immediate treatment for hypokalaemia that has resulted in an arrest is to give concentrated infusions of potassium while carefully monitoring the serial potassium measurements. Most ICU/accident and emergency (A&E) departments and coronary care units (CCUs) will have an arterial blood gas analyser that enables the potassium to be measured in 1 minute.

The patients who are most at risk of hyperkalaemia are those with renal failure or Addison's disease (Fordjour et al. 2012, Weisberg 2008). The immediate treatment for hyperkalaemia is to give intravenous calcium. This has the effect of protecting the myocardium during the cardiac arrest. If the patient is successfully resuscitated, it will be essential to monitor their serum potassium and, if it remains high, to commence therapy to lower or remove the potassium (RCUK 2010a, 2010b).

Hypothermia

Hypothermia should be suspected in any submersion or immersion injury. During a prolonged resuscitation attempt, a patient who was normothermic at the onset of cardiac arrest may become hypothermic (RCUK 2010b). A low-reading thermometer should be used if available. Resuscitation in the presence of hypothermia may be prolonged.

Thrombosis – coronary or pulmonary

The most common cause of thromboembolic or mechanical circulatory obstruction is a massive pulmonary embolus. Options for definitive treatment include thrombolysis or, if available, cardiopulmonary bypass and operative removal of the clot (RCUK 2010b).

Tamponade

This is where there is an acute effusion of fluid in the pericardial space and as it enlarges, the heart is splinted and finally cannot

beat. The fluid is usually blood but can be malignant or infected fluid (Dolan and Preston 2006). The most common cause for a sudden tamponade is trauma. The immediate treatment is the insertion of a catheter or surgical drainage of the fluid (Harper 2010). After drainage, the cause of the tamponade should be sought and corrected where possible, for example with appropriate antibiotic therapy for a bacterial aetiology or surgical repair of a myocardial laceration (Harper 2010).

Toxicity: poisoning and drug intoxication

Poisoning rarely leads to cardiac arrest but it is a leading cause of death in patients less than 40 years old. Self-poisoning with therapeutic or recreational drugs is the main reason for hospital admission (RCUK 2010b). There are few specific therapeutic measures for poisons that are useful in the immediate situation. The emphasis must be on intensive supportive therapy, with correction of hypoxia, acid/base balance and electrolyte disorders. Specialist help can be obtained by telephoning one of the regional National Poisons Information Service Centres (RCUK 2010b).

Tension pneumothorax

A tension pneumothorax is the sudden collapse of a lung, usually under pressure, which results in a severe change in intrathoracic pressure and cessation of the heart as a pump (Bersten et al. 2009). The most common causes are:

- trauma
- acute lung injury
- mechanical ventilation of the newborn.

The immediate treatment is the insertion of a large-bore cannula into the second intercostal space at the midclavicular line of the affected side (RCUK 2010b). Arrangements should be made for the insertion of a formal chest tube and underwater seal drain (see Procedure guideline 9.5: Chest drain: insertion).

Evidence-based approaches

Sudden death as a result of cardiac arrest is responsible for 60% of ischaemic heart disease deaths across Europe (RCUK 2010b). Survival to hospital discharge is cited as 10.7% of all types of cardiac arrest with survival being higher (21.2%) in ventricular fibrillation arrests (RCUK 2010b).

Changes to adult basic life support (BLS) guidelines have been made to reflect the importance of performing high-quality chest compressions. The rescuer should reduce the number and duration of pauses during chest compressions (RCUK 2010b).

Cardiopulmonary resuscitation guidelines in the UK are researched and implemented by the Resuscitation Council UK, and BLS and advanced life support (ALS) guidelines are changed according to their recommendations. The duration of collapse is frequently difficult to estimate accurately, so CPR should be given before attempted defibrillation outside hospital, unless the arrest is witnessed by a healthcare professional or an automated external defibrillator (AED) is being used (RCUK 2010b).

In contrast, there is no evidence to support or refute the use of CPR before defibrillation for in-hospital cardiac arrest. For this reason, after in-hospital VF/VT cardiac arrest, a shock should be given as soon as possible (RCUK 2010b). Continuing good-quality CPR may improve the amplitude and frequency of fine VF and improve the chance of successful defibrillation to a perfusing rhythm, as fine VF is difficult to distinguish from asystole and very unlikely to be shocked successfully (Eftestol et al. 2002, RCUK 2010a).

Rationale

The basic technique involves a rapid simple assessment of the patient followed by BLS resuscitation. The first international consensus evidence-based guidelines on resuscitation were

published in 2000 (AHA/ILCOR 2000, Shuster et al. 2010). These guidelines were reviewed in 2004/05 by the International Liaison Committee on Resuscitation and published in 2005 (AHA/ILCOR 2000). These internationally agreed guidelines based on research and audit now form the basis for the European resuscitation guidelines (Baskett et al. 2005) as well as the UK resuscitation guidelines (RCUK 2010b).

Changes to Resuscitation Council UK guidelines suggest that the rescuer should not stop to check the patient or discontinue CPR unless the person starts to show signs of regaining consciousness, such as coughing, opening eyes, speaking or moving purposefully, and starts to breathe normally (RCUK 2010b).

Indications

- The patient is unconscious, has absent or agonal (gaspings) respirations and has no pulse (Perkins et al. 2005). Other clinical features such as pupil size, cyanosis and pallor are unreliable and so the practitioner should not waste time looking for them (Skinner and Vincent 1997).

Contraindications

- Do not attempt cardiopulmonary resuscitation orders (DNACPR).
- If the environment is going to place the rescuer at risk, do not attempt resuscitation until the environment is secured.

Do not attempt cardiopulmonary resuscitation (DNACPR)

Survival after in-hospital cardiac arrest is still only in the region of 10–20% depending on numerous factors, such as initial cardiac ECG rhythm, co-morbidities, age, performance status, reason for hospital admission and cause of cardiac arrest (Meaney et al. 2010, NCEPOD 2012). In an attempt to reduce the number of futile resuscitation attempts, many hospitals and organizations have introduced formal DNACPR policies, which can be applied to individual patients in specific circumstances. Healthcare professionals must be able to show that their decisions relating to CPR are compatible with the Human Rights Act 1998 implemented on 2 October 2000 (e.g. the right to life, the right to be free from inhuman or degrading treatment and freedom of expression) (BMA 2000, 2007, BMA et al. 2002). The following guidelines are based on those provided in a joint statement by the British Medical Association (BMA), the Royal College of Nursing (RCN) and the Resuscitation Council UK (BMA 2007). (*Note:* Where no decision has been made and the express wishes of the patient are unknown, CPR should be performed without delay.) Each hospital should audit all CPR attempts and assess what proportion of patients should have had a DNACPR decision in place prior to the arrest and should not have undergone CPR, rather than have the decision made after the first arrest. This will improve patient care by avoiding undignified and potentially harmful CPR attempts during the dying process (NCEPOD 2012).

- Sensitive advance discussion between experienced medical/nursing staff and patients regarding attempting CPR should be encouraged but not forced. Neither patients, nor those close to them, can demand treatment that is clinically inappropriate. If the healthcare team believes that CPR will not restart the heart and breathing, this should be explained to the patient in a sensitive way. (*Note:* In England, Wales and Northern Ireland, no person is legally entitled to give consent to medical treatment on behalf of another adult.) Information about CPR needs to be realistic. Written information explaining CPR should be available for patients and those close to them to read. The BMA, in liaison with the Resuscitation Council UK, RCN and Age Concern England, has published an information leaflet that may help patients and

families to discuss DNAR with medical and nursing staff (BMA 2007).

- Patients are entitled to refuse CPR even when there is a reasonable chance of success (Mental Capacity Act 2005).
- Some patients may ask that no DNACPR order be made. Patients cannot demand treatment which the healthcare team judges to be inappropriate, but all efforts should be made to accommodate their wishes and preferences.
- An advance DNACPR order should only be made after consideration of the likely clinical outcome, the patient's wishes and their human rights. It should be considered on an individual patient basis where:
 - attempting CPR will not start the patient's heart and breathing
 - there is no benefit in restarting the patient's heart and breathing
 - the expected benefit is outweighed by the burdens (RCUK 2010b).
- The overall responsibility for decisions about CPR and DNACPR orders rests with the consultant in charge of the patient's care. Issues should, however, be discussed with other members of the healthcare team, the patient and people close to the patient where appropriate.
- There are exceptional cases where resuscitation discussions with a patient may be inappropriate, for example where senior members of the medical and nursing team consider that CPR would be futile and that such a discussion would cause the patient unnecessary distress and anguish. This could apply to patients in the terminal phase of their illness.
- The most senior members of the medical and nursing team available should clearly document any decisions made about CPR in the patient's medical and nursing notes. The decision should be dated and the reasons for it given. This information must be communicated to all other relevant healthcare professionals (NCEPOD 2012). Unless it is against the wishes of the patient, their family should also be informed.
- The DNACPR order should be reviewed on each admission or in light of changes in the patient's condition (BMA et al. 2002).
- Finally, it should be noted that a DNACPR order applies only to CPR and should not reduce the standard of medical or nursing care (NCEPOD 2012).

Principles of care

Failure of the circulation for 3–4 minutes will lead to irreversible cerebral damage (Docherty and Hall 2002). BLS acts to slow down the deterioration of the brain and the heart until defibrillation and/or ALS can be provided (RCUK 2010b).

Assessment

There are two stages of assessment.

- An immediate assessment by the rescuer to ensure that CPR may safely proceed (i.e. checking there is no immediate danger to the rescuer from any hazard, for example electrical power supply).
- Assessment by the rescuer of the likelihood of injury sustained by the patient, particularly injury to the cervical spine. Although there may be no external evidence of injury, the immediate situation may provide the necessary evidence. For example, trauma to the cervical spine should be suspected in an accelerating/decelerating injury such as a road traffic accident with a motor-bike travelling at speed.

Once these two aspects have been assessed, the patient's level of consciousness should be checked by gently shaking his shoulders and asking loudly if he is all right (Figure 9.45). If there is no response, the rescuer should commence the BLS assessment (Figure 9.46) immediately.

Figure 9.45 Initial verbal assessment.

Note: If the arrest is witnessed or monitored and a defibrillator is not immediately to hand, a single precordial thump should be administered. If delivered within 30 seconds after cardiac arrest, a sharp blow with a closed fist on the patient's sternum may convert VF back to a perfusing rhythm (RCUK 2010b).

Defibrillation

Defibrillation causes a simultaneous depolarization of the myocardium and aims to restore normal rhythm to the heart. This is the definitive treatment for VF and pulseless VT. It has been suggested that about 60% of adults who collapse because of non-traumatic cardiac arrest are found to be in VF when first attached to a monitor (Nolan et al. 2010). In hospital, cardiac arrest is more likely to present as non-VF/VT, in other words asystole or PEA. Early defibrillation is a vital link in the chain of survival and developments in public access defibrillation and first responder defibrillation by ward nurses in hospitals are focusing firmly on this link. Delay in defibrillation decreases the chances of success, in the absence of bystander CPR, by 10–12% each minute (Nolan et al. 2010).

Nurses are often first on the scene at a cardiac arrest, highlighting the obvious need for nurse-led defibrillation at ward level. While not all nurses are trained in defibrillation, they should understand why it is necessary and how it is done and be able to assist in an emergency (Austin and Snow 2000). Resuscitation guidelines suggest asking for an AED, if one is available, as it can be used safely and effectively without previous training (RCUK 2010b). The aim of an effective defibrillation strategy is to reduce the pre-shock pause to less than 5 seconds by planning ahead and continuing cardiac compressions during charging, and using a very brief safety check (RCUK 2010b).

Method of basic life support

Basic life support is sometimes known as the 'ABC'.

Airway

The rescuer should look in the mouth and remove any visible obstruction (leave well-fitting dentures in place). The most likely obstruction in an unconscious person is the tongue. The head tilt/chin lift manoeuvre (Figure 9.47), which removes the tongue from occluding the oropharynx, is an effective method of opening an airway and relieving obstruction in 80% of patients (Simmons 2002).

Note: If there is any suspicion of cervical spine injury, establish a clear upper airway by performing a jaw thrust or chin lift with manual in-line stabilization.

Breathing

Keeping the airway open, the rescuer should look, listen and feel for breathing (more than an occasional gasp or weak attempts

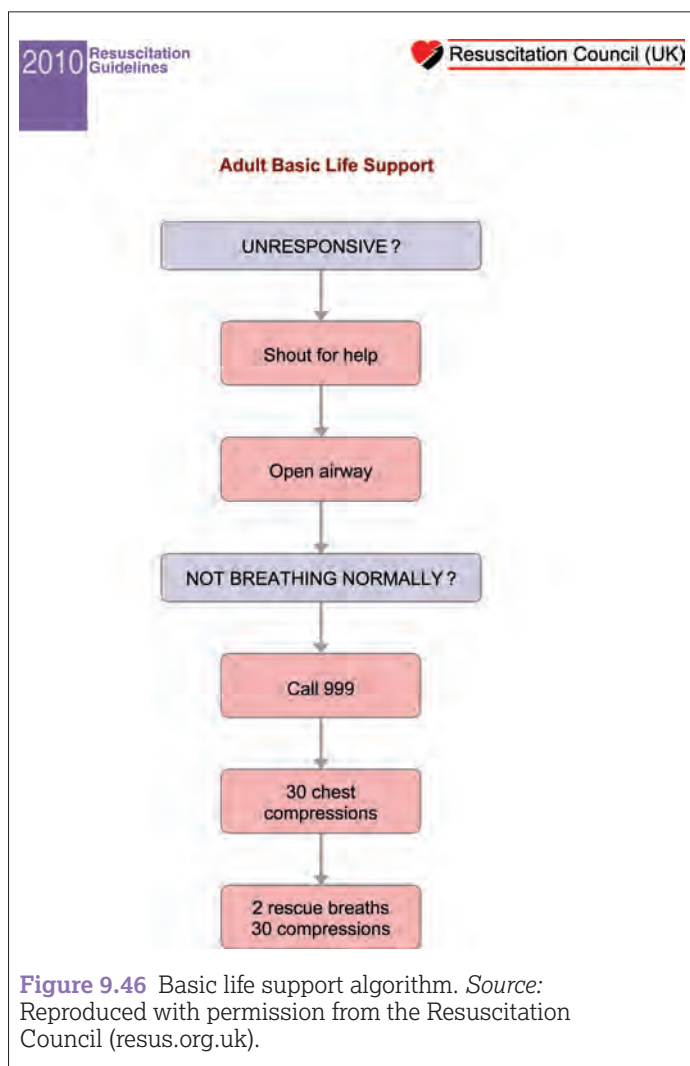

Figure 9.47 Head tilt/chin lift manoeuvre.

Figure 9.48 The recovery position.

at breathing) for up to 10 seconds. If the patient is breathing, they should be turned into the recovery position (Figure 9.48). If the adult patient is not breathing and there is no suspicion of trauma or drowning, an immediate call for the cardiac arrest team should be made. It should be noted that in 40% of cases a person who has arrested still has agonal (gaspings) respirations and these can be mistaken for normal breaths (Hauff et al. 2003).

Artificial ventilation must then be commenced and maintained. If there are no aids to ventilation available then direct mouth-to-mouth ventilation should be used. There have been isolated reports of infections such as tuberculosis (TB) and severe acute respiratory syndrome (SARS) following mouth-to-mouth ventilation but never transmission of HIV (RCUK 2010a). There is no evidence to quantify the degree of risk to the rescuer by performing mouth-to-mouth ventilation but, as it is widely acknowledged that some people are reluctant in spite of the lack of evidence, an allowance has been made for them to only perform chest compressions (RCUK 2010b). The recommended length for each breath is now 1 second (RCUK 2010b).

When cardiac arrest occurs in hospital, the Resuscitation Council recommends the use of adjuncts such as the pocket mask or the bag mask unit. These can be used to avoid direct person-to-person contact and some devices may reduce the risk of cross-infection between patient and rescuer (RCUK 2010b). In 2005, in recognition of the concern about providing mouth-to-mouth resuscitation, the guidelines changed and the BLS algorithm now starts with chest compressions and then proceeds to two breaths (RCUK 2010b).

One of the most easily learnt aids is the 'mouth-to-facemask' method (Figure 9.49) in which a ventilation mask with a one-way valve and an oxygen attachment port is used. The mask directs the patient's exhaled air and any fluid away from the rescuer and the oxygen port allows attachment of oxygen with enrichment up to 45%.

If the operator is skilled in airway management, a bag valve mask may be used. When the bag is attached to oxygen, high levels, of up to 85%, can be obtained. However, it should be emphasized that to manipulate the head tilt and hold on a facemask while squeezing a bag is a procedure that requires considerable skill and practice and is most safely achieved by two people, one holding the mask and one squeezing the bag (RCUK 2010b) (Figure 9.50).

The most effective method of airway management is to use an endotracheal tube, thus enabling the application of 100% oxygen (RCUK 2010b, Robertson et al. 1998). This method of airway management is included in the ALS algorithm (see Figure 9.65).

Figure 9.49 Mask with one-way valve over patient's nose and mouth and rescuer giving breath.

Circulation

Circulation is assessed by looking for any signs of movement, including swallowing or breathing. If trained to do so, a check should also be made for the carotid pulse (Figure 9.51) for up to 10 seconds. If no circulation is detected, it must be maintained by compressions. The correct place to compress is in the centre of the

Figure 9.50 Two people using Ambu-bag and mask.

Figure 9.51 Carotid pulse check.

lower half of the sternum (Figure 9.52). The rescuer should position themselves vertically above the patient with arms straight and elbows locked. The sternum should be pressed down to depress it by 5–6 cm. This should be repeated at a rate of about 100–120 times a minute. After 30 compressions, two rescue breaths are given, continuing compressions and rescue breaths in a ratio of 30:2 (RCUK 2010b). There is evidence that chest compressions are often interrupted and that this is associated with a reduction in the chance of survival. New adult ALS guidelines (RCUK 2010b) suggest an increased emphasis on the importance of minimal interruption in high-quality chest compressions throughout any ALS intervention; therefore, chest compressions are now continued while a defibrillator is charging, which will minimize the pre-shock pause. It is therefore imperative that interruptions to chest compressions are minimized by effective co-ordination between rescuers (Eftestol et al. 2002, RCUK 2010b, van Alem et al. 2003).

Legal and professional issues

All members of the healthcare professions who attempt resuscitation will be expected to employ the highest professional standards of care, in line with their level of training. In general, there are two means by which the risk of personal liability may be minimized. The first is by good practice and the second is by taking out adequate indemnity insurance (NMC 2015, RCUK 2010a). To ensure best practice, make sure that regular updates for BLS and if appropriate ALS training are maintained.

The Resuscitation Council UK guidelines state that if rescuers are not able, or are unwilling, to give rescue breaths, they should give chest compressions alone (RCUK 2010b).

Figure 9.52 Correct positioning of hands for external compressions.

Whenever CPR is carried out (outside the hospital setting), particularly on an unknown victim, there is some risk of cross-infection, associated particularly with giving rescue breaths. Normally, this risk is very small and has to be set against the inevitability that a person in cardiac arrest will die if no assistance is given.

Competencies

Cardiopulmonary resuscitation standards and training

The Resuscitation Council UK (RCUK), formed in 1981, aims to promote the education of lay and professional personnel in the most effective methods of resuscitation appropriate to their needs. In its report *CPR Guidance for Clinical Practice and Training in Hospitals* (Resuscitation Council 2004), the Council made a number of recommendations relating to the provision of a resuscitation service in hospital.

- *Resuscitation committee*: this should comprise medical and nursing staff who advise on the role and composition of the cardiac arrest team, resuscitation equipment and resuscitation training equipment.
- *Resuscitation training officer (RTO)*, who should be responsible for training in resuscitation, equipment maintenance and the auditing of resuscitation/clinical trials.
- *Resuscitation training*: hospital staff should receive at least annual resuscitation training appropriate to their level and role. Medical and nursing staff should receive basic resuscitation training and should be encouraged to recognize patients who are at risk of having a cardiac arrest and call for appropriate help early. This is the most effective method of improving outcome (Jevon 2002). All medical staff should have advanced resuscitation training and senior nurses and doctors working in acute specialties (CCU, ITU, A&E) should hold a valid RCUK ALS certificate.
- *Cardiac arrest team*: each hospital should have a team of approximately five people including a minimum of two doctors (physician and anaesthetist), an ALS-trained nurse, the RTO and a porter when possible. Clear procedures should be available for calling the cardiac arrest team. The Resuscitation Council has recommended the development of a medical emergency team which recognizes patients at risk of having a cardiac arrest and initiates the most appropriate clinical intervention to prevent it (Jevon 2002). Track and trigger systems and NEWS (NICE 2007, RCP 2012) alert nurses to when a patient is deteriorating so that they can initiate interventions and early referral to critical care outreach teams or medical emergency teams (DH 2000, NICE 2007, RCP 2012). Hospital staff are often trained in BLS techniques (see Figure 9.46) that are more appropriate for the single lay rescuer in an out-of-hospital environment. These new guidelines are aimed primarily at healthcare professionals who are first to respond to an in-hospital cardiac arrest (Figure 9.53). Some of the guidelines are also applicable to healthcare professionals in other clinical settings (Resuscitation Council 2004).

Pre-procedural considerations

Equipment

All hospital wards and appropriate departments, for example theatre, computed tomography (CT) scanning, should have a standardized cardiac arrest trolley or box. Resuscitation equipment should be checked on a daily basis (RCUK 2010b) by the staff on the wards or clinical areas responsible for it, and a record of this check should be maintained. Defibrillators should also be standardized. The use of AEDs or shock advisory defibrillators (Colquhoun 2008) is recommended to reduce mortality from cardiac arrests related to ischaemic heart disease (Jevon 2002). The RCUK recommends that defibrillation should be a basic skill requirement of all nurses (Colquhoun 2008, RCUK 2010a).

Training should be provided in the use of AEDs but, if there is no trained individual present when a cardiac arrest occurs, the

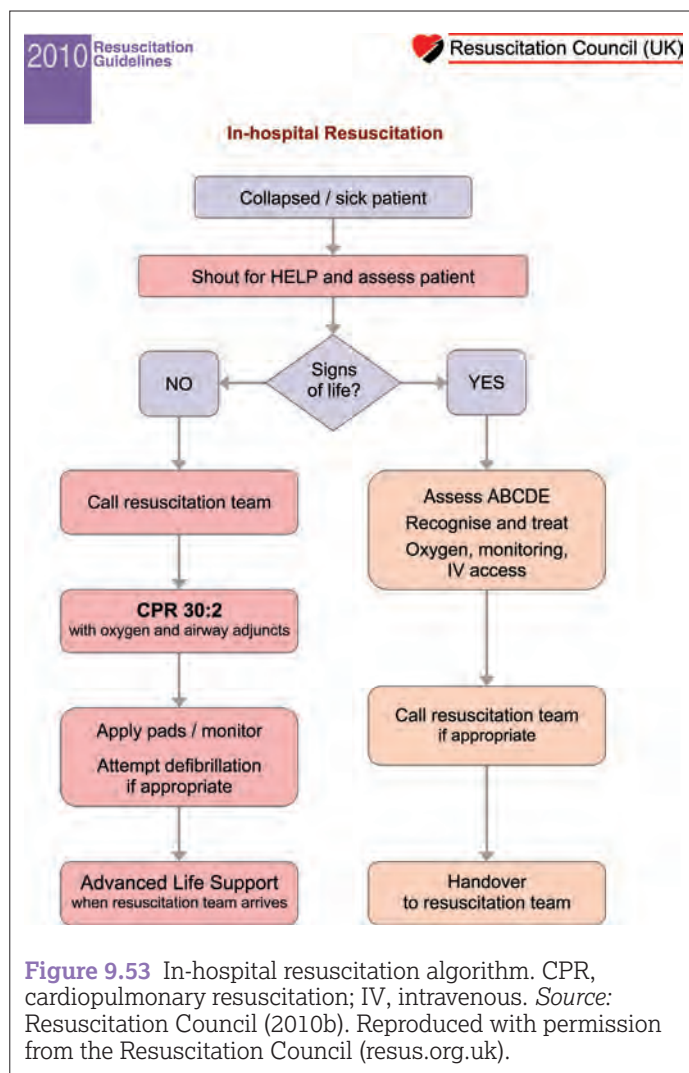

Figure 9.54 Placement of defibrillation pads attached to defibrillator on patient's chest.

RCUK advises that an untrained individual should attempt AED defibrillation. The administration of a defibrillatory shock should not be delayed by waiting for more highly trained personnel to arrive. The same principle should apply to individuals whose period of qualification has expired (RCUK 2010b).

Placement of self-adhesive electrodes (defibrillation pads)

The right electrode should be placed to the right of the sternum below the clavicle and the left paddle vertically in the midaxillary line approximately level with the position V6 used in electrocardiogram (ECG) monitoring (Figure 9.54).

Safe defibrillation practice

Defibrillation in an environment where high flows of oxygen are present could represent a danger to patients and rescuers. It is therefore essential to ensure that oxygen tubing and equipment are moved away from the chest when defibrillation is performed. Using adhesive electrodes to deliver the shock as opposed to paddles may also minimize the danger (RCUK 2010b).

A *pocket mask with oxygen port* (Figure 9.55) may be used as an adjunct to administer mouth-to-mask ventilation for a patient with respiratory arrest. The patient should be in the supine position with the head in the sniffing position (head tilt, chin lift – see Figure 9.47). Apply the mask to the patient's face using the thumbs of both hands. Lift the jaw into the mask with the remaining fingers by exerting pressure behind the angles of the jaw (jaw

thrust). Blow through the inspiratory valve and watch the chest rise. Stop inflation and allow the chest to fall before blowing in the second breath.

A *self-inflating resuscitation bag* with oxygen reservoir (Nolan et al. 2010) and tubing (Figure 9.56) may be used to administer

Figure 9.55 Pocket mask with oxygen port.

Figure 9.56 Self-inflating resuscitation bag with oxygen reservoir.

high inspired oxygen concentrations to a patient and can be connected to a facemask, laryngeal mask or tracheal mask. As the bag is squeezed, the contents are delivered to the patient's lungs and, on release, the expired gas is diverted to the atmosphere via a one-way valve and the bag then refills automatically via an inlet at the opposite end. Used alone, the bag-valve apparatus ventilates the patient's lungs with ambient air only (FiO_2 : 0.21), which can be increased to around 45% by attaching oxygen tubing and increasing the flow to 5–6 L/min directly to the bag adjacent to the air intake. If a reservoir system is attached and the oxygen flow is increased to 10 L/min, an inspired oxygen concentration of approximately 85% can be achieved (RCUK 2010b).

An *oropharyngeal airway* is a curved plastic tube, flanged and reinforced at the oral end with a flattened shape to ensure that it fits neatly between the tongue and the hard palate (Nolan et al. 2010). It is used to overcome backward tongue displacement in an unconscious patient. Oropharyngeal airways come in sizes 2, 3 and 4, for small, medium and large adults respectively. The right size is chosen by measuring the oropharyngeal airway from the patient's incisors to the angle of the jaw/mandible, as indicated in Figure 9.57a.

Figure 9.57 (a) Measure the Guedel airway from the corner of the mouth to the angle of the jaw. (b) Insert the airway in an upside-down position to the junction of the hard and soft palate. (c) Rotate the airway 180° once you have reached the junction of the hard and soft palate. (d) Insert the airway until it lies in the oropharynx.

Figure 9.58 Yankauer sucker.

The technique for insertion of an oropharyngeal airway in the unconscious patient is as follows.

- Open the patient's mouth and ensure, by looking into the mouth, that there is no foreign material that may be pushed into the larynx.
- Insert the airway into the mouth in the 'upside-down' position as far as the junction of the hard and soft palate and then rotate the airway through 180° (see Figure 9.57). Then insert the airway until it lies in the oropharynx. This rotation technique minimizes the chance of pushing the tongue backwards and downwards which would further obstruct the airway (RCUK 2010b).

Use of the incorrect size oropharyngeal airway may result in trauma, laryngospasm and/or worsening of the airway obstruction.

Suction equipment such as a wide-bore suction end (Yankauer sucker – Figure 9.58) should be used to remove liquid (blood, saliva and gastric contents) from the upper airway. This is done best under direct vision during intubation but should not result in any delay in achieving a definitive airway. If tracheal suction is necessary, it should be as brief as possible and preceded and followed by ventilation with 100% oxygen.

Endotracheal suction catheters (Figure 9.59) are used to clear secretions from endotracheal or tracheostomy tubes or laryngeal airway masks (Hallstrom et al. 2000, RCUK 2010b).

A *laryngeal mask airway* (LMA) (size 4) or Combitube (small) consists of a wide-bore tube with an elliptical inflated cuff

Figure 9.59 Endotracheal/tracheostomy suction catheter.

Figure 9.60 Laryngeal mask airway.

designed to seal around the laryngeal opening. It is easier to ventilate a patient using bag-valve-LMA ventilation than using bag-valve-facemask ventilation, because of difficulty in ensuring no air leak on the facemask, especially if there is only one person available to ventilate the patient. The LMA is a reliable and safe device and has a high success rate, after a short period of training (Figure 9.60) (Hallstrom et al. 2000, RCUK 2010b).

A *McGill forceps* (Figure 9.61) is a curved forceps which can be used by the anaesthetist for a difficult intubation and to help introduce an endotracheal tube during intubation (Figure 9.62). Tracheal intubation is considered to be superior to other advanced techniques of airway management because the airway is reliably isolated from foreign material in the oropharynx (Hallstrom et al. 2000). Extensive training and regular practice are required to acquire and maintain the skills of intubation, and endotracheal tubes (oral, cuffed, sizes 6, 7 and 8) are kept on emergency trolleys and should be sized according to the patient's size and gender.

An *introducer* such as a gum elastic bougie (Figure 9.63) or a semi-rigid stylet is a useful aid to intubation. Water-soluble lubricating jelly is used prior to intubation or insertion of the LMA or nasopharyngeal airway to aid smooth insertion.

A *laryngoscope* (Figure 9.64) with both curved Macintosh and long blades is used by the anaesthetist to visualize the vocal cords prior to intubation. It consists of a handle with either rechargeable or removable batteries and a light source, which needs to be checked regularly, as well as just before use, and in case of malfunction spare batteries and light sources need to be available (RCUK 2010b).

Assessment and recording tools

Decisions relating to CPR ideally should have been documented prior to a cardiac arrest. Every hospital should have a 'do not attempt resuscitation' (DNAR) policy based on national guidelines (BMA et al. 2002, Jevon 2001).

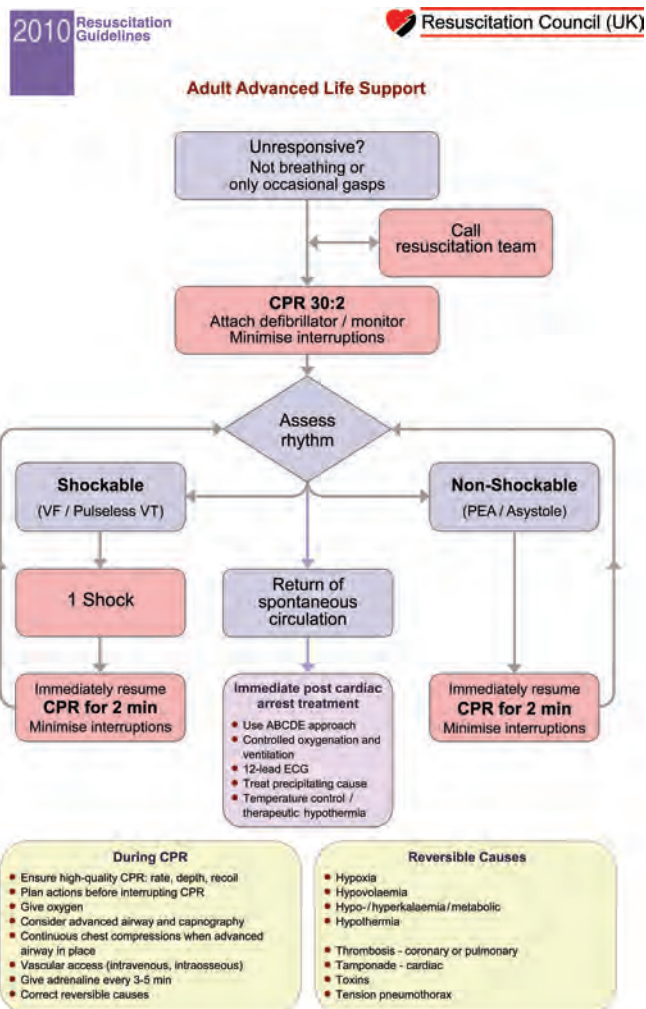

Figure 9.65 The advanced life support algorithm for the management of cardiac arrest in adults. CPR, cardiopulmonary resuscitation; ECG, electrocardiogram; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia. *Source:* Resuscitation Council (2010b). Reproduced with permission from the Resuscitation Council (resus.org.uk).

During and after a cardiac arrest, all resuscitation attempts should be documented for auditing purposes, ideally using a nationally recognized template such as the Utstein template (recommended for use by the RCUK). If these recommendations are implemented, standards in resuscitation and resuscitation training should improve (Jevon 2002).

Pharmacological support

Only a few drugs are indicated during the immediate management of a cardiac arrest and there is only limited scientific evidence supporting their use. Drugs should be considered only after a sequence of shocks has been delivered (if indicated) and chest compressions and ventilation started (RCUK 2010b). Central venous access is optimum as it allows for drugs to be delivered rapidly. However, this is dependent on the skills available. If a peripheral intravenous cannula is already in place, it should be used first (RCUK 2010b). It is also possible to administer drugs using the intraosseous route, which is used commonly in the resuscitation of children.

The drugs used in the treatment of cardiac arrest are as follows.

- **Adrenaline** 1 mg (10 mL of a 1:10,000 solution) given intravenously. The main purpose of adrenaline is to utilize its inotropic effect to maintain coronary and cerebral perfusion during a prolonged resuscitation attempt. It is the first drug used in cardiac arrest of any aetiology. Adrenaline is included in the ALS universal algorithm (Figure 9.65), 1 mg to be given every 3–5 minutes (Nolan et al. 2010).
- **Atropine** is no longer recommended routinely in patients with asystole or PEA, since the 2010 RCUK guidelines update (RCUK 2010b).
- **Amiodarone** (300 mg in 20 mL) should be considered in VF or pulseless VT. It increases the duration of the action potential in the atrial and ventricular myocardium; thus the QT interval is prolonged. In refractory VT or VF following recovery from cardiac arrest, a further 300 mg may be given followed by an infusion of 900 mg over 24 hours (RCUK 2010b). *Note:* Lidocaine can still be considered if amiodarone is not available (RCUK 2010b).
- **Calcium chloride** (10 mL of 10%) is only given during resuscitation when specifically indicated; that is, for the treatment of PEA caused by hyperkalaemia, hypocalcaemia or overdose of calcium channel-blocking drugs (RCUK 2010b). Although it plays a vital role in the cellular mechanisms underlying myocardial contraction, there are few data supporting any

beneficial action for calcium following most cases of cardiac arrest (RCUK 2010b).

- **Sodium bicarbonate** 8.4% is only used in prolonged cardiac arrest or according to serial blood gas analyses. Potential adverse effects of excessive sodium bicarbonate administration include hypokalaemia, exacerbation of respiratory acidosis and increased affinity of haemoglobin for oxygen. The high concentration of sodium can also exacerbate cerebral oedema. Other adverse effects are increased cardiac irritability and impaired myocardial performance. Sodium bicarbonate is usually given in 25–50 mmol aliquots and repeated as necessary. It can also be given in the special circumstances of tricyclic overdose or hyperkalaemia (Winser 2001).
- **Magnesium sulphate:** magnesium (4–8 mmol of 50%) should be given in cardiac arrest where there is a suspicion of hypomagnesaemia as this may precipitate refractory VF/VT (Nolan et al. 2010). It is important to recognize torsades de pointes. Many of these patients are hypomagnesaemic and/or hypokalaemic and part of effective treatment (prevention of recurrent episodes) will be giving intravenous magnesium and correction of any other electrolyte abnormality. The normal value for magnesium is 0.8–1.2 mmol/L (Nolan et al. 2010).

Use pre-filled syringes (mini-jets) whenever possible for speed and ease of use (Figure 9.66). Drugs should be considered only

Figure 9.66 (a) Mini-jet vial and administration chamber with Luer-Lok connector. (b) Remove caps from both mini-jet vials and administration chamber. (c) Screw mini-jet vial into administration chamber. (d) Push vial gently to ensure that medication can be administered and connect Luer-Lok to intravenous device and inject entire contents, followed by 0.9% sodium chloride flush.

after chest compressions and ventilation have been started and, where indicated, defibrillation attempted.

Specific patient preparation

Education

NEWS (National Early Warning Score) (RCP 2012) is a track and trigger system which alerts nurses to when a patient is deteriorating in order to initiate interventions and early referral to critical care outreach teams (DH 2000, NICE 2007, RCP 2012).

This is the most effective method of improving outcome (Jevon 2002). All medical staff should have advanced resuscitation training and senior nurses and doctors working in acute specialties (CCU, ITU, A&E) should hold a valid RCUK ALS certificate.

The importance of prevention of cardiac arrest cannot be highlighted enough. Using a structured communication tool, such as Situation, Background, Assessment, Recommendation (SBAR) (Christie and Robinson 2009, NHS Institute for Innovation and Improvement 2011, RCP 2012), may help to identify patients at risk in a timely manner (RCUK 2010b).

Procedure guideline 9.14 Cardiopulmonary resuscitation

498

Essential equipment

- Airway management
 - Pocket masks with oxygen port
 - Self-inflating resuscitation bag with oxygen reservoir and tubing
 - Clear facemasks in sizes 4, 5 and 6
 - Oropharyngeal airways in sizes 2, 3 and 4
 - Yankauer suckers × 2
 - Endotracheal suction catheters × 10
 - Laryngeal mask airway (size 4) or Combitube (small)
 - McGill forceps
 - Endotracheal tubes: oral, cuffed, sizes 6, 7 and 8
 - Gum elastic bougie
 - Lubricating jelly
 - Laryngoscopes × 2: normal and long blades
 - Spare laryngoscope bulbs and batteries
 - 1 inch ribbon gauze/tape
 - Scissors
 - Syringe: 20 mL
 - Clear oxygen mask with reservoir bag
 - Oxygen cylinders × 2 (if no wall oxygen)
 - Cylinder key

Circulation equipment

- Intravenous cannulas: 18 gauge × 3, 14 gauge × 3
- Hypodermic needles: 21 gauge × 10
- Syringes: 2 mL × 6, 5 mL × 6, 10 mL × 6, 20 mL × 6
- Cannula securement dressings and tapes × 4
- Seldinger wire central venous catheter kits × 2
- 12 gauge non-Seldinger central venous catheter × 2
- Intravenous administration sets × 3
- 0.9% sodium chloride: 1000 mL bags × 2

Pre-procedure

Action

- 1 Note time of arrest, if witnessed.

Rationale

Lack of cerebral perfusion for approximately 3–4 minutes can lead to irreversible brain damage (RCUK 2010b, **C**).

Procedure

- 2 Give patient precordial thump only in witnessed collapse and in cardiac monitored arrest if defibrillator not immediately available.
- 3 Summon help. If a second nurse is available, they can call for the cardiac arrest team, bring emergency equipment and screen off the area.
- 4 Lie patient flat on a firm surface/bed. If on a chair, lower the patient to the floor, ensuring that the head is supported.
- 5 If patient is in bed, remove bed head and ensure adequate space between back of bed and wall.

This may restore cardiac rhythm, which will give a cardiac output. **E**

Single precordial thump has low success rate for cardioversion of shockable rhythm (Haman et al. 2009, **E**).

Maintain patient's privacy and dignity. CPR is more effective with two rescuers. One is responsible for inflating the lungs and the other for chest compressions. Continue until medical help arrives (RCUK 2010b, **C**).

Effective external cardiac massage can be performed only on a hard surface (RCUK 2010b, **C**).

To allow easy access to patient's head in order to facilitate intubation. **E**

Optional equipment

- Extra ECG electrodes
- Extra defibrillation gel pads unless using fast patch electrodes
- Clock
- Gloves/goggles/aprons
- A sliding sheet or similar device should be available for safe handling

Medicinal Products

Immediately available pre-filled syringes of:

- Amiodarone: 300 mg × 1
- Adrenaline: 1 mg (1:10,000) × 4

Other readily available drugs used in CPR

- Epinephrine (adrenaline): 1 mg (1:10,000) × 4
- Sodium bicarbonate 8.4%: 50 mL × 1
- Calcium chloride 10%: 10 mL × 2
- Lidocaine: 100 mg × 2
- 0.9% sodium chloride: 10 mL ampoules × 10
- Naloxone: 400 g × 2
- Epinephrine/adrenaline 1:1000 × 2
- Amiodarone: 150 mg × 4
- Magnesium sulphate 50% solution: 2 g (4 mL) × 1
- Potassium chloride 40 mmol × 1
- Adenosine: 6 mg × 10
- Hydrocortisone: 200 mg × 1
- Glucose 10%: 500 mL × 1

<p>6 Ensure a clear airway. If cervical spine injury is excluded, extend, not hyperextend, the neck (thus lifting the tongue off the posterior wall of the pharynx). This is best achieved by lifting the chin forwards with the finger and thumb of one hand while pressing the forehead backwards with the heel of the other hand (see Figure 9.47). If this fails to establish an airway, there may be obstruction by a foreign body. Try to remove the obstruction if visible. Insert oropharyngeal Guedel airway if you have appropriate training. See Figure 9.57.</p> <p>Do not remove well-fitted dentures.</p>	<p>To establish and maintain airway, thus facilitating ventilation (RCUK 2010b, C).</p> <p>They help to create a mouth-to-mask seal during ventilation. E</p>
<p>7 Place the heel of one hand in the centre of the sternum and place the other on top, ensuring that the hands are located between the middle and the lower half of the sternum. Ensure that only the heel of the dominant hand is touching the sternum.</p> <p>Place the other hand on top, straighten the elbows and make sure shoulders are directly over the patient's chest. The sternum should be depressed sharply by 5–6 cm. The cardiac compressions should be forceful, and sustained at a rate of 100–120 per minute.</p>	<p>To ensure accuracy of external cardiac compression and reduced delay in commencing cardiac compressions (RCUK 2010b, C).</p> <p>This produces a cardiac output by applying direct downward force and compression (Smith 2000, R3).</p>
<p>8 Apply facemask with Ambu-bag over nose and mouth. Compress bag in a rhythmical fashion: the bag should be attached to an oxygen source, 12–15 litres. In order to deliver +85% oxygen, a reservoir may be attached to the Ambu-bag. However, if oxygen is not immediately available, the Ambu-bag will deliver ambient air.</p> <p>9 Maintain cardiac compression and ventilation at a ratio of 30:2. This rate can be achieved effectively by counting out loud 'one and two and', and so on. There should be a slight pause to ensure that the delivered breath is sufficient to cause the patient's chest to rise. This must continue until cardiac output returns and the patient has a palpable blood pressure.</p>	<p>Room air contains only 21% oxygen. In shock, a low cardiac output, together with ventilation/perfusion mismatch, results in severe hypoxaemia. The importance of providing a high oxygen gradient from mouth to vital cells cannot be exaggerated and so oxygen should be added during CPR as soon as it is available (80–100% is desirable) (Simmons 2002, R3).</p> <p>Counting aloud will ensure co-ordination of ventilation and compression ratio. To maintain circulation and oxygenation, thus reducing risk of damage to vital organs. E</p>
<p>10 When the cardiac arrest team arrives, it will assume responsibility for the arrest in liaison with the ward staff.</p>	<p>To ensure an effective expert team co-ordinates the resuscitation (RCUK 2010b, C).</p>
<p>11 Attach patient to ECG monitor using three electrodes or defibrillation patches/paddles.</p>	<p>To obtain adequate ECG signal. Accurate recording of cardiac rhythm will determine the appropriate treatment to be initiated. E</p>
<p>Intubation in CPR</p>	
<p>12 Continue to ventilate and oxygenate the patient before intubation.</p>	<p>The risks of cardiac arrhythmias due to hypoxia are decreased (RCUK 2010b, C).</p>
<p>13 Equipment for intubation should be checked before handing to appropriate medical/nursing staff.</p> <p>(a) Suction equipment is operational.</p> <p>(b) The cuff of the endotracheal tube inflates and deflates.</p> <p>(c) The endotracheal tube is well lubricated.</p> <p>(d) That catheter mount with swivel connector is ready for use.</p>	<p>To ensure all equipment is working prior to use. E</p>
<p>14 During intubation, the anaesthetist may request cricoid pressure. This involves compressing the oesophagus between the cricoid ring and the sixth cervical vertebra.</p>	<p>To prevent the risk of regurgitation of gastric contents and the consequent risk of pulmonary aspiration (RCUK 2010b, C).</p>
<p>15 Recommence ventilation and oxygenation once intubation is completed.</p>	<p>Intubation should interrupt resuscitation only for a maximum of 16 seconds to prevent the occurrence of cerebral anoxia (Handley et al. 1997, R3).</p>
<p>16 Once the patient's trachea has been intubated, chest compressions, at a rate of 100–120 per minute, should continue uninterrupted (except for defibrillation and pulse check when indicated) and ventilation should continue at approximately 12 breaths per minute. Compression should continue while the defibrillator is charging.</p>	<p>Uninterrupted compression results in a substantially higher mean coronary perfusion pressure. A pause in chest compressions allows the coronary perfusion pressure to fall. On resuming compressions, there is some delay before the original coronary perfusion pressure is restored (RCUK 2010b, C). Reducing the pre-shock pause improves time of compression which has a more favourable outcome for the patient (Deakin et al. 2010, C).</p>

(continued)

Procedure guideline 9.14 Cardiopulmonary resuscitation (*continued*)**Action****Rationale****Intravenous access in CPR**

17 Venous access must be established through a large vein as soon as possible.

To administer emergency cardiac drugs and fluid replacement (RCUK 2010b, **C**).

18 Asepsis should be maintained throughout.

To prevent local and/or systemic infection (Fraise and Bradley 2009, **E**).

19 The correct rate of infusion is required.

To ensure maximum drug and/or solution effectiveness. **E**

20 Accurate recording of the administration of solutions infused and drugs added is essential.

To maintain accurate records, provide a point of reference in the event of queries and prevent any duplication of treatment (NMC 2010, **C**).

500

Defibrillation

21 Apply pads/paddles to chest. It may be necessary to shave the chest.

To ensure the pads/paddles are applied correctly and make adequate contact which enhances electrical contact (van Alem et al. 2003, **E**).

22 Remove oxygen source at least 1 metre from patient unless intubated.

To reduce the risk of sparks igniting the oxygen source (Nolan et al. 2005, **E**).

23 The person delivering the shock must ask all members of the resuscitation team to stand clear of the patient.

To ensure that none of the resuscitation team are in contact with the patient or the bed as they may also receive the shock (Perkins and Lockey 2008, **E**).

24 Deliver a single shock to treat VF/pulseless VT.

To terminate pulseless VT, VF and restart the heart by depolarizing its electrical conduction system and delivering brief measured electrical shocks to the chest wall or the heart muscle itself (Eftestol et al. 2002, **E**; Wik et al. 2003, **R1**).

Post-procedure

25 Check patient by assessing airway, breathing, circulation, blood pressure and urine output.

To ensure a clear airway, adequate oxygenation and ventilation and aim to maintain normal sinus rhythm and a cardiac output adequate for perfusion of vital organs. To ensure adequacy of ventilation and oxygenation (Perkins and Lockey 2008, **E**).

26 Check arterial blood gases.

To ensure rapid correction of acid/base balance, potassium, glucose and haemoglobin results as an ABG result is available much quicker than laboratory blood results (RCUK 2010b, **C**).

27 Check full blood count, clotting and biochemistry.

To exclude anaemia as a contributor to myocardial ischaemia. A clotting disorder may have contributed to a major haemorrhage. Replacement stored blood for transfusion has fewer clotting factors and the patient may require replacement of clotting factors usually in the form of fresh frozen plasma. **E**

To assess renal function and electrolyte balance (K^+ , Mg^{2+} and Ca^{2+}). To ensure normoglycaemia. To commence serial cardiac enzyme assay (Nolan et al. 2005, **C**; RCUK 2010b, **C**).

28 Monitor patient's cardiac rhythm and record 12-lead ECG.

Normal sinus rhythm is required for optimum cardiac function (RCUK 2010b, **C**). An assessment of whether cardiac arrest has been associated with a myocardial infarction should be made, as the patient may be suitable for coronary angioplasty or thrombolytic therapy (Nolan et al. 2005, **C**).

29 A chest X-ray should be taken.

To establish correct position of tracheal tube, gastric tube and central venous catheter. To exclude left ventricular failure, pulmonary aspiration and pneumothorax. To establish size and shape of heart (Nolan et al. 2006, **C**).

30 Continue respiratory therapy aiming for SpO_2 94–98% for adults.

Hypoxia and hypercarbia both increase the likelihood of a further cardiac arrest (RCUK 2010b, **C**).

31 Assess patient's level of consciousness. This can be done by use of the Glasgow Coma Scale. Although this is intended primarily for head injury, it is clinically relevant. It contains five levels of consciousness.

Once a heart has been resuscitated to a stable rhythm and cardiac output, the organ that influences an individual's survival most significantly is the brain. Initial assessment and regular monitoring will alert the nurse to any changes in function (RCUK 2010b, **C**).

(a) Conscious and alert

(b) Drowsy but responsive to verbal commands

(c) Unconscious but responsive to minimal painful stimuli

(d) Unconscious and responsive to deep painful stimuli

(e) Unconscious and unresponsive.

32 The patient should be stable prior to any transfer and nursed in the appropriate position, that is semi-Fowler or the recovery position. Avoid nursing supine as this physiologically hinders cardiac output and respiration, unless clinically indicated for patients with acute head or spinal cord injury. Careful explanation and reassurance are vital at all times, particularly if the patient is conscious and aware.

Transferring a patient post arrest may pose risks because of changes in their haemodynamic status. This is due to movement of the trolley – inertia, changes in environment and/or changing equipment, which may impact negatively on the patient's physiological status (Shirley and Bion 2004, **E**).

Nursing a patient in semi-Fowler's position ensures good air entry and reduces risks of aspiration for patients not contraindicated for head of bed to be elevated (Tablan et al. 2004, **C**).

Problem-solving table 9.7 Prevention and resolution (Procedure guideline 9.14)

Problem	Cause	Prevention	Suggested action
Defibrillator not working.	Battery pack not charged.	Ensure defibrillator is plugged into the mains so battery can recharge.	Check defibrillator when doing emergency trolley checks as per hospital policy.
No trace when ECG dots or pads are on patient.	ECG dots or pads dry. Test plug connected to lead.	Change ECG dots/pads as they can dry out. Ensure that the test plug is not attached.	Check expiry dates of ECG dots/pads when checking emergency trolley/equipment. After emergency trolley checks, ensure that the test plug is no longer attached.
Staff unable to use defibrillator.	Not had training.	Mandatory yearly BLS training for staff who will be present during CPR, and ALS every 3 years for staff who work in specialized areas, for example critical care. Standardize equipment throughout the hospital.	Find a member of staff who is trained in using defibrillator. AED defibrillators should be available as they can be used by people without previous training.
Laryngoscope light not working.	Laryngoscope handle not charged.	Ensure that the laryngoscope handle is charged using rechargeable batteries or new batteries inserted. Change laryngoscope light.	Check laryngoscope when doing resuscitation equipment checks as per hospital policy. If using rechargeable batteries, ensure laryngoscope handle is docked. Have spare batteries if not using rechargeable. Have spare light bulbs/spare disposable laryngoscope blades on the emergency trolley.
Portable suction not working.	Battery pack not charged. Incorrectly connected tubing.	Ensure that suction unit is plugged in so battery can charge. Check that tubing correctly connected.	Check portable suction is on charge and tubing correctly connected when checking resuscitation equipment as per hospital policy.
Emergency drugs missing/expired.	Trolley not checked. Equipment removed without being replaced.	Have a checklist of the emergency drugs that need to be on the resuscitation trolley.	Check drugs and expiry dates when checking resuscitation equipment and resuscitation trolley as per hospital policy and lock trolley for safekeeping of drugs.
Equipment missing off resuscitation trolley.	Removal of equipment without replacing or returning it.	Have a checklist of all equipment needed on resuscitation trolley.	Check resuscitation trolley list as per hospital policy. Replace any missing or expired equipment. Seal/lock trolley after checks/use. Educate all staff not to remove equipment from trolley other than in a cardiac arrest.

Post-procedural considerations

Immediate care

Following stabilization of the patient post cardiac or respiratory arrest, consideration should be given to moving them to an appropriate critical care or high-dependency environment. All established monitoring should continue during transfer and the patient should be transferred by individuals capable of monitoring the patient and responding appropriately to any change in their condition, including a further cardiac arrest. A critical care outreach service or designated transfer team, if available, may contribute to the care of the patient during stabilization and transfer (Nolan et al. 2006, RCUK 2010b, Shirley and Bion 2004).

502 Ongoing care

The patient's haemodynamic status should be continually monitored post resuscitation, as well as observing their level of consciousness, respiration rate and if possible urine output. Monitor blood glucose levels in adults with sustained return of spontaneous circulation (ROSC) after cardiac arrest. Maintaining blood glucose values >10 mmol/L, they should be treated in an HDU/ICU environment, but hypoglycaemia must be avoided (RCUK 2010b). Documentation of physiological parameters needs to continue and any change in haemodynamic status needs to be reported to the medical team or senior nursing staff attending to the patient prior to transfer to the CCU or HDU.

The Intensive Care Society (UK) has published guidelines for the transport of the critically ill adult (www.ics.ac.uk). These outline the requirements for equipment and personnel when transferring critically ill patients (Nolan et al. 2006, RCUK 2006, Sandroni et al. 2007, Shirley and Bion 2004).

Careful explanation and reassurance must be given to the patient before transfer, particularly if the patient is conscious and aware. The patient's relatives will require considerable support and will need to be kept informed of the transfer of their relative and to where. It is important that if the family were not present during the arrest, the appropriate member of the medical team contacts the next of kin and informs them of the arrest and its outcome. If the patient has survived, the next of kin/family will need to know that the patient has been moved to a more appropriate environment for continued monitoring.

Note: Whether the resuscitation attempt was successful or not, the pastoral needs of all those associated with the arrest should not be forgotten (RCUK 2010b, Sandroni et al. 2007).

Documentation

Good record keeping is an integral part of nursing practice, and is essential to the provision of safe and effective care (NMC 2010). There must be documentary evidence of how decisions relating to the patient were made. Accurate recording of the administration of solutions infused and drugs added is essential. All resuscitation attempts should be audited, ideally using a nationally recognized template such as the Utstein template (recommended by the RCUK 2010b). Hospitals should collect data regarding cardiac arrest for the National Cardiac Arrest Audit (NCAA) (RCUK 2010b).

Education of patient and relevant others

Prevention of cardiac arrest is the most important factor for survival. Education of the patient and relevant others needs to start at first contact with healthcare professionals regarding lifestyle changes, diet, exercise, smoking cessation, and regular check-ups to treat or control any underlying causes such as hypertension and diabetes.

Complications

Some possible complications may arise from cardiopulmonary resuscitation.

- Gastric distension due to bagging too forcefully and/or too quickly, causing air to enter the stomach. A nasogastric tube

should be inserted as soon as the airway is secure, to help prevent and manage gastric distension which may cause vomiting and possible aspiration into the lungs.

- Fractured ribs, sternum, punctured lungs can occur as a result of chest compressions. The correct placement of hands during chest compression is vital in helping to prevent fracturing of ribs and sternum.
- Transmission of disease through mouth-to-mouth ventilation. The use of a pocket resuscitation mask with a one-way valve will prevent the transmission of infection from bodily fluids during ventilation (DH 2007).

Overview

In clinical practice nursing staff are required to instigate, participate or assist in diagnostic tests and the collection of body fluids and/or specimens for varying purposes. This chapter will discuss common diagnostic tests encountered in clinical practice.

Diagnostic tests

Definition

A diagnostic test is a procedure that is used to aid in the detection and/or diagnosis of disease (Chernecky and Berger 2013, Higgins 2013).

Related theory

Diagnostic tests are undertaken to aid in diagnosis and treatment of various conditions. The tests are used to identify diseases from their characteristics, signs and symptoms and to identify changes or abnormalities. Diagnostic tests include blood sampling from a vein or from central venous access devices to determine the haematological and biochemical status of patients, lumbar puncture for diagnostic and treatment purposes, liver biopsy, semen collection and cervical swabbing. Depending on the clinical picture, radiological investigations such as X-ray, computed tomography (CT) or magnetic resonance imaging (MRI) may be required. Other more invasive diagnostic procedures such as endoscopy may also be required.

Evidence-based approaches

Rationale

Diagnostic tests are essential in the healthcare setting but their selection and use must be considered carefully. The overuse of diagnostic tests is a contributor to needless healthcare costs, hence it is essential that healthcare providers and professionals ensure that the tests used are of adequate benefit to the patient's health (Qaseem et al. 2012). This leads to poor quality services and continuing financial pressure on departments and organizations (Korenstein et al. 2012). For example, a faecal sample from a patient who also has a history of recent travel would be investigated for organisms not normally looked for in a specimen from a patient without such a history. The sensitivity of the organism to a range of antimicrobials can then be tested to decide on the most appropriate and effective mode of treatment (Higgins 2013). Diagnostic tests may include the collection of samples or procedures that assist in the diagnosis and treatment of a patient's condition.

Successful laboratory diagnosis depends upon the collection of specimens at the appropriate time, using the correct technique and equipment, and transporting them to the designated laboratory safely without delay (Box 10.1). For this to be achieved, it is essential that there is good liaison between medical, nursing, portering and laboratory staff (Mims 2004).

Indications

Conducting a diagnostic test or collecting a specimen is often the first crucial step in determining diagnosis and subsequent mode

of treatment for patients with suspected infections or to aid in the diagnosis of specific conditions. In other aspects the collection or test may help determine variation from normal values such as blood sampling or endoscopic findings.

Principles of care

Nursing staff play a key role within the diagnostic testing process because they often identify the need for diagnostic and/or microbiological investigations, initiate the collection of specimens and assume responsibility for timely and safe transportation to the laboratory (Higgins 2013). Specimen collection is often the first crucial step in investigations that define the nature of the disease, determine a diagnosis and therefore the mode of treatment.

Methods of investigation

Initial examination

The initial assessment of the patient will determine the potential diagnostic tests or samples that are required. Dependent on how the patient progresses, their clinical history and/or symptom progression will determine the need for further diagnostic tests. For example, specimens will be initially examined for clinical variables such as odour, appearance, consistency and turbidity. Foul-smelling, purulent material is suggestive of anaerobic bacteria, cloudy cerebrospinal fluid (CSF) or urine suggests the presence of neutrophils, stool may contain blood or mucus and parasites such as roundworms or tapeworms which are visible to the naked eye (Gould and Brooker 2008).

Direct microscopy

The majority of specimens will then undergo direct microscopic investigation which is valuable as an early indication of the causative organism. High magnification is required to visualize viruses, which are then identified according to their characteristic shapes (Gould and Brooker 2008). Certain parasitic protozoa, such as those causing malaria, are identified by direct microscopy which necessitates the specimen being delivered to the laboratory as quickly as possible whilst the protozoa are mobile and therefore visible (Higgins 2013). In combination with clinical presentations, this may be enough to initiate or change targeted treatments until a more definitive diagnosis is reached (Weston 2008).

Gram staining

Gram staining is a process by which staining substances are added to a sample to differentiate the type of organisms present. Cells with differing properties stain differently in relation to the structure of their cell wall (Mims 2004).

Gram staining allows for the differentiation between Gram-positive bacteria (e.g. *Staphylococcus aureus*), which stain purple, and Gram-negative bacteria (e.g. *Escherichia coli*), which stain pink when viewed under the microscope. This can be used to guide the choice of antimicrobial therapy until other investigation methods can provide a definitive identification of pathogenic micro-organisms (Mims 2004).

Culture

Depending upon the type of specimen sent to the laboratory and the suspected causative organism, a liquid or solid medium will be selected to enable further identification. Clinical specimens are inoculated onto agar plates or into nutrient broth, then incubated for a certain period of time and observed for growth (Weston 2008). Different species or strains have different growth rates; for example, *Pseudomonas* and *Clostridium* multiply in approximately 10 minutes, *Escherichia coli* has a growth rate of 8 hours whilst *Mycobacterium tuberculosis* takes 18–24 hours to grow (Weston 2008). Growth of bacteria is seen as colonies on the culture media and the size, colour and shape vary according to the type of bacteria identified (Gould and Brooker 2008).

Fungal organisms grow in the same type of media as those used for bacteria, although they generally require an incubation

Box 10.1 Good practice in specimen collection

- Appropriate to the patient's clinical presentation.
- Collected at the right time.
- Collected in a way that minimizes the risk of contamination.
- Collected in a manner that minimizes the health and safety risk to all staff handling the sample.
- Collected using the correct technique, with the correct equipment and in the correct container.
- Documented clearly, informatively and accurately on the request forms.
- Stored/transported appropriately.

Source: Higgins (2008 a,b). Reproduced with permission from EMAP Publishing Ltd.

period of 24–48 hours (Higgins 2013). Pathogenic fungi can also be grown on special mycological media, upon which they grow better with less risk of bacterial overgrowth (Mims 2004). Fungi are identified by their characteristic appearance on the surface of the agar and microscopic appearance (Gould and Brooker 2008). The presence of fungi, such as *Candida albicans*, is sometimes difficult to interpret because they are commonly present in the upper respiratory, alimentary and female genital tracts, and on the skin of healthy people. However, in patients who are immunocompromised this fungus can lead to systemic disease (Garber 2001).

Viruses cannot be cultured outside living cells, although cells grown in nutrient material can be used to culture certain viruses. Their identification is indicated by the characteristic way in which they change the shape of the cell (Gould and Brooker 2008).

Antibiotic sensitivity

Once the pathogenic organism has been identified, it is vital to establish which antibiotics it is sensitive to so the appropriate therapy can be prescribed (Gould and Brooker 2008). The bacteria are inoculated onto a solid media plate and paper discs impregnated with different antibiotics are placed over them and incubated. If the bacteria are sensitive to a particular antibiotic, their growth is inhibited, resulting in a clear zone around the disc.

Serology

Serology is useful in identifying viral infections and bacterial infections with difficult culture organisms and is based upon the host's immunological reaction. Detection of antigens or antibodies in serum, which are activated in response to infection, may suggest that the patient is, or has been, infected (Higgins 2013).

Despite the disadvantage of the test being performed retrospectively, antibody testing is the main method for diagnosing viral infections (Mims 2004). Two serum tests are collected, once at the beginning of the illness and again at 10–14 days, and compared for changes in antibody content. A raised content suggests that the patient's infection is current (Mims 2004).

Histology

Histology is the study of cells and tissues within the body. It also studies how the tissues are arranged to form organs. The histological focus is on the structure of individual cells and how they are arranged to form the individual organs. The types of tissues that are recognized are epithelial, connective, muscular and nervous (Junqueira and Carneiro 2005).

The tissues are examined under a light microscope where light passes through the tissue components after they have been stained. As most tissues are colourless, they are stained with dyes to enable visualization. An alternative is the electron microscope in which the cells and tissue can be viewed at magnifications of about 120,000 times (Junqueira and Carneiro 2005).

Legal and professional issues

An organization providing diagnostic services must have clear identifiable policies and procedures. Bidirectional communication must be open between the department, organizational board and national bodies to ensure appropriate care is delivered. Monitoring processes must be in place to identify potential clinical or organizational risks and have a clear reporting mechanism.

Competencies

In accordance with the NMC's *The Code: Standards of Conduct, Performance and Ethics* (NMC 2015), the collection of specimens should be undertaken by professionals who are competent and feel confident that they have the knowledge, skill and understanding to do so, following a period of appropriate training and assessment. For microbiological sampling, this will include knowledge and understanding of the collection, handling and transportation of samples to optimize quality and minimize contamination and inadvertent subversion of the specimen, all of which may have subsequent implications for patient treatment and care.

Consent

It is therefore essential that healthcare practitioners gain consent before beginning any treatment or care; this includes the collection of samples or conducting a diagnostic test (NMC 2013). Consent is continuous throughout any patient episode and the practitioner must ensure that the patient is kept informed at every stage (Marsden 2007). For specimen collection this includes:

- informing the patient of the reason for specimen collection
- what the procedure will involve
- ascertaining their level of understanding (especially if they need to be directly involved in the sampling technique)
- how long the results may take to be processed
- how the results will be made available
- information about the implications this may have for their care.

Risk management

New research and evidence continue to be produced. It is essential that any risk or change in practice is communicated to clinicians. Alerts from the Medicines and Healthcare Products Regulatory Agency (MHRA) and changes in practice should be acted upon. Several agencies such as the Health Protection Agency (HPA) also contribute new guidance and best practice using the latest available evidence.

Accurate record keeping and documentation

Good record keeping is an integral part of nursing practice, and it is essential to the provision of safe and effective care (NMC 2010). Accurate, specific and timely documentation of specimen collection or diagnostic tests should be recorded in the patient notes, care plan or designated record charts/forms such as a microbiological flow chart that details when a specimen was collected, results of analysis, sensitivities or resistance to antimicrobials and changes/modifications to treatment. It is also important to ensure that electronic records are up to date. This assists in the communication and dissemination of information between members of the interprofessional healthcare team.

Pre-procedural considerations

Equipment

There is a variety of equipment/tools designed for the collection of specimens such as sterile pots, swabs and other receptacles (Figure 10.1, Figure 10.2, Figure 10.3, Figure 10.4). Advice should be sought from the microbiology department about the best type of container for the required investigation (Higgins 2013). It is essential that the specimen and its transport container are appropriate for the type of organism being investigated; for example, bacterial swabs contain a transport medium that is incompatible with viral specimen analysis. Failure to utilize the correct collection method leads to inaccurate results so it is vital that an adequate quantity of material is obtained to allow complete microbiological examination.

Equipment used for transportation

Within healthcare institutions, specimens should be transported in deep-sided trays that are not used for any other purpose, and are disinfected weekly and whenever contaminated (HSE 2003), or robust, leak-proof containers that conform to 'Biological Substances, Category B – UN3373' regulations (HSE 2005). Specimens that need to be moved outside the hospital must be transported using a triple-packaging system (HSE 2005). This consists of a watertight, leak-proof, absorbent primary container, a durable, watertight, leak-proof secondary container and an outer container that complies with 'Biological Substances, Category B – UN 3373' standards (Pankhurst and Coulter 2009). A box for transportation is essential and should carry a warning label for hazardous material. It must be made of smooth impervious material, such as plastic or metal, which will retain liquid and can be easily disinfected and cleaned in the event of a spillage (HSE 2003).

Figure 10.1 Sputum pot.

Handling specimens

Specimens should be obtained using safe techniques and practices, and practitioners should be aware of the potential physical and infection hazards associated with the collection of diagnostic specimens within the healthcare environment. Standard (universal) infection control precautions should be adopted by healthcare workers who have direct contact or exposure to the blood, bodily fluids, secretions and excretions of patients (European Biosafety Network 2010, Gould and Brooker 2008). In addition to personal protection, the person collecting the specimen should also be

Figure 10.2 Various stool pots.

Figure 10.3 Urine pot.

mindful of the collective health and safety of other people involved in the handling of samples. Every health authority must ensure that medical, nursing, phlebotomy, portering and any other staff involved in handling specimens are trained to do so (RCN 2012).

In relation to specimen collection, standard (universal) infection control precautions should include the following (Tilmouth and Tilmouth 2009).

- Hand hygiene.
- The use of personal protection equipment (PPE).
- Safe sharps management.
- Safe handling, storage and transportation of specimens.
- Waste management.
- Clean environment management.
- Personal and collective management of exposure to body fluids and blood.

Figure 10.4 Variety of swabs.

Selection of PPE should be based upon an assessment of risk of exposure to body fluids. As minimum precautions, gloves and aprons should be worn when handling all body fluids. Protective face wear (e.g. goggles, masks and visors) should be worn during any procedure where there is risk of blood, bodily fluid, secretions or excretions splashing into the eyes or face (Gould 2002, RCN 2012).

Specimens should be placed in a double, self-sealing bag with one compartment containing the specimen and the other containing the request form. The specimen container used should be appropriate for the purpose and the lid should be securely closed immediately to avoid spillage and contamination. The specimen should not be overfilled and not be externally contaminated by the contents. Any accidental spillages must be cleaned up immediately by staff wearing appropriate protective equipment (HSE 2003, RCN 2012).

If a specimen is suspected or known to present an infectious hazard, particularly Hazard Group 3 pathogens (such as hepatitis B or C virus, HIV, *Mycobacterium tuberculosis*), this must be clearly indicated with a 'danger of infection' label on the specimen and the request form to enable those handling the specimen to take appropriate precautions (HSE 2003).

Specimens from patients who have recently been treated with toxic therapy such as gene therapy, cytotoxic drugs, radioactivity or active metabolites need to be handled with caution. Local guidelines on the labelling, bagging and transportation of such samples to the laboratory should be followed. For example, in the case of gene therapy, the specimen must be labelled with a 'bio-hazard' label, double bagged and transported to the laboratory in a secure box with a fastenable lid.

Selecting specimens

Selecting a specimen that is representative of the disease process is critical to the ability of the laboratory to provide information that is accurate, significant and clinically relevant. Incorrect specimen selection or technique can be life threatening to patients (Wegerhoff 2006). Specimens should only be taken when there are clinical signs of infection (or in the case of specific swabs, such as skin or nasal swabs, as part of an infection screening regimen). Signs of infection such as fever should trigger a careful clinical assessment to ensure that unnecessary tests are avoided and the most useful laboratory samples are obtained to identify therapeutic options (Gould and Brooker 2008). Specimens may also be collected for other diagnostic procedures such as cervical smears, semen collection and lumbar puncture. Tissue sampling may also be indicated during endoscopy or biopsies.

Wherever possible, specimens should be collected before patients are commenced on any treatment such as antibiotics or antiseptics. Treatment with antibiotics before the causative organism has been identified may inhibit its growth, so that it is not easily detected during analysis, yielding a misleading false negative (Weston 2008). If, however, the patient is already receiving such treatment, this must be clearly indicated on the requisition form.

Assessment and recording tools

Request forms

The form should include as much information as possible as this allows the laboratory or department conducting the investigation to select the most appropriate equipment and/or media for examination (Weston 2008).

Request forms should include the following information.

- Patient's name, date of birth, ward and/or department.
- Hospital number.
- Investigation required so as to avoid indiscriminate specimen analysis which wastes time and money.
- Date and time of specimen collection.
- Type and site of specimen. This should specify the actual anatomical site, such as 'abdominal wound', as this allows the

laboratory to differentiate the target and non-target pathogens and assess the significance of results based upon the flora normally associated with that site (Wegerhoff 2006).

- Diagnosis and relevant clinical information which can help in the interpretation of a sample (Higgins 2013).
- Relevant signs and symptoms.
- Relevant history, for example recent foreign travel.
- Present or recent antimicrobial therapy.
- Whether the patient is immunocompromised as these patients are highly susceptible to opportunistic infections and non-pathogenic organisms (Weston 2008).
- Consultant's name.
- Name and contact details of the doctor requesting the investigation, as it may be necessary to telephone the result before the report is dispatched.
- If a high-risk specimen, it should be labelled with a 'danger of infection' label (HSE 2003).

Communication

For certain specimens that have specific collection techniques or require prompt processing, communication with the laboratory before the sample collection and/or providing information that a sample is being sent to the laboratory can improve efficiency of processing and accuracy of results. Where a diagnostic test is to be undertaken, it is essential that the patient is prepared appropriately with consideration of fasting times, the cessation of certain medications and post-procedural care. A patient information leaflet explaining the test can be given to prepare the patient. Communication with the department where the test will be conducted is essential.

Collecting specimens

The production of high-quality, accurate results which are clinically useful is very much dependent upon the quality of the specimen collection (Higgins 2013, Wegerhoff 2006). The greater the quantity of material sent for laboratory examination, the greater the chance of isolating a causative organism.

Specimens should be taken as soon as possible after the manifestation of clinical signs and symptoms. The timing of specimen collection is especially important during the acute phase of viral infections. Many viral illnesses have a prodromal phase where multiplication and shedding of the virus are usually at their peak and when the patient is most infective (Mims 2004). This is often before the onset of clinical illness and has often ceased by about day 5 from the onset of symptoms. At this stage, the patient's immune response against the virus has already been mounted and may therefore affect organism isolation (Winter 2005).

Specimens are readily contaminated by poor technique and analysis of such specimens could lead to adverse outcomes such as misdiagnosis, misleading results, extended length of stay, inappropriate therapy or potentially disastrous consequences for the patient (Wegerhoff 2006). Therefore, a clean technique must be used to avoid inadvertent contamination of the site of the sample or the specimen itself. Specimens should also be collected in sterile containers with close-fitting lids.

Post-procedural considerations

Labelling specimens

Prompt microbiological analysis is only possible if specimens and their accompanying request forms are sent with specific, accurate and complete patient information. Incorrectly labelled or unlabelled specimens will be discarded (HSE 2003).

Samples should include the following information.

- Patient's name, date of birth, ward and/or department.
- Hospital number.
- Date and time of specimen collection.
- Type and site of specimen. This should specify the actual anatomical site such as 'abdominal wound' as this allows the

Table 10.1 Types of organisms

Organism	Definition
Aerobic	Aerobic bacteria will only grow in the presence of oxygen
Anaerobic	Anaerobic bacteria prefer an atmosphere of reduced oxygen, such as deep in wound bed tissue, and facultative anaerobes can grow in either the presence or absence of oxygen
Bacteria	Bacteria are unicellular organisms that multiply and die very rapidly, especially once removed from their optimum environment
Virus	Viruses are intracellular parasites that hijack the genetic material of the host cell, and are therefore unable to multiply outside living cells

Source: Adapted from Gould and Brooker (2008), Higgins (2013), Winter (2005).

laboratory to differentiate the target and non-target pathogens and assess the significance of results based upon the flora normally associated with that site (Wegerhoff 2006).

- If a high-risk specimen, it should be labelled with a ‘danger of infection’ label (HSE 2003).

Transporting specimens

An awareness of the type of organism being investigated and their growth requirements gives the healthcare professional an insight into the correct collection, storage and transportation methods (Table 10.1). Most micro-organisms are also extremely susceptible to environmental fluctuations such as pH, temperature, ultraviolet rays and oxidizing agents (Gould and Brooker 2008). Incorrect or prolonged storage or transportation may result in the organism not surviving before cultures can be made (Gill et al. 2005). Delays in transporting a specimen to the laboratory can compromise the specimen’s integrity, leading to false-negative or -positive results, because the sample is no longer representative of the disease process (Higgins 2013).

The sooner a specimen arrives in the laboratory, the greater the chance of organisms being identified. Some pathogens do not survive once they have left the host, whilst normal body flora within the sample may proliferate and overgrow, inhibiting or killing the pathogen (Weston 2008).

If delays are anticipated, samples need to be stored appropriately, depending on the nature of the specimen, until they can be processed. For example, blood cultures need to be incubated at 37°C, whereas swabs must be either refrigerated or kept at ambient temperature, depending on the site from which they were taken.

The transport of clinical specimens must conform to health and safety legislation and regulations, and there are more specific guidelines on the labelling, transport and reception of specimens within clinical laboratories and similar facilities (HSE 2003).

Blood: obtaining samples from a peripheral vein (venepuncture)

Definition

Venepuncture is the procedure of entering a vein with a needle (Weller 2009).

Anatomy and physiology

The superficial veins of the upper limb are most commonly chosen for venepuncture. These veins are numerous and accessible, ensuring that the procedure can be performed safely and with

minimum discomfort (McCall and Tankersley 2012). In adults, veins located on the dorsal portion of the foot may be selected but there is an increased risk of complications, especially if the patient has diabetes or a history of vascular/coagulation disorders (Hoeltke 2013). Therefore, veins in the lower limbs should be avoided where possible.

Vein choice

The veins commonly used for venepuncture are those found in the antecubital fossa because they are sizeable veins capable of providing copious and repeated blood specimens (Weinstein and Plumer 2007). However, the venous anatomy of each individual may differ. The main veins of choice are the (Figure 10.5):

- median cubital veins
- cephalic vein
- basilic vein
- metacarpal veins (used only when the others are not accessible).

Median cubital vein

The median cubital vein may not always be visible, but its size and location make it easy to palpate. It is also well supported by subcutaneous tissue, which prevents it from rolling under the needle (Hoeltke 2013).

Figure 10.5 (a) Superficial veins of the forearm. (b) Superficial veins of dorsal aspect of the hand.

Cephalic vein

On the lateral aspect of the wrist, the cephalic vein rises from the dorsal veins and flows upwards along the radial border of the forearm as the median cephalic, crossing the antecubital fossa as the median cubital vein. Care must be taken to avoid accidental arterial puncture, as this vein crosses the brachial artery. It is also in close proximity to the radial nerve (Dougherty 2008, Jenkins and Tortora 2013).

Basilic vein

The basilic vein, which has its origins in the ulnar border of the hand and forearm (Marieb and Hoehn 2010), is often overlooked as a site for venepuncture. It may well be prominent but is not well supported by subcutaneous tissue, making it roll easily, which can result in difficult venepuncture. Owing to its position, a haematoma may occur if the patient flexes the arm on removal of the needle, as this squeezes blood from the vein into the surrounding tissues (McCall and Tankersley 2012, Weinstein and Plumer 2007). Care must also be taken to avoid accidental puncture of the median nerve and brachial artery (Garza and Becan-McBride 2013).

Metacarpal veins

The metacarpal veins are easily visualized and palpated. However, the use of these veins may not be suitable in the elderly because skin turgor and subcutaneous tissue are diminished which makes the veins more difficult to anchor (McCall and Tankersley 2012, Weinstein and Plumer 2007).

Layers of the vein

Veins consist of three layers: the tunica intima, the tunica media and the tunica adventitia.

Tunica intima

The tunica intima is a smooth endothelial lining, which allows the passage of blood cells. If it becomes damaged, the lining may become roughened, leading to an increased risk of thrombus formation (Jenkins and Tortora 2013, Weinstein and Plumer 2007). Within this layer are folds of endothelium called valves, which keep blood moving towards the heart by preventing backflow. Valves are present in larger vessels and at points of branching and are seen as noticeable bulges in the veins (Jenkins and Tortora 2013). However, when suction is applied during venepuncture, the valve can compress and close the lumen of the vein, thus preventing the withdrawal of blood (Weinstein and Plumer 2007). Therefore, if detected, venepuncture should be performed above the valve in order to facilitate collection of the sample (Weinstein and Plumer 2007).

Tunica media

The tunica media, the middle layer of the vein wall, is composed of muscular tissue and nerve fibres, both vasoconstrictors and vasodilators, which can stimulate the vein to contract or relax. This layer is not as strong or stiff as an artery and therefore veins can distend or collapse as the pressure rises or falls (Jenkins and Tortora 2013, Waugh and Grant 2010, Weinstein and Plumer 2007). Stimulation of this layer by a change in temperature, mechanical or chemical stimulation can produce venous spasm, which can make a venepuncture more difficult.

Tunica adventitia

The tunica adventitia is the outer layer and consists of connective tissue, which surrounds and supports the vessel (Jenkins and Tortora 2013).

Arteries tend to be placed more deeply than veins and can be distinguished by the thicker walls, which do not collapse, the presence of a pulse and the bright red blood. It should be noted that aberrant arteries may be present; these are arteries located superficially in an unusual place (Jenkins and Tortora 2013, Weinstein and Plumer 2007).

Choosing a vein

The choice of vein must be that which is best for the individual patient. The most prominent vein is not necessarily the most suitable vein for venepuncture (Weinstein and Plumer 2007). There are two stages to locating a vein:

- 1 visual inspection
- 2 palpation.

Visual inspection

Visual inspection is the scrutiny of the veins in both arms and is essential prior to choosing a vein. Veins adjacent to foci of infection, bruising and phlebitis should not be considered, owing to the risk of causing more local tissue damage or systemic infection (Dougherty 2008). An oedematous limb should be avoided as there is danger of stasis of lymph, predisposing to complications such as phlebitis and cellulitis with increased risk of causing tissue damage from the tourniquet application (Hoeltke 2013, Smith 1998). Areas of previous venepuncture should be avoided as a build-up of scar tissue can cause difficulty in accessing the vein and can result in pain due to repeated trauma (Hoeltke 2013).

Palpation

Palpation is an important assessment technique, as it determines the location and condition of the vein, distinguishes veins from arteries and tendons, identifies the presence of valves and detects deeper veins (Dougherty 2008). The nurse should always use the same fingers for palpation as this will increase sensitivity and the ability of the nurse to know what they are feeling. The less dominant hand should be used for palpation so that in the event of a missed vein, the nurse can repalpate and realign the needle (Hoeltke 2013). The thumb should not be used as it is not as sensitive and has a pulse, which may lead to confusion in distinguishing veins from arteries in the patient (Weinstein and Plumer 2007).

Thrombosed veins feel hard and cord-like, and should be avoided along with tortuous, sclerosed, fibrosed, inflamed or fragile veins, which may be unable to accommodate the device to be used and will result in pain and repeated venepunctures (Dougherty 2008). Use of veins which cross over joints or bony prominences and those with little skin or subcutaneous cover, for example the inner aspect of the wrist, will also subject the patient to more discomfort (Dougherty 2008). Therefore, preference should be given to a vessel that is unused, easily detected by inspection and palpation, patent and healthy. These veins feel soft and bouncy and will refill when depressed (Weinstein and Plumer 2007).

Evidence-based approaches

Rationale

Indications

Venepuncture is carried out for two reasons:

- to obtain a blood sample for diagnostic purposes
- to monitor levels of blood components and a patient's condition (Garza and Becan-McBride 2013).

Contraindications (to using certain veins/areas)

- Previous surgery to an affected limb with axillary lymph node clearance.
- Lymphoedema on a particular limb.
- Amputation, fracture and cerebrovascular accident affecting limb.

Methods of improving venous access

- *Application of a tourniquet:* this promotes venous distension. The tourniquet should be tight enough to impede venous return

but not restrict arterial flow. It should be placed about 7–8 cm above the venepuncture site. It may be more comfortable for the patient to position it over a sleeve or paper towel to prevent pinching the skin. The tourniquet should not be left on for longer than 1 minute as this may result in haemoconcentration, or pooling of the blood or haemolysis leading to inaccurate blood results (Hoeltke 2013, Saleem et al. 2009).

- The patient may be asked to clench the fist and encourage venous distension but should avoid 'pumping' as this action may affect certain blood results, for example potassium where cell damage releases potassium (Ernst 2005, Garza and Becan-McBride 2013).
- Lowering the arm below heart level also increases blood supply to the veins.
- Light tapping of the vein may be useful but can be painful and may result in the formation of a haematoma in patients with fragile veins, for example thrombocytopenic patients (Dougherty 2008).
- The use of heat in the form of a warm pack or by immersing the arm in a bowl of warm water for 10 minutes helps to encourage venodilation and venous filling (Lenhardt et al. 2002).
- Ointment or patches containing small amounts of glyceryl trinitrate have been used to improve local vasodilation to aid venepuncture (Weinstein and Plumer 2007).

Methods for insertion

Asepsis is vital when performing a venepuncture as the skin is breached and a foreign device is introduced into a sterile circulatory system. The two major sources of microbial contamination are:

- cross-infection from practitioner to patient
- skin flora of the patient.

Good handwashing and drying techniques are essential on the part of the nurse or healthcare professional and gloves should be changed between patients (see Chapter 3: Infection prevention and control).

To remove the risk presented by the patient's skin flora, firm and prolonged rubbing with an alcohol-based solution, such as chlorhexidine 0.5% in 70% alcohol, is advised (RCN 2010). This cleaning should continue for about 30 seconds, although some authors state a minimum of 1 minute or longer (Weinstein and Plumer 2007). The area that has been cleaned should then be allowed to dry to: (i) facilitate coagulation of the organisms, thus ensuring disinfection, and (ii) prevent a stinging pain on insertion of the needle due to the alcohol on the end of the needle. The skin must not be touched or the vein repalpated prior to venepuncture (McCall and Tankersley 2012).

Legal and professional issues

Venepuncture is one of the most commonly performed invasive procedures in the NHS and is now routinely undertaken by nurses. In order to perform venepuncture safely, the nurse must have basic knowledge of the following.

- The relevant anatomy and physiology.
- The criteria for choosing both the vein and device to use.
- The potential problems which may be encountered, how to prevent them and necessary interventions.
- The health and safety/risk management of the procedure, as well as the correct disposal of equipment (RCN 2010).

Certain principles, such as adherence to an aseptic technique, must be applied throughout (see Chapter 3: Infection prevention and control). The circulation is a closed sterile system and a venepuncture, however quickly completed, is a breach of this system, providing a means of entry for bacteria.

Nurses must be aware of the physical and psychological comfort of the patient (Hoeltke 2013). They must appreciate the value

of adequate explanation and simple measures to prevent the complications of venepuncture, such as haematoma formation, when it is neither a natural nor acceptable consequence of the procedure (Hoeltke 2013).

Risk management

The number of litigation cases within the healthcare environment has increased in recent years (Garza and Becan-McBride 2013). It is therefore vital that nurses receive accredited and appropriate training, supervision and assessment by an experienced member of staff (RCN 2010). The nurse is then accountable and responsible for ensuring that skills and competence are maintained and knowledge is kept up to date, in order to fulfil the criteria set out in *The Code* (NMC 2015).

Pre-procedural considerations

Safety of the practitioner

It is recommended that well-fitting gloves are worn during any procedure that involves handling blood and body fluids, particularly venepuncture and cannulation (ICNA 2003, NHS Employers 2007, RCN 2010). This is to prevent contamination of the practitioner from potential blood spills. Whilst it is recognized that gloves will not prevent a needlestick injury, the wiping effect of a glove on a needle may reduce the volume of blood to which the hand is exposed, thereby reducing the volume inoculated and the risk of infection (ICNA 2003, Mitchell Higgs 2002, NAO 2003). However, there is no substitute for good technique and practitioners must always work carefully when performing venepuncture.

A range of safety devices is now available for venepuncture which can reduce the risk of occupational percutaneous injuries amongst healthcare workers, in particular vacuum blood collection systems (CDCP 1997). New regulations require the use of safer sharps systems that incorporate protective mechanisms such as safety shields or covers. Where practical, all conventional devices are to be replaced (HSE 2013). Used needles should always be discarded directly into an approved sharps container, without being resheathed (Garza and Becan-McBride 2013, RCN 2010). Specimens from patients with known or suspected infections such as hepatitis or HIV should have a biohazard label attached. The accompanying request forms should be kept separately from the specimen to avoid contamination (HSE 2003). All other non-sharp disposables should be placed in a universal clinical waste bag.

Equipment

Tourniquets

There are several types of tourniquet available. A good-quality, buckle closure, single hand release type is most effective but the choice will depend on availability and operator. Consideration should be given to the type of material and the ability to decontaminate the tourniquet. Fabric tourniquets that cannot be cleaned are not recommended (Golder et al. 2000, RCN 2010). Disposable tourniquets are available for single use and should be discarded immediately after use, especially where there is potential for microbial cross-contamination (RCN 2010, Warekois et al. 2007). A blood pressure cuff can be applied instead of a tourniquet as it will apply pressure over a wider area and make the veins more prominent. The cuff should be inflated halfway between the diastolic and systolic reading. The need for disposable cuffs should also be considered where cross-contamination may occur.

Needles

The intravenous devices commonly used to perform a venepuncture for blood sampling are a straight steel needle and a steel winged infusion device. The optimum gauge to use is 21 swg (standard wire gauge), which measures internal diameter: the

Figure 10.6 A vacuumed collection system: two blood culture bottles, Vacutainer holder and Vacutainer 'butterfly'.

smaller the gauge size, the larger the diameter. This enables blood to be withdrawn at a reasonable speed without undue discomfort to the patient or possible damage to the blood cells (McCall and Tankersley 2012).

Vacuum systems

A vacuum system consists of a plastic holder which contains or is attached to a double-ended needle or adaptor (Figure 10.6). It is important to use the correct Luer adaptor to ensure a good connection and avoid blood leakage (Garza and Becan-McBride 2013). The blood tube is vacuumed in order to ensure that the exact amount of blood required is withdrawn when the tube is

pushed into the holder. Filling ceases once the tube is full, which removes the need for decanting blood and also reduces blood wastage. The system can also be attached to winged infusion devices (Dougherty 2008).

A number of vacuum systems can be used for taking blood samples. These are simple to use and cost-effective. The manufacturer's instructions should be followed. Vacuum systems reduce the risk of healthcare workers being contaminated, because they offer a completely closed system during the process of blood withdrawal and there is no necessity to decant blood into bottles (Dougherty 2008). This makes them the safest method for collecting blood samples.

Blood collection tubes are available in various sizes and have different coloured tops dependent on the type of additives. The colour coding of the tops is generally universal but may vary depending on manufacturer. Local policy must be referred to in order to select the correct tubes for specific tests (Table 10.2). Blood tubes should be used in a sequence referred to as the 'order of draw' to minimize the transferring of additives. The correct volume of blood should be collected into each tube to prevent erroneous results. The expiry dates on the tubes should also be monitored regularly.

Equipment available will depend on local policy (Table 10.3), but with increasing concern about the possibility of contamination to the practitioner, blood collection systems with integrated safety devices are now readily available and should be used for all procedures (HSE 2013, RCN 2010). However, the nurse must always select the device after assessing the condition and accessibility of the vein.

Pharmacological support

It is important to remember that patients may fear venepuncture and in some cases suffer from needle phobia. The use of topical local anaesthetic cream may be beneficial for anxious patients or for venepuncture in children (Weinstein and Plumer 2007).

Table 10.2 Blood collection tubes

Tube	Additive	Specimen	Determinations	Instructions
Blood culture	Culture medium and anticoagulant	Whole blood	Aerobic followed by anaerobic – use aerobic bottle only if not enough blood for both bottles	
Light blue	Sodium citrate	Plasma	PT, INR, APTT, D-dimers, fibrinogen, thrombophilia screen (4 light blue + 1 EDTA tube), lupus (3 light blue tubes)	Fill tube completely and invert tube gently 3–4 times
Red	No additive	Serum	Antibiotic levels, steroid hormones, B ₁₂	Do not need to invert tube
Gold	Clot activator and serum separator	Serum	Routine chemistry, lipids, thyroid (TFT), drug levels including lithium, proteins, supply additional tube for troponin I levels	Invert 5–6 times
Green	Sodium or lithium heparin and plasma separator	Plasma	Plasma determinations in chemistry	Invert 8–10 times
Lavender	EDTA	Whole blood	FBC, sickle screen, haemoglobin, electrophoresis, red cell folate, malaria, lead, mercury, thalassaemia, PTH, ESR	Invert 8–10 times
Pink	EDTA	Whole blood	Antibody and group screen	Invert 8–10 times
Grey	Sodium fluoride & (K) oxalate	Plasma	Alcohol, glucose, lactate	Invert 8–10 times
Royal blue	Heparin or EDTA or nothing	Plasma or serum	Trace elements, manganese, zinc, whole blood	Invert 8–10 times

Source: Dojcinovska (2011). Reproduced with permission from John Wiley & Sons.

APTT, activated partial thromboplastin time; EDTA, ethylenediamine tetra-acetic acid; ESR, erythrocyte sedimentation rate; FBC, full blood count; INR, international normalized ratio; PTH, parathyroid hormone; PTT, partial thromboplastin time; TFT, thyroid function test.

Table 10.3 Choice of intravenous device

Device	Gauge	Advantages	Disadvantages	Use
Needle	21	Cheaper than winged infusion devices. Easy to use with large veins	Rigid. Difficult to manipulate with smaller veins in less conventional sites. May cause more discomfort. Venous access only confirmed when sample tube attached	In large, accessible veins in the antecubital fossa. When small quantities of blood are to be drawn
Winged infusion device with safety feature	21	Flexible due to small needle shaft. Easy to manipulate and insert at any site. Increases the success rate of venepuncture and causes less discomfort (Hefler et al. 2004). Usually shows a 'flashback' of blood to indicate a successful venepuncture	More expensive than steel needles. The 12–30 cm length of tubing on the device may be caught and dislodge the needle	Veins in sites other than the antecubital fossa. When quantities of blood greater than 20 mL are required from any site
	23	Flexible due to small needle shaft. Easy to manipulate and insert at any site. Causes less discomfort. Smaller swg and therefore useful with fragile veins	More expensive than steel needles, plus there can be damage to cells which can cause inaccurate measurements in certain blood samples, for example potassium	Small veins in more painful sites, for example inner aspect of the wrist, especially if measurements are related to plasma and not cellular components

swg, standard wire gauge.

Further information can be found in Chapter 14: Vascular access devices: insertion and management.

Non-pharmacological support

Patient anxiety about the procedure may result in vasoconstriction. The nurse's manner and approach will also have a direct bearing on the patient's experience (Garza and Becan-McBride 2013). Approaching the patient with a confident manner and giving adequate explanation of the procedure may reduce anxiety. Careful preparation and an unhurried approach will help to relax the patient and this in turn will increase vasodilation (Dougherty 2008, Weinstein and Plumer 2007).

Specific patient preparation

- Injury, disease or treatment, for example amputation, fracture and cerebrovascular accident, may prevent the use of a limb for venepuncture, thereby reducing the venous access. Use of a limb may be contraindicated because of an operation on one side of the body, for example mastectomy and axillary node dissection, as this can lead to impairment of lymphatic drainage, which can influence venous flow regardless of whether there is obvious lymphoedema (Cole 2006, Berreth 2010, Hoeltke 2013).
- The age and weight of the patient will also influence choice. Young children have short fine veins and the elderly have prominent but fragile veins. Care must be taken with fragile veins and the largest vein should be chosen along with the smallest gauge device to reduce the amount of trauma to the vessel (Weinstein and Plumer 2007). Malnourished patients will often present with friable veins (Dougherty 2008).
- If the patient is in shock or dehydrated there will be poor superficial peripheral access. It may be necessary to take blood after

the patient is rehydrated as this will promote venous filling and blood will be obtained more easily (Dougherty 2008).

- Medications can influence the choice of vein in that patients on anticoagulants or steroids or those who are thrombocytopenic tend to have more fragile veins and will be at greater risk of bruising both during venepuncture and on removal of the needle. Therefore choice may be limited by areas of bruising present or the inability to access the vessel without causing bruising (Dougherty 2008).
- The temperature of the environment will influence venous dilation. If the patient is cold, no veins may be evident on first inspection. Application of heat, for example in the form of a warm compress or soaking the arm in warm water, will increase the size and visibility of the veins, thus increasing the likelihood of a successful first attempt (Lenhardt et al. 2002, Weinstein and Plumer 2007).
- Venepuncture itself may cause the vein to collapse or go into a spasm. This will produce discomfort and a reduction in blood flow. Careful preparation and choice of vein will reduce the likelihood of this and stroking the vein or applying heat will help resolve it (Dougherty 2008).
- Involving patients in the choice of vein, even if it is simply to choose the non-dominant arm, can increase a feeling of control which in turn helps to relieve anxiety (Hudak 1986, Morris 2011).
- The environment is also another important consideration. In the inpatient and outpatient settings, lighting, ventilation, privacy and position must be checked and optimized where possible. This will ensure that the patient and the operator are both comfortable. Having adequate lighting is also beneficial as it illuminates the procedure, ensuring the operator has a good view of the vein and equipment (Dougherty 2008).

Procedure guideline 10.1 Venepuncture

Essential equipment

- Clean tray or receiver
- Tourniquet or sphygmomanometer and cuff
- 21 swg multiple sample safety needle or 21/23 swg winged safety infusion device and multiple sample Luer adaptor
- Plastic tube holder, standard
- Appropriate vacuumed specimen tubes
- Swab saturated with chlorhexidine in 70% alcohol, or isopropyl alcohol 70%
- Low-linting gauze swabs
- Sterile adhesive plaster or hypoallergenic tape
- Specimen request forms
- Non-sterile, well-fitting gloves
- Plastic apron (optional)
- Sharps bin

Pre-procedure

Action	Rationale
1 Approach the patient in a confident manner and explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Allow the patient to ask questions and discuss any problems which have arisen previously.	Anxiety results in vasoconstriction; therefore, a patient who is relaxed will have dilated veins, making access easier. E
3 Consult the patient as to any preferences and problems that may have been experienced at previous venepunctures. Check if they have any allergies.	To involve the patient in the treatment. To acquaint the nurse fully with the patient's previous venous history and identify any changes in clinical status, for example mastectomy, as both may influence vein choice (Dougherty 2008, E). To prevent allergic reactions, for example to latex or chlorhexidine (McCall and Tankersley 2012, E ; MHRA 2012 C).
4 Check that the identity of the patient matches the details on the request form by asking for their full name and date of birth and checking their identification bracelet (where appropriate). If the patient is unable to communicate then check the identity band for full name, date of birth and hospital number. Clarity may need to be gained with a relative/carer or registered nurse/doctor to whom the patient is known.	To ensure the sample is taken from the correct patient (NPSA 2007a, C ; RCN 2010, C).
5 Assemble the equipment necessary for venepuncture.	To ensure that time is not wasted and that the procedure goes smoothly without unnecessary interruptions. E
6 Carefully wash hands using bactericidal soap and water or bactericidal alcohol handrub, and dry before commencement.	To minimize risk of infection (DH 2010, C ; Fraise and Bradley 2009, E).
7 Check hands for any visibly broken skin, and cover with a waterproof dressing.	To minimize the risk of contamination to the practitioner (DH 2010, C ; Fraise and Bradley 2009, E).
8 Check all packaging before opening and preparing the equipment on the chosen clean receptacle.	To maintain asepsis throughout and check that no equipment is damaged. E

Procedure

9 Take all the equipment to the patient, exhibiting a confident manner.	To help the patient feel more at ease with the procedure. E
10 Support the chosen limb on a pillow.	To ensure the patient's comfort and facilitate venous access. E
11 Apply a tourniquet to the upper arm on the chosen side, making sure it does not obstruct arterial flow. If the radial pulse cannot be palpated then the tourniquet is too tight (Weinstein and Plumer 2007). The position of the tourniquet may be varied; for example, if a vein in the hand is to be used it may be placed on the forearm. A sphygmomanometer cuff may be used as an alternative.	To dilate the veins by obstructing the venous return (Dougherty 2008, E). To increase the prominence of the veins. E To promote blood flow and therefore distend the veins (Lenhardt et al. 2002, R3).
12 If the tourniquet does not improve venous access, the following methods can be used. <i>Either:</i> The arm may be placed in a dependent position. The patient may be asked to clench their fist. <i>Or:</i>	To improve venous access (Dougherty 2008, E).

(continued)

Procedure guideline 10.1 Venepuncture (continued)

Action	Rationale
The veins may be tapped gently or stroked. Or: Remove the tourniquet and apply moist heat, for example a warm compress, soak limb in warm water or, with prescription, apply glyceryl trinitrate ointment/patch (Weinstein and Plumer 2007).	
13 Select the vein by careful palpation to determine size, depth and condition (Action figure 13).	To prevent inadvertent insertion of the needle into other anatomical structures (Witt 2011, E).
14 Release the tourniquet.	To ensure patient comfort. E
15 Select the device, based on vein size, site and volume of blood to be taken. Use a 23 swg winged infusion device for small veins, metacarpal or feet veins.	To reduce damage or trauma to the vein and prevent haemolysis (Dougherty 2008, E ; RCN 2010, C).
16 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To maintain asepsis and minimize the risk of infection (DH 2010, C ; Fraise and Bradley 2009, E).
17 Reapply the tourniquet.	To dilate the veins by obstructing the venous return (Dougherty 2008, E).
18 Put on gloves.	To prevent possible contamination of the practitioner (NHS Employers 2007, C).
19 Clean the patient's skin carefully for 30 seconds using an appropriate preparation, for example chlorhexidine in 70% alcohol, and allow to dry. Do not repalpate or touch the skin (Action figure 19).	To maintain asepsis and minimize the risk of infection (DH 2010, C ; Fraise and Bradley 2009, E). To prevent pain on insertion (Dougherty 2008, E ; Fraise and Bradley 2009, E ; RCN 2010, C).
20 Remove the cover from the needle and inspect the device carefully.	To detect faulty equipment, for example bent or barbed needles. If these are present place them in a safe container, record batch details and return to manufacturer (MHRA 2005, C ; RCN 2010, C).
21 Anchor the vein by applying manual traction on the skin a few centimetres below the proposed insertion site (Action figure 21).	To immobilize the vein. To provide countertension to the vein which will facilitate a smoother needle entry (Dougherty 2008, E).
22 Insert the needle smoothly at an angle of approximately 30°. However, the angle will depend on size and depth of the vein (see Action figure 21).	To facilitate a successful, pain-free venepuncture. E
23 Reduce the angle of descent of the needle as soon as a flashback of blood is seen in the tubing of a winged infusion device or when puncture of the vein wall is felt.	To prevent advancing too far through vein wall and causing damage to the vessel (Dougherty 2008, E).
24 Slightly advance the needle into the vein, if possible.	To stabilize the device within the vein and prevent it becoming dislodged during withdrawal of blood. E
25 Do not exert any pressure on the needle.	To prevent a puncture occurring through the vein wall. E
26 Withdraw the required amount of blood using a vacuumed blood collection system (Action figure 26). Collect blood samples in the following order: <ul style="list-style-type: none"> • blood culture • coagulation • serum tube with or without clot activator or gel separator (glass, non-additive tubes can be filled before the coagulation tube) • additive tubes such as: <ul style="list-style-type: none"> (a) gel separator tubes (may contain clot activator or heparin) (b) heparin tubes (c) EDTA • all other tubes (Garza and Becan-McBride 2013). 	To minimize the risk of transferring additives from one tube to another and bacterial contamination of blood cultures (manufacturer's guidelines, C).
27 Release the tourniquet. In some instances this may be necessary at the beginning of sampling as inaccurate measurements may be caused by haemostasis, for example when taking blood to assess calcium levels.	To decrease the pressure within the vein. E
28 Remove tube from plastic tube holder.	To prevent blood spillage caused by vacuum in the tube (Campbell et al. 1999, E).

Action Figure 13 Palpating the vein.

Action Figure 19 Cleaning the skin.

Action Figure 21 Anchoring the skin.

Action Figure 26 Attach sample bottle to holder.

(continued)

Procedure guideline 10.1 Venepuncture (continued)

Action	Rationale
29 Place a low-linting swab over the puncture point.	To apply pressure. E
30 Remove the needle, but do not apply pressure until the needle has been fully removed.	To prevent pain on removal and damage to the intima of the vein. E
31 Activate safety device and then discard the needle immediately in sharps bin.	To reduce the risk of accidental needlestick injury (HSE 2013, C).
32 Apply digital pressure directly over the puncture site. Pressure should be applied until bleeding has ceased; approximately 1 minute or longer may be required if current disease or treatment interferes with clotting mechanisms.	To stop leakage and haematoma formation. To preserve vein by preventing bruising or haematoma formation. E
33 The patient may apply pressure with a finger but should be discouraged from bending the arm if a vein in the antecubital fossa is used.	To prevent leakage and haematoma formation (Morris 2011, E).
34 Gently invert the tube at least six times.	To prevent damage to blood cells and to mix with additives (manufacturer's guidelines, C).
35 Label the bottles with the relevant details at the patient's side.	To ensure that the specimens from the right patient are delivered to the laboratory, the requested tests are performed and the results returned to the correct patient's records (NMC 2010, C ; NPSA 2007a, C).
Post-procedure	
36 Inspect the puncture point before applying a dressing.	To check that the puncture point has sealed. E
37 Confirm whether the patient is allergic to adhesive plaster.	To prevent an allergic skin reaction. E
38 Apply an adhesive plaster or alternative dressing.	To cover the puncture and prevent leakage or contamination. E
39 Ensure that the patient is comfortable.	To ascertain whether patient wishes to rest before leaving (if an outpatient) or whether any other measures need to be taken. E
40 Remove gloves and discard waste, making sure it is placed in the correct containers, for example sharps into a designated receptacle.	To ensure safe disposal and avoid laceration or other injury of staff (DH 2006a, C ; Fraise and Bradley 2009, E). To prevent reuse of equipment (MDA 2000, C).
41 Follow hospital procedure for collection and transportation of specimens to the laboratory.	To make sure that specimens reach their intended destination. E
42 Document the procedure in the patient's records if taken whilst an inpatient.	To ensure timely and accurate record keeping (NMC 2010, C).

Problem-solving table 10.1 Prevention and resolution (Procedure guideline 10.1)

Problem	Cause	Prevention	Suggested action
Pain.	Use of vein in sensitive area (e.g. wrist).	Avoid using veins in sensitive areas wherever possible. Use local anaesthetic cream.	Complete procedure as quickly as possible.
Anxiety.	Previous trauma.	Minimize the risk of a traumatic venepuncture. Use all methods available to ensure successful venepuncture.	Approach patient in a calm and confident manner. Listen to the patient's fears and explain what the procedure involves. Offer patient opportunity to lie down. Suggest use of local anaesthetic cream (Lavery and Ingram 2005).
	Fear of needles.		All of the above and perhaps referral to a psychologist if fear is of phobic proportions.

Problem	Cause	Prevention	Suggested action
Limited venous access.	Repeated use of same veins. Peripheral shutdown. Dehydration. Hardened veins (due to scarring and thrombosis). Poor technique/choice of vein or device.	Use alternative sites if possible. Ensure the room is not cold. Ensure correct device and technique are used.	Do not attempt the procedure unless experienced. Put patient's arm in warm water. Apply glycerol trinitrate patch. May be necessary to rehydrate patient prior to venepuncture. Do not use these veins as venepuncture will be unsuccessful.
Needle inoculation of or contamination to practitioner.	Unsafe practice. Incorrect disposal of sharps.	Maintain safe practice. Activate safety device. Ensure sharps are disposed of immediately and safely.	Follow accident procedure for sharps injury, for example make site bleed and apply a waterproof dressing. Report and document. An injection of hepatitis B immunoglobulin or triple therapy may be required.
Accidental blood spillage.	Damaged/faulty equipment. Reverse vacuum.	Check equipment prior to use. Use vacuumed plastic blood collection system. Remove blood tube from plastic tube holder before removing needle.	Report within hospital and/or MHRA. Ensure blood is handled and transported correctly.
Missed vein.	Inadequate anchoring. Poor vein selection. Wrong positioning. Lack of concentration. Poor lighting. Difficult venous access.	Ensure that only properly trained staff perform venepuncture or that those who are training are supervised. Ensure the environment is well lit.	Repalpate, withdraw the needle slightly and realign it, providing the patient is not feeling any discomfort. Ensure all learners are supervised. If the patient is feeling pain, then the needle should be removed immediately. Ask experienced colleague to perform the procedure.
Spurt of blood on entry.	Bevel tip of needle enters the vein before entire bevel is under the skin; usually occurs when the vein is very superficial.		Reassure the patient. Wipe blood away on removal of needle.
Blood stops flowing.	Through puncture: needle inserted too far. Contact with valves. Venous spasm. Vein collapse. Small vein. Poor blood flow.	Correct angle. Palpate to locate. Results from mechanical irritation and cannot be prevented. Use veins with large lumen. Use a smaller device. Avoid use of small veins wherever possible. Use veins with large lumens.	Draw back the needle, but if bruising is evident, then remove the needle immediately and apply pressure. Withdraw needle slightly to move tip away from valve. Gently massage above the vein or apply heat. Release tourniquet, allow veins to refill and retighten tourniquet. May require another venepuncture. Apply heat above vein.

Post-procedural considerations

Immediate care

It is important to ensure that the needle is removed correctly on completion of blood sampling and that the risk of haematoma formation is minimized. Pressure should be applied as the needle is removed from the skin. If pressure is applied too early, it causes the tip of the needle to drag along the intima of the vein, resulting in sharp pain and damage to the lining of the vessel (McCall and Tankersley 2012).

The practitioner should ensure that firm pressure is maintained until bleeding has stopped. The patient should also be instructed to keep their arm straight and not bend it as this also increases the risk of bruising (Moini 2013). A longer period of pressure may be necessary where the patient's blood may take longer to clot, for example if the patient is receiving anticoagulants or is thrombocytopenic. The practitioner may choose to apply the tourniquet

over the venepuncture site to ensure even and constant pressure on the area (Dougherty 2008). Alternatively, they can elevate the arm slightly above the heart to decrease venous pressure (McCall and Tankersley 2012).

The practitioner should inspect the site carefully for bleeding or bruising before applying a dressing to the site, and the patient leaving the department. If bruising has occurred, the patient should be informed of why this has happened and given instructions for what to do to reduce the bruising and any associated pain.

Complications

Complications that may occur when venepuncture is performed include arterial puncture, nerve injury, haematoma, fainting and infection. Careful assessment and preparation will minimize the risks but if they occur then appropriate action should be taken immediately.

Arterial puncture

To prevent an arterial puncture, careful assessment of vein selection is necessary. The nurse should palpate the vessel prior to needle insertion to confirm the absence of a pulse; the angle of insertion should be less than 40° and in the event of a missed vein, blind probing should be avoided (McCall and Tankersley 2012).

An arterial puncture can be identified by bright red blood, rapid blood flow and pain. The needle should be removed immediately and pressure applied for 5 minutes by the nurse. A pressure dressing should be applied and the patient should receive verbal and written advice to follow in the event of increased pain, swelling or loss of sensation. No tourniquet or blood pressure cuff should be reapplied to the arm for 24 hours. The incident should be documented in the patient's notes (Dougherty 2008).

524 Nerve injury

Careful vein selection and needle insertion should minimize the risk of nerve injury. The angle of insertion should be less than 40° and blind probing should be avoided (Morris 2011). In the event of a nerve injury, the patient may complain of a sharp shooting pain, burning or electric shock sensation that radiates down the arm and they may experience numbness/tingling in the fingers. The needle should be removed immediately to prevent further nerve damage (McCall and Tankersley 2012). The patient should receive verbal and written advice to follow if the pain/numbness continues for more than a few hours. The incident should be documented in the patient's notes (Dougherty 2008).

Haematoma

Haematoma formation is the most common complication of venepuncture (McCall and Tankersley 2012). A haematoma develops when blood leaks from the vein into the surrounding tissues. It may be caused by the needle penetrating completely through the vein wall, the needle only being partially inserted, or insufficient pressure on the site when the needle is removed. If a haematoma develops, the needle should be removed immediately and pressure applied. In the event of a large haematoma developing, the nurse can apply an ice pack to relieve pain and swelling. The application of Hirudoid cream, which is used for the treatment of superficial thrombophlebitis, or arnica cream may be beneficial (BNF 2014).

The patient should receive verbal and written advice as a haematoma may lead to a compression injury to the nerve (Morris 2011). The incident should be documented in the patient's notes (Dougherty 2008).

Fainting

Fainting may occur during or immediately following venepuncture. The patient may complain of feeling light-headed and appear pale and sweaty. Loss of consciousness may occur suddenly so the nurse should be vigilant throughout the procedure and routinely confirm with the patient that they do not feel unwell or faint. In the event of the patient feeling faint, the nurse should remove the device immediately, apply pressure to the site and encourage the patient to lower the head and breathe deeply. The application of a cold compress to the forehead and increased ventilation (open a window if clinically acceptable) may help to make the patient more comfortable. If the patient suffers a loss of consciousness, the nurse should call for assistance and ensure the patient's safety until they recover. The patient should not be allowed to leave the department until fully recovered and be advised not to drive for at least 30 minutes (Garza and Becan-McBride 2013, McCall and Tankersley 2012). The incident should be documented in the patient's notes and the patient advised to inform staff on future occasions.

Infection

Infection at the venepuncture site is a rare occurrence (McCall and Tankersley 2012). Aseptic technique should be maintained with careful attention to hand washing and skin preparation. The venepuncture site should not be repalpated after cleaning and the site should be covered for 15–20 minutes after the procedure. Infection at the venepuncture site should be reported to a doctor as antibiotics may be required (Hart 2008).

Blood sampling from a central venous catheter

Evidence-based approaches

Methods of taking blood samples from a central venous access device

Obtaining blood samples from a central venous access device (CVAD) can lead to inaccurate results, especially coagulation values, if the correct method is not followed to ensure removal of any drug/solution prior to sampling (Frey 2003, INS 2011, Mendez 2012). A number of methods may be used to withdraw samples and there appears to be no significant difference in laboratory results and no evidence of haemolysis or haemodilution (Adlard 2008, Holmes 1998, Mendez 2012, RCN 2010).

- *Discard method:* this is the method most commonly used in the clinical setting (recommended by the Royal Marsden Hospital and demonstrated within Procedure guideline 10.2: Central venous access devices: taking a blood sample for vacuum sampling) where the first 6–10 mL of blood is withdrawn and discarded (Gorski et al 2010, Holmes 1998, Mendez 2012, Warekois et al. 2007). This ensures removal of any heparin, drugs or saline solution but may result in excessive blood removal in small children or those requiring multiple samples, for example for pharmacokinetic tests (Adlard 2008, Mendez 2012).
- *Push–pull (mixing) method:* a syringe is attached to the catheter, the catheter is flushed with 0.9% sodium chloride, then 6 mL is withdrawn and pushed back without removing the syringe; this is repeated three times. This removes any residual solution and reduces exposure to blood and there is no blood wastage (Adlard 2008, Holmes 1998, Mendez 2012). This method supposes that mixing of blood eliminates intravenous fluids and heparin from the catheter lumen (Cosca et al. 1998). However, it may be difficult to obtain enough blood to exchange 3–4 times.
- *Reinfusion method:* this method is performed by taking the first 6 mL of blood, capping off the syringe, taking the samples and then reinfusing the blood first taken (Adlard 2008, Mendez 2012). It does not result in depleted blood volume but there is a risk of blood exposure. The discard syringe could be confused with the specimen sample and there could be contamination or clots in the sample for reinfusion and there is a chance of haemolysis with agitation of blood (Adlard 2008, Frey 2003, Mendez 2012).

Pre-procedural considerations

It is preferable to use the distal lumen of a multilumen catheter when obtaining a sample and, where these catheters have different-sized lumens, the largest should be reserved for blood sampling (Dougherty 2006, Gorski et al. 2010). However, if a CVAD will not bleed then it may be necessary to take blood from a peripheral vein.

Procedure guideline 10.2 Central venous access devices: taking a blood sample for vacuum sampling

Essential equipment

- Sterile dressing pack
- Alcohol-based handwash solution
- Extra 10 mL blood bottle without heparin or sterile 10 mL syringe
- Vacuum system container holder (shell)
- Vacuum system adaptor
- Clean tray or receiver
- Trolley
- Appropriate vacuumed blood bottles or
- Needleless injection cap (as necessary)

Medicinal products

- 10 mL syringe containing 0.9% sodium chloride
- Flushing solution as per policy
- 2% chlorhexidine in 70% alcohol swab

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient. Check forms to ascertain sample bottles required and check patient's identity.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To ensure correct bottles are used and blood is taken from correct patient (NPSA 2007a, **C**; RCN 2010, **C**).

Procedure

- 2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. To reduce the risk of cross-infection (DH 2010, **C**).
- 3 Prepare a tray or trolley and take it to the bedside. Clean hands as above. Open sterile pack and prepare equipment. To reduce the risk of contamination of contents (DH 2010, **C**).
- 4 If intravenous fluid infusion is in progress, switch it off. To prevent spillage of fluid following disconnection. **E**
- 5 Where required, disconnect the administration set from the catheter and cover the end of the set with sterile cap. To reduce the risk of contaminating the end of the administration set. **E**
- 6 Clean hands with a bactericidal alcohol handrub. Put on non-sterile gloves. To prevent contamination of practitioner's hands with blood. **E**
- 7 Clean hub or needlefree cap thoroughly with a 2% chlorhexidine in 70% alcohol swab. Allow to dry. To enable disinfection process to be completed (DH 2010, **C**).
- 8 Connect the vacuum container holder and adaptor, then attach via the needleless injection cap and release clamp. To maintain a closed system and prevent contamination of practitioner or air entry. **E**
- 9 Attach extra sample bottle; fill and discard. To remove blood, heparin and intravenous fluids from the 'dead space' of the catheter. Samples from this 'dead space' are likely to cause inaccuracies in blood tests, because of the risk of contamination of the sample with heparin, sodium chloride or glucose and so on (Cosca et al. 1998, **R5**; Holmes 1998, **R4**).
- 10 Attach required sample bottles in correct order of draw for requested specimens. To obtain sample. It is not necessary to clamp the catheter when changing collection bottles, as the system is not open. **E**
- 11 Reclamp catheter and detach vacuum container holder. To prevent blood loss or air embolism. **E**
- 12 Flush with 10 mL 0.9% sodium chloride, using the push-pause method (i.e. 1 mL at a time). To create turbulence, ensure removal of all blood in the catheter and prevent occlusion (INS 2011, **C**).
- 13 Reconnect the administration set, unclamp the catheter and recommence infusion or attach new needle-free injection cap. Release clamp and flush catheter through injection cap using the push-pause method and finishing with the positive pressure technique. To prevent the catheter clotting between uses (Dougherty 2006, **E**; Gorski et al. 2010, **E**).
- 14 Ensure that blood samples have been placed in the correct containers and invert as necessary to prevent clotting. To make certain that the specimens, correctly presented and identified, are delivered to the laboratory, enabling the requested tests to be performed and the results returned to the correct patient's records (RCN 2010, **C**).
- 15 Label them with patient's name, number, date of birth, etc. at patient's bedside and send them to the laboratory with the appropriate forms. To prevent mislabelling when away from the patient. To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).

Post-procedure

- 16 Remove gloves and discard waste, making sure it is placed in the correct containers, e.g. sharps into a designated receptacle. To ensure correct clinical waste management and to reduce the risk of cross-infection (DH 2006a, **C**).
- 17 Document the procedure in the patient's records. To ensure timely and accurate record keeping (NMC 2010, **C**).

Procedure guideline 10.3 Central venous access devices: taking a blood sample for syringe sampling

This may be necessary if the CVAD does not bleed when using a vacuum system, for example with silicone peripherally inserted central cannulas (PICCs).

Essential equipment

- Sterile dressing pack
- Alcohol-based handwash solution
- Extra 10 mL syringe
- Clean tray or receiver
- Appropriate blood bottles
- Sterile syringe of appropriate size for sample required

- Needleless injection cap (as necessary)
- Trolley

Medicinal products

- Flushing solution as per policy
- 10 mL syringe containing 0.9% sodium chloride
- 2% chlorhexidine in 70% alcohol swab

Pre-procedure

526

Action**Rationale**

- 1 Explain and discuss the procedure with the patient. Check forms to ascertain sample bottles required and check patient's identity.

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To ensure correct bottles are used and blood is taken from correct patient (NPSA 2007a, **C**; RCN 2010, **C**).

Procedure

- 2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.
- 3 Prepare a tray or trolley and take it to the bedside. Clean hands as above. Open sterile pack and prepare equipment.
- 4 If intravenous fluid infusion is in progress, switch it off.
- 5 Where required, disconnect the administration set from the catheter and cover the end of the set with sterile cap.
- 6 Clean hands with a bactericidal alcohol handrub. Put on non-sterile gloves.
- 7 Clean hub or needle-free cap thoroughly with a 2% chlorhexidine in 70% alcohol swab. Allow to dry.
- 8 Attach a 10 mL syringe to the needleless injection cap. Release the clamp and withdraw 5–10 mL of blood.
- 9 Clamp and remove syringe and discard.
- 10 Attach a new syringe of appropriate size. Unclamp and withdraw the required amount of blood.
- 11 Clamp and detach the syringe.
- 12 Decant blood into sample bottles.
- 13 Flush with 10 mL 0.9% sodium chloride, using the push-pause method (i.e. 1 mL at a time).
- 14 Reconnect the administration set, unclamp the catheter and recommence infusion or attach new needleless injection cap. Release clamp and flush catheter through injection cap using the push-pause method and finishing with the positive pressure technique.

To reduce the risk of cross-infection (DH 2010, **C**).

To reduce the risk of contamination of contents (DH 2010, **C**).

To prevent spillage of fluid following disconnection. **E**

To reduce the risk of contaminating the end of the administration set. **E**

To minimize the risk of introducing infection into the catheter, and prevent contamination of practitioner's hands with blood. To enable disinfection process to be completed (DH 2007a, **C**; INS 2011, **C**).

To enable disinfection process to be completed (DH 2007a, **C**; INS 2011, **C**).

To remove blood, heparin and intravenous fluids from the 'dead space' of the catheter. Samples from this 'dead space' are likely to cause inaccuracies in blood tests (Cosca et al. 1998, **R5**; Holmes 1998, **R4**).

To discard contaminated sample and prevent mixing (Cosca et al. 1998, **R5**; Holmes 1998, **R4**).

To obtain the sample. **E**

To prevent blood spillage or air entry. **E**

To ensure blood is placed into sample bottles as soon as possible. **E**

To create turbulence, ensure removal of all blood in the catheter and prevent occlusion (INS 2011, **C**).

To prevent the catheter clotting between uses (Dougherty 2006, **E**; Gorski et al. 2010, **E**).

Post-procedure

- 15 Remove gloves and discard waste, making sure it is placed in the correct containers, e.g. sharps into a designated receptacle.
- 16 Ensure that blood samples have been placed in the correct containers and agitated as necessary to prevent clotting.
- 17 Label them with patient's name, number, date of birth, etc. at patient's bedside and send them to the laboratory with the appropriate forms.
- 18 Document the procedure in the patient's records.

To ensure correct clinical waste management and to reduce the risk of cross-infection (DH 2006a, **C**).

To make certain that the specimens, correctly presented and identified, are delivered to the laboratory, enabling the requested tests to be performed and the results returned to the correct patient's records (RCN 2010, **C**).

To prevent mislabelling when away from the patient. To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).

To ensure timely and accurate record keeping (NMC 2010, **C**).

Problem-solving table 10.2 Prevention and resolution (Procedure guidelines 10.2 and 10.3)

Problem	Cause	Prevention	Action
Difficulty may be encountered when taking blood samples.	<p>This is more common when the central venous catheter is made of silicone and has been in place for a long time. One of the causes is that the tip of the soft catheter lies against the wall of the vessel and the suction required to draw blood brings this into close contact, leading to temporary occlusion. There could also be a collapse of the catheter walls when using the vacuum system which may necessitate the use of syringes to obtain the blood.</p> <p>The tip of the catheter may be covered in a fibrin sheath, which may result in partial withdrawal occlusion (PWO).</p> <p>Pinch-off syndrome occurs when a CVAD inserted via the percutaneous subclavian site is compressed by the clavicle and first rib and aspirating blood becomes difficult (Mirza et al. 2004).</p>	Tip position in lower superior vena cava or right atrium.	<p>Measures to try to dislodge the tip include asking the patient to:</p> <ul style="list-style-type: none"> a cough and breathe deeply b roll from side to side c raise his/her arms d perform the Valsalva manoeuvre, if possible e increase general activity, for example walk up and down stairs (Gorski et al. 2010). <p>This may be resolved with rapid flushing of the catheter with 0.9% sodium chloride or a dilute solution of heparin. If due to PWO then a fibrinolytic agent may be necessary to remove the fibrin (Goossens et al. 2013; Kumar et al. 2013).</p> <p>Ask patient to lift arm to side. If blood aspiration improves and there is little resistance on flushing, suspect pinch-off and request chest X-ray and cathetergram to check for catheter damage or embolism.</p>

Post-procedural considerations

Whichever method is used, once the samples have been taken it is vital that the catheter is adequately flushed with 0.9% sodium chloride followed where appropriate with a heparin solution, to reduce the risk of clot formation and subsequent infection and/or occlusion (Dougherty 2006, Gorski et al. 2010, RCN 2010).

Arterial sampling

Definition

Arterial blood sampling is the collection of blood from an artery for laboratory testing to determine acid/base balance and check electrolytes and haemoglobin amongst other blood tests (Milzman and Janchar 2013).

Usually blood is drawn from the radial artery in the wrist. It may also be drawn from an artery on the inside of the elbow or groin, in an emergency, provided the healthcare practitioner is trained to do so. The brachial and femoral arteries do not have adequate collateral supplies and are not routinely used for sampling. A pulse is felt by pressing on the area above an artery. If blood is drawn at the wrist, the healthcare provider will usually check the pulse to make sure blood is flowing into the hand from the radial and ulnar arteries in the forearm (Milzman and Janchar 2013).

Anatomy and physiology

Arteries transport blood away from the heart and they vary in size. The arteries consist of three layers: tunica adventitia, tunica media and the tunica intima (Jenkins and Tortora 2013). The brachial artery terminates as the radial and ulnar arteries, and an extensive collateral network of superficial and deep palmar arteries connects the radial and ulnar circulations. This normal pattern is present in 84% of patients. In 5% of cases, the radial artery is derived from the superficial brachial artery while the ulnar and interosseous arteries continue to originate from the brachial artery (Brzezinski et al. 2009).

Evidence-based approaches

Rationale

Arterial blood gas (ABG) sampling provides valuable information on the acid/base balance at a specific point in the course of a patient's illness (Brzezinski et al. 2009). There are two methods for sampling an arterial blood gas: arterial puncture and via arterial cannula, the latter usually in the intensive care unit (ICU) or high dependency unit (HDU).

Indications

- Identification of respiratory, metabolic and mixed acid/base disorders, with or without physiological compensation, by means of pH ($[H^+]$) and carbon dioxide (CO_2) levels (partial pressure of CO_2).
- Measurement of the partial pressures of respiratory gases involved in oxygenation and ventilation.
- Monitoring of acid/base status, as in patient with diabetic ketoacidosis (DKA) on insulin infusion; ABG and venous blood gas (VBG) could be obtained simultaneously for comparison, with VBG sampling subsequently used for further monitoring.
- Assessment of the response to therapeutic interventions such as mechanical ventilation in a patient with respiratory failure.
- Determination of arterial respiratory gases during diagnostic evaluation (e.g. assessment of the need for home oxygen therapy in patients with advanced chronic pulmonary disease).
- Procurement of a blood sample in an acute emergency setting when venous sampling is not feasible (many blood chemistry tests could be performed from an arterial sample) (Danckers and Fried 2013).

Contraindications

Absolute contraindications for ABG sampling include the following.

- An abnormal modified Allen test (Figure 10.7), in which case consideration should be given to attempting puncture at a different site.

Figure 10.7 Modified Allen test. (a) Step 1. (b) Step 2. (c) Step 3.

- Local infection or distorted anatomy at the potential puncture site (e.g. from previous surgical interventions, congenital or acquired malformations, or burns).
- The presence of arteriovenous fistulas or vascular grafts, in which case arterial vascular puncture should not be attempted.
- Known or suspected severe peripheral vascular disease of the limb involved.

Relative contraindications include the following.

- Severe coagulopathy.
- Anticoagulation therapy with warfarin, heparin and derivatives, direct thrombin inhibitors or factor X inhibitors; aspirin is not a contraindication for arterial vascular sampling in most cases.
- Use of thrombolytic agents, such as streptokinase or tissue plasminogen activator (Danckers and Fried 2013).

Arterial puncture

Arterial puncture may result in spasm, intraluminal clotting or bleeding and haematoma formation, as well as a transient obstruction of blood flow. These factors may decrease the arterial flow in distal tissues unless adequate collateral arterial vessels are available. The radial artery at the wrist is the best site for obtaining an arterial sample because it is near the surface, relatively easy to palpate and stabilize, and usually has good col-

lateral supply from the ulnar arteries. This can be confirmed by a modified Allen test (Figure 10.7).

Multiple puncture attempts will increase the risk of injury, not only due to the direct trauma but also associated with vasospasm (Lipsitz 2004). If the patient requires repetitive blood sampling, it may be more appropriate to admit the patient to a more clinically suitable area where arterial cannulation is possible. This not only minimizes both the distress to the patient and time taken by skilled personnel in obtaining each sample, but reduces the risks associated with multiple punctures (Brzezinski et al. 2009). It is worth noting that morbidity associated with arterial cannulation is less than that associated with five or more arterial punctures (Bersten et al. 2009) (see Chapter 14: Vascular access devices). Radial artery catheterization is a relatively safe procedure with a 0.09% incidence of permanent ischaemic complications. Although its anatomy in the forearm and hand is variable, adequate collateral flow in the event of radial artery thrombosis is present in most patients (Brzezinski et al. 2009).

Pre-procedural considerations

Specific patient preparation

Ideally, prior to obtaining any arterial blood gas sample (Figure 10.8), the patient should be in a respiratory steady state

Figure 10.8 Arterial blood gas sampling.

for 15–20 minutes. The oxygen should not be reduced, and if ventilated, suction should not be attempted and ventilation parameters not adjusted (Weinstein and Plumer 2007). Arterial sampling or cannulation is associated with a considerable amount of pain due to adjacent nerves and deeper puncture than venous sampling or cannulation. ABG sampling may be difficult to perform in patients who are unco-operative or in whom pulses cannot be easily identified (Danckers and Fried 2013).

Pain can be reduced by using local anaesthetic, which would also allow the healthcare provider to perform sampling without the patient moving their arm too much. In an emergency, there may be no time for local anaesthetic application but, when it is feasible to wait for local anaesthetic to take effect before attempting arterial puncture, studies suggest higher success rates for arterial sampling (Sado and Deakin 2005). Despite its controversial value in predicting post-procedure ischaemia due to a radial arterial thrombosis, the modified Allen test is still widely used, and should be performed prior to accessing the radial artery to confirm patent collateral circulation to the hand. Adjuncts to the Allen test, e.g. pulse oximetry, have not been shown to increase the diagnostic power of the test (Brzezinski et al. 2009). The modified Allen test is performed by firmly compressing the radial and ulnar arteries together with the patient's fist clenched (Step 1). The patient is then asked to open their hand (Step 2) and the arteries are released one at a time to check their ability to return blood flow to the hand, turning it pink again (Step 3) (Williams 1998). If blood flow to the hand returns within <10 sec after release of only the ulnar artery, it is presumed the radial artery can be used for sampling (Benit et al. 1996, Jarvis et al. 2000).

Where a sample is taken from an established arterial cannula, certain volumes of blood should be withdrawn and discarded. This is to ensure that any 0.9% sodium chloride, blood and small emboli from the dead space within the cannula and the three-way tap have been removed. Discarded volumes will vary according to arterial cannula placement due to the length of the arterial cannula.

- Peripheral artery cannula: take 3 mL and discard.
- Femoral artery cannula: take 5 mL and discard (Danckers and Fried 2013).

When using a vacuum system, take one bottle and discard prior to obtaining requested samples.

Arterial blood gas sampling may be difficult to perform in patients who are unco-operative or in whom pulses cannot be easily identified. Challenges arise when healthcare personnel are unable to position the patient properly for the procedure. This sit-

uation is commonly seen in patients with cognitive impairment, advanced degenerative joint disease or essential tremor. The amount of subcutaneous fat in overweight and obese patients may limit access to the vascular area and obscure anatomical landmarks. Arteriosclerosis of peripheral arteries, as seen in elderly patients and those with end-stage kidney disease, may cause increased rigidity in the vessel wall (Danckers and Fried 2013).

Equipment

Different types of blood gas syringes are available: some are pre-heparinized, some are vented and self-fill on arterial blood sampling. If an arterial cannula is inserted in an HDU or CCU environment then a sodium chloride 0.9% infusion is required to keep the cannula open (NPSA 2008a). If continuous arterial monitoring is done via a cannula, further equipment is required, including a transducer, connected to a cardiac monitor and pressure bag (O'Hare and Chilvers 2001).

Legal and professional issues

The practitioner will document their action in the patient's case notes and report the procedure, including assessment of the patient as detailed above and any complications with the procedure itself. Any identified complications must be reported to a doctor as soon as practically possible. Practitioners are required to demonstrate knowledge of potential dangers and complications associated with the procedure. In addition, the practitioner will demonstrate knowledge of the signs and symptoms of associated complications, and be able to identify appropriate action to safeguard the patient. Practitioners will undertake the role with due reference to the NMC Code (NMC 2015).

Competencies

Staff who undertake arterial puncture must be competent to do so. Each practitioner must be able to perform the relevant procedure in accordance with the hospital policy or guidelines. Practitioners should not attempt arterial puncture more than twice on the same patient and must refer to another experienced practitioner when practice limitations are recognized.

Risk management

Arterial infusion devices must be clearly identified. This means labelling or use of other safety solutions such as marked devices adopted by some trusts (O'Hare and Chilvers 2010). Any infusion (or additive) attached to an arterial device must be prescribed and checked before administration. Further checks should be made at regular intervals and key points (such as shift handover). Staff should use only sodium chloride 0.9% to keep devices open. Labels should clearly identify contents of infusion bags, even when pressure bags are used (NPSA 2008a).

Sampling from arterial devices is risky and should only be done by competent, trained staff. Trusts should raise awareness of risks and review local guidelines. These should include criteria for requests for blood gas analyses; sampling technique, monitoring and interpretation of results (including unexpected results) (NPSA 2008a) (see Chapter 14: Vascular access devices).

To minimize risks, clinical teams should ask themselves the following questions (NPSA 2008a).

- Have I recorded the clinical reason for inserting this device?
- Is it clearly marked as an arterial device?
- Do I need to take this sample?
- Do I know how to do this safely (e.g. removing air from sample)?
- Have I picked the right infusion fluid bag? Did someone else check this?
- Can the label be seen, even if pressure bags are used?
- Is the reading from the sample within the expected range? Could it have been contaminated?

Procedure guideline 10.4 Arterial puncture: radial artery**Essential equipment**

- Sterile dressing pack
- Non-sterile gloves and apron
- Trolley
- Clean tray or receiver
- Sterile adhesive plaster or hypoallergenic tape
- 2 mL syringe for local anaesthetic
- 20 G needle for local infiltration
- 18 G needle

- Sharps container
- Pre-heparinized arterial blood gas syringe (some syringes are vented or self-filling, others require user to draw back to fill – check manufacturer's instructions)
- 22 G needle for sampling

Medicinal products

- 2% chlorhexidine in 70% alcohol
- Lidocaine 1%

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient. Obtain valid consent in all cases except in emergencies when the patient is unable to consent.
- 2 Check the patient's identity and allergy status.
- 3 Check the concentration of oxygen the patient is breathing and body temperature at time of sampling and document it on sampling results.
- 4 Check the patient's current coagulation screen, platelet count, medical history and prescription chart for anticoagulation therapy.
- 5 Prepare trolley and take to bedside.
- 6 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.

Rationale

- To ensure the patient understands the procedure and gives their valid consent (NMC 2013, **C**). To minimize anxiety which may distort analysis or exacerbate symptoms. **E**
- Consent may not be possible in certain clinical scenarios, such as a critically ill patient with rapid decompensation or a patient with an altered level of consciousness (Danckers and Fried 2013, **E**).
- To ensure procedure is undertaken with the correct patient and to minimize risk of allergic reaction (NPSA 2007a, **C**; RCN 2010, **C**).
- Inspired oxygen concentration and temperature parameters are required to interpret arterial blood gases accurately (Weinstein and Plumer 2007, **E**).
- To identify possible risk of bleeding and haematoma formation post procedure and, where appropriate, to prevent puncture until coagulation is corrected (Danckers and Fried 2013, **E**).
- To reduce the risk of cross-infection (DH 2010, **C**).
- To reduce the risk of cross-infection (DH 2010, **C**).

Procedure

- 7 Assume a stable and comfortable position. If possible, sit down on a chair or stool near the patient.
- 8 Inspect and assess the tissues and anatomical structures surrounding the intended sampling site.
- 9 Locate and palpate the radial artery with the middle and index fingers of the non-dominant hand.
- 10 Perform the modified Allen test (see Figure 10.7).
- 11 Prepare the patient in supine position: with forearm supinated at the wrist, gently extend the wrist at 40° over a rolled towel whilst avoiding overextension (ask for assistance if required) to bring the radial artery to a more superficial plane (Danckers and Fried 2013).
- 12 Clean hands and open the pack and place equipment onto it.
- 13 Withdraw the plunger of the ABG syringe 1–2 mL before the puncture. If using a vented sample syringe, withdraw fully.
- 14 Place a sterile field under the patient's wrist and maintain aseptic technique throughout the procedure.

- To maximize the chance of successful sampling at the first attempt therefore minimizing patient discomfort. To prevent back strain in the practitioner and minimize the risk of a needlestick injury. **E**
- To identify any areas of excoriation/infection, poor perfusion or other puncture sites. If any of these are present the site should not be used (Weinstein and Plumer 2007, **E**).
- To assess maximum pulsation to ensure radial artery is optimum site for successful puncture. The dominant hand will be used to perform puncture (Weinstein and Plumer 2007, **E**).
- To confirm patency of ulnar artery circulation and assess collateral circulation to the hand in the event of radial artery damage, for example thrombosis (White 2003, **E**).
- To reduce the risk of the patient moving unexpectedly which could result in through-puncture (Hudson et al. 2006, **E**; Lipsitz 2004, **E**). To flex the hand slightly to facilitate insertion. **E**
- Overextension of the wrist is discouraged, because interposition of flexor tendons may make the pulse difficult to detect (Danckers and Fried 2013, **E**).
- To ensure all equipment required is prepared. **E**
- To reduce blood haemolysis. Arterial pressure causes a brisk pulsatile reflux of blood into the syringe (unless the patient is severely hypotensive) (Weinstein and Plumer 2007, **E**).
- To minimize the risk of infection (DH 2010, **C**).

15 Clean hands and then clean site with chlorhexidine in 70% alcohol and allow to dry.	To minimize the risk of infection (DH 2010, C).
16 Prepare and administer subcutaneous local anaesthetic. Only inject 0.5–1 mL of the anaesthetic to create a small dermal papule at the site of puncture.	To minimize pain during the procedure. Local vasodilation effects of the local anaesthetic may reduce vasospasm, making for a successful puncture (Lipsitz 2004, E). Using larger amounts or injecting the anaesthetic into deeper planes may distort the anatomy and hinder identification of the vessel (Danckers and Fried 2013, E).
17 After the skin is punctured but just before the anaesthetic is injected, the clinician should pull back the plunger to confirm that the needle is not inside a blood vessel; intravascular placement will be indicated by blood filling up the anaesthetic syringe.	Injecting local anaesthetic directly intravascularly may cause cardiac arrhythmias (Danckers and Fried 2013, E).
18 Clean hands with bactericidal skin cleaning solution or wash with soap and water.	To minimize the risk of infection (DH 2010, C).
19 Apply non-sterile gloves, take care not to touch the puncture site after cleaning.	To minimize the risk of infection and prevent contamination of hands with blood (Loveday et al. 2014, C).
20 Uncap the ABG syringe, attach the 22 G needle and hold it with two fingers of the dominant hand.	To guide position of radial artery and aid successful puncture. E
21 Angle the needle at 30–45°, with the bevel of the needle up just distal to the planned puncture site. Whilst palpating the radial pulse proximal to the planned puncture site, advance the needle slowly, aiming in the direction of the artery until a flashing pulsation is seen in the hub of the needle.	To minimize trauma to the artery. E Rapid insertion may result in a through-puncture (White 2003, E). Take care not to touch the puncture site after cleaning, to minimize risk of infection (DH 2010, C). Pulsatile flow indicates access to radial artery. E Arterial pressure causes blood to pulsate spontaneously back into the syringe (Weinstein and Plumer 2007, E).
22 Slowly aspirate by gently pulling the plunger of the arterial gas syringe to a minimum of 0.6 mL of blood for the sample (check recommended amount of blood as directed by manufacturer's guidelines). If using a vented sample syringe, aspiration is not required as the syringe will fill automatically.	To minimize vasospasm. E To ensure optimal volume is obtained in order to ensure an appropriate mix of blood with heparin (see manufacturer's guidelines, C).
23 Withdraw the needle, immediately followed by application of pressure using a low-linting swabs.	To prevent haematoma formation and excessive bleeding. E
24 Discard the sharp into a sharps container. Promptly return the wrist to the neutral position following sampling.	To ensure correct clinical waste management and to reduce the risk of sharps injury (DH 2006a, C). Prolonged hyperextension may be associated with changes in median nerve conduction (Chowet et al. 2004, R4).
25 Apply pressure for a minimum of 5 minutes or until no signs of bleeding are observed. Ask for assistance from another nurse if necessary.	To minimize blood loss and to ensure pressure exerted to prevent haematoma and blood loss (RCN 2010, C). Assistance with pressure application enables the sample to be analysed swiftly (Bucher 2001, E).
Post-procedure	
26 Dispose of equipment safely.	To prevent contamination of others (DH 2010, C).
27 Expel any air bubbles from the syringe, and cap the arterial syringe.	To keep sample airtight and avoid inaccuracies (White 2003, E).
28 Label with patient's name, number, date of birth, etc. at the patient's bedside.	To prevent mislabelling when away from the patient. To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
29 Send sample immediately to area of ABG analysis machines such as laboratory, ICU, HDU, theatres or A&E departments. If sample reading is going to be delayed, pack sample on ice to prevent clotting of blood in syringe.	ABG samples can be processed immediately and usually a result can be obtained within minutes. E Arterial blood samples should be obtained in strict anaerobic conditions and should be placed on ice and held at 0°C until analysis (Knowles et al. 2006, E).
30 Check puncture site and apply a clean, sterile, low-linting gauze dressing. Secure with tape.	To maintain pressure and prevent haematoma formation. E
31 Clearly document rationale for procedure in patient's notes and verbally communicate arterial analysis findings to relevant medical and nursing teams.	To acknowledge accountability for actions and ensure effective communication. To ensure prompt and appropriate treatment (NMC 2010, C).

Procedure guideline 10.5 Arterial blood gas sampling: arterial cannula**Essential equipment**

- Sterile dressing pack
- 5 mL Luer-Lok syringe
- Non-sterile gloves and apron
- Sterile Luer-Lok cap
- 2% chlorhexidine in 70% alcohol
- Bactericidal alcohol handrub
- Clean tray or receiver
- Trolley
- Pre-heparinized arterial blood gas syringe

Pre-procedure**Action****Rationale**

- 1 Explain and discuss the procedure with the patient. Obtain valid consent in all cases except in emergencies when the patient is unable to consent. To ensure the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- 2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. To minimize the risk of cross-infection (DH 2010, **C**).
- 3 Prepare trolley. To minimize the risk of cross-infection (DH 2010, **C**).
- 4 Apply gloves and apron. To prevent contamination of hands with blood (DH 2010, **C**).
- 5 Check the three-way tap is closed to port (**Action figure 5**). To prevent back-flow of blood and blood spillage. **E**
- 6 Press silence button on arterial monitor for duration of sampling. The continual alarm disturbs both the patient and others in the unit. Alarms of no clinical significance should be minimized (Chambrin 2001, **R5**).

Procedure

- 7 Remove cap from three-way tap and clean port with a swab soaked in 2% chlorhexidine in 70% alcohol and allow to dry. To minimize the risk of infection (DH 2010, **C**).
- 8 Attach 5 mL Luer-Lok syringe. To remove saline, old blood and small emboli from the dead space within the cannula (Dancker and Fried 2013, **E**).
- 9 Turn three-way tap to artery and port (**Action figure 9**). To prevent contamination of blood with flush solution. **E**
- 10 Slowly withdraw 3–5 mL volume of blood. To prevent the artery going into spasm (Lipsitz 2004, **R5**).
- 11 Turn three-way tap diagonally to close off both the artery and flush (see **Action figure 16**). To enable the syringe to be removed without blood loss; to prevent backflow from artery. **E**
- 12 Remove 5 mL syringe and discard. To discard the contaminated sample. **E**
- 13 Connect the blood gas syringe to the three-port. In order to withdraw the sample. **E**
- 14 Turn three-way tap on to artery and port (see **Action figure 9**). To withdraw arterial blood. **E**
- 15 Slowly remove the recommended amount of blood (0.6–1 mL). To prevent the artery going into spasm, ensuring the correct volume of blood mixes with the heparin in the gas syringe (Lipsitz 2004, **R5**).
- 16 Turn three-way tap diagonally to close off both the artery and flush (**Action figure 16**). To prevent haemorrhage or blood spillage. **E**
- 17 Remove the gas syringe, gently rotate syringe. To ensure the blood and heparin contained within the syringe are mixed. **E**

Post-procedure

- 18 Turn three-way tap onto 'open to port' position; to flush the port, apply a sterile swab to the port, flush by squeezing the actuator (see manufacturer's instructions) (**Action figure 18**). The swab will absorb the blood, preventing contamination. **E**
Blood is cleared from the port, reducing risk of thrombosis and microemboli (O'Hare and Chilvers 2001, **E**).
- 19 Turn three-way tap to 'open to artery' position and flush cannula towards the artery, by gently squeezing actuator. As cannula is flushed observe digits for signs of blanching, discolouration or complaints of pain from the patient. Blood is cleared from the cannula and arterial tubing. **E**
To ensure early recognition of proximal or distal embolism. **E**
- 20 Clean port with chlorhexidine in 70% alcohol swab and allow to dry. To minimize the risk of infection (DH 2010, **C**).
- 21 Apply new sterile Luer-Lok cap and check it is secure. To minimize infection and prevent exsanguination (Hart 2006, **E**).
- 22 Remove gloves and wash hands. To minimize infection (Hart 2006, **E**).

23 Check pressure infuser cuff is inflated to 300 mmHg.

24 Analyse or send to nearest blood gas analyser and document result and report abnormalities.

To prevent backflow of blood into circuit. **E**

To obtain result. **E**

To ensure timely and accurate record keeping (NMC 2010, **C**).

Action Figure 5 Three-way tap: closed to port.

Action Figure 9 Three-way tap: turned to artery and port.

Action Figure 16 Three-way tap: turned diagonally to close off flush, artery and port.

Action Figure 18 Three-way tap: turned to flush and port.

Post-procedural considerations

Monitoring and follow-up of patient are essential. After the blood sampling procedure, nursing staff should monitor the patient for early and late signs and symptoms of potential complications. Active profuse bleeding at the puncture site might raise suspicion of vessel laceration. Femoral artery bleeding carries an increased risk of circulatory compromise because of the large calibre and deep location of the vessel, which allow larger amounts of blood to accumulate without initially giving rise to clinical findings (Danckers and Fried 2013).

A rapidly expanding haematoma may compromise regional circulation and increase the risk of compartment syndrome, especially in the forearm. This manifests as pain, paraesthesias, pallor and absence of pulses. Paresis and persistent pain may indicate a nerve lesion. Limb skin colour changes, absent pulses and distal coldness may be seen in ischaemic injury from artery occlusion caused by thrombus formation or vasospasm. Infection at the puncture site should be considered in the presence of regional erythema and fever (Danckers and Fried 2013).

Complications

Although patients with severe coagulopathy are at higher risk for bleeding complications, no clear evidence on the safety of arterial puncture in the setting of coagulopathy exists. In patients with coagulopathy, careful evaluation of the need for ABG sampling is recommended (Danckers and Fried 2013).

Complications of ABG sampling include the following.

- Local haematoma
- Artery vasospasm
- Arterial occlusion
- Air or thrombus embolism
- Local anaesthetic anaphylactic reaction
- Infection of the puncture site
- Needlestick injury to healthcare personnel
- Vessel laceration
- Vasovagal response
- Haemorrhage
- Local pain (Danckers and Fried 2013)

Blood tests

Evidence-based approaches

Rationale

Blood tests are routinely collected to:

- define baseline results
- confirm disease
- monitor disease
- regulate therapy/treatment.

It is important that the correct blood tube is used for each test. The blood tubes contain special additives relevant to the type of test required, usually indicated by the colour of the tube top. The practitioner should ensure that the correct tube is selected by referring to local hospital guidelines. Correct ‘order of draw’ should be followed to avoid transferring additive from one tube to another when filling (Garza and Becan-McBride 2013).

Numerous blood tests are available. Blood samples are sent to various departments within the laboratory, such as haematology, biochemistry and microbiology. Brief outlines of some routine tests are given below. Please refer to specialist reference texts for more detail.

Haematology

The full blood count (FBC) is the most commonly requested blood test (Higgins 2013). The FBC involves monitoring the levels of

red blood cells (erythrocytes), white blood cells (leucocytes) and platelets (thrombocytes). Variations to normal values can indicate anaemia, infection and thrombocytopenia (Table 10.4).

Group and save (blood transfusion)

All patients who require a blood transfusion need to have their blood type confirmed. It is essential that correct patient identification and accurate labelling are maintained. The sample will be screened to determine the ABO and Rh (Rhesus) type. All staff should receive formal documented training in blood transfusion practice (McClelland 2007) (see Chapter 7: Nutrition, fluid balance and blood transfusion.)

Biochemistry

Urea and electrolytes are the most common biochemistry tests requested (Table 10.5).

Liver function tests

There are numerous tests which are used to assess liver function. Additional tests include alkaline phosphatase (AP), gamma-glutamyl transpeptidase (GGT), aspartate aminotransferase (AST) and alanine aminotransferase (ALT).

Microbiology

Various types of sample may be sent to the microbiology laboratory for screening, for example microbiological drug assays. Blood tests sent to microbiology may include screening for hepatitis B, hepatitis C and HIV.

Table 10.4 Haematology

Test	Reference range	Functions/additional information
Red blood cells	Men: 4.5–6.5 × 10 ¹² /L Women: 3.9–5.6 × 10 ¹² /L	The main function of the RBC is the transport of oxygen and carbon dioxide
Haemoglobin	Men: 135–175 g/L Women: 115–155 g/L	Haemoglobin (Hb) is a protein pigment found within the RBC which carries the oxygen. Anaemia (deficiency in the number of RBCs or Hb content) may occur for many reasons. Changes to cell production, deficient dietary intake or blood loss may be relevant and need to be investigated further
White blood cells	Men: 3.7–9.5 × 10 ⁹ /L Women: 3.9–11.1 × 10 ⁹ /L	The function of the WBC is defence against infection There are different kinds of WBC: neutrophils, lymphocytes, monocytes, eosinophils and basophils Leucopenia is a WBC count lower than 3.7 and is usually associated with the use of cytotoxic drugs Leucocytosis (high levels of neutrophils and lymphocytes) occurs as the body’s normal response to infection and after surgery Leukaemia involves an increased WBC count caused by changes in cell production in the bone marrow. The leukaemic cells enter the blood in increased numbers in an immature state
Platelets	Men: 150–400 × 10 ⁹ /L Women: 150–400 × 10 ⁹ /L	Clot formation occurs when platelets and the blood protein fibrin combine A patient may be thrombocytopenic (low platelet count) due to drugs/poor production or have a raised count (thrombocytosis) with infection or autoimmune disease
Coagulation/INR	INR range 2–3 (in some cases a range of 3–4.5 is acceptable)	Coagulation occurs to prevent excessive blood loss by the formation of a clot (thrombus). However, a clot that forms in an artery may block the vessel and cause an infarction or ischaemia which can be fatal (Blann 2007) Aspirin, warfarin and heparin are three drugs used for the prevention and/or treatment of thrombosis It is imperative that patients on warfarin therapy receive regular monitoring to ensure a balance of slowing the clot-forming process and maintaining the ability of the blood to clot (Blann 2007)

INR, international normalized ratio; RBC, red blood cell; WBC, white blood cell.

Table 10.5 Biochemistry

Test	Reference range	Functions/additional information
Sodium	135–145 mmol/L	<p>The main function of sodium is to maintain extracellular volume (water stored outside the cells), acid/base balance and the transmitting of nerve impulses</p> <p>Hypernatraemia (serum sodium >145 mmol/L) may be an indication of dehydration due to fluid loss from diarrhoea, excessive sweating, increased urinary output or a poor oral intake of fluid. An increased salt intake may also cause an elevation</p> <p>Hyponatraemia (serum sodium <135 mmol/L) may be indicated in fluid retention (oedema)</p>
Potassium	3.5–5.2 mmol/L	<p>Potassium plays a major role in nerve conduction, muscle function, acid/base balance and osmotic pressure. It has a direct effect on cardiac muscle, influencing cardiac output by helping to control the rate and force of each contraction</p> <p>The most common cause of hyperkalaemia (serum potassium >5.2 mmol/L) is chronic renal failure. The kidneys are unable to excrete potassium. The level may be elevated due to an increased intake of potassium supplements during treatment. Tissue cell destruction caused by trauma/cytotoxic therapy may cause a release of potassium from the cells and an elevation in the potassium plasma level. It may also be observed in untreated diabetic ketoacidosis</p> <p>Urgent treatment is required as hyperkalaemia may lead to changes in cardiac muscle contraction and cause subsequent cardiac arrest</p> <p>The main cause of hypokalaemia (serum potassium <3.5 mmol/L) is the loss of potassium via the kidneys during treatment with thiazide diuretics. Excessive/chronic diarrhoea may also cause a decreased potassium level</p>
Urea	2.5–6.5 mmol/L	<p>Urea is a waste product of metabolism that is transported to the kidneys and excreted as urine. Elevated levels of urea may indicate poor kidney function</p>
Creatinine	55–105 µmol/L	<p>Creatinine is a waste product of metabolism that is transported to the kidneys and excreted as urine. Elevated levels of creatinine may indicate poor kidney function</p>
Calcium	2.20–2.60 mmol/L	<p>Most of the calcium in the body is stored in the bone but ionized calcium, which circulates in the blood plasma, plays an important role in the transmission of nerve impulses and functioning of cardiac and skeletal muscle. It is also vital for blood coagulation</p> <p>High calcium levels (hypercalcaemia >2.6 mmol/L) can be due to hyperthyroidism, hyperparathyroidism or malignancy. Elevation in calcium levels may cause cardiac arrhythmia, potentially leading to cardiac arrest (Blann 2007)</p> <p>Tumour cells can cause excessive production of a protein called parathormone-related polypeptide (PTHrP) which causes a loss of calcium from the bone and an increase in the blood calcium levels. This is a major reason for hypercalcaemia in cancer patients (Higgins 2013)</p> <p>Hypocalcaemia (<2.20 mmol/L) is often associated with vitamin D deficiency due to inadequate intake or increased loss due to gastrointestinal disease. Mild hypocalcaemia may be symptomless but severe hypocalcaemia may cause increased neuromuscular excitability and cardiac arrhythmias. It is also a common feature of chronic renal failure (Higgins 2013)</p>
C-reactive protein (CRP)	<10 mg/L	<p>Elevation in the CRP level can be a useful indication of bacterial infection. CRP is monitored after surgery and for patients who have a high risk of infection. The CRP level can help monitor the severity of inflammation and assist in the diagnosis of conditions such as systemic lupus erythematosus (SLE), ulcerative colitis and Crohn's disease (Higgins 2013)</p>
Albumin	35–50 g/L	<p>Albumin is a protein found in blood plasma which assists in the transport of water-soluble substances and the maintenance of blood plasma volume</p>
Bilirubin	(total) <17 µmol/L	<p>Bilirubin is produced from the breakdown of haemoglobin; it is transported to the liver for excretion in bile. Elevated levels of bilirubin may cause jaundice</p>

Blood cultures

Definition

A blood culture is a specimen of blood obtained from a single venepuncture or CVAD for the purpose of detecting blood-borne organisms (bacteria or fungi) and their associated infections (Lee et al. 2007). Inoculation of an aerobic and an anaerobic sample of blood in two separate bottles comprises a set of blood cultures.

Related theory

Blood cultures are an essential part of the management of patients with serious blood-borne infections and are known as the gold standard investigation (HPA 2014a), enabling the identification of the causative pathogens, antimicrobial susceptibility and treatment guidance (Shore and Sandoe 2008). Bacteraemia and fungaemia are associated with high morbidity and mortality amongst hospitalized patients, particularly those with compromised host

defences (Panceri et al. 2004). The accurate and timely detection of the organism and sensitivities has significant diagnostic and prognostic importance (HPA 2014a).

Micro-organisms may be present in the blood intermittently or continuously, depending upon the source of infection (HPA 2014a). In order to determine whether there is a bacteraemia (bacteria in the blood), the bacteria must be 'grown' or 'cultured'. The blood sample taken must be added to a culture medium (a liquid containing nutrients essential for bacterial growth). The blood cultures then need time in an appropriate environment for the bacteria (if any) to grow. This usually takes around 6–18 hours, but slow-growing species can take longer. If there is evidence of bacterial growth, this will then be stained and examined under a microscope to determine species and then tested for sensitivity (Higgins 2013).

536 Evidence-based approaches

Rationale

Indications

There are many signs and symptoms in the patient which may suggest bacteraemia but clinical judgement is required. The following indicators should be taken into account when assessing a patient for signs of bacteraemia or sepsis which would then indicate the need for blood culture sampling (Dellinger et al. 2013, HPA 2014a).

- Core temperature out of normal range ($>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$)
- Focal signs of infection
- Abnormal heart rate (raised), blood pressure (low or raised) or respiratory rate (raised)
- Chills or rigors
- Raised or very low white blood cell count
- New or worsening confusion/altered levels of consciousness (Higgins 2013)

Coburn et al. (2012) suggest that an isolated fever or leucocytosis does not necessitate the collection of blood cultures, unless the patient is immunocompromised or endocarditis is suspected. Asai et al. (2012) also recognized the limitations of blood culture sampling in the terminally ill patient and do not recommend the routine use of this diagnostic tool for patients at the end of life. However, professional judgement will be required for each individual case.

Methods of blood culture specimen collection

In recognition of the importance of taking accurate blood cultures, there is now national guidance that implements procedure and policy to improve the quality of blood culture investigations and to reduce the risk of blood sample contamination (HPA 2014a). Contamination can come from a number of sources: the patient's skin, the equipment used to obtain the sample, the practitioner or the general environment (Murray and Masur 2012). Failure to use an aseptic technique or careful procedures when obtaining blood cultures can cause a 'false-positive' result which may lead to extensive diagnostic testing, excessive antibiotic use, prolonged hospitalization and artificially raised incidence rates (Dellinger et al. 2013).

In order to optimize the identification of causative organisms, the taking of a peripheral sample is recommended and two sets of cultures should be taken at separate times and from separate sites. This will help eliminate the possibility of a false positive (Myers and Reyes 2011).

The initial samples should be obtained directly from a peripheral vein and not from existing peripheral cannulas or immediately above a cannula site, and the femoral vein should be avoided for venepuncture because it is difficult to ensure adequate skin cleansing and disinfection (DH 2007b).

If the patient has an existing vascular access device (VAD) which has been *in situ* for more than 48 hours or is suspected

as a source of infection, a sample should also be taken from the device (Myers and Reyes 2011). Dellinger et al. (2013) suggest that, if feasible, a set of cultures should be taken from each lumen of the VAD.

It is suggested that the blood cultures should be taken when the temperature is rising or as soon as possible following a spike in temperature as this is when the serum concentration of the bacteria is at its highest (Higgins 2013).

Blood cultures should be taken prior to commencing or changing antimicrobial therapy as antibiotics may delay or prevent bacterial growth, causing a falsely negative result (HPA 2014a). In accordance with the Surviving Sepsis Campaign 2012 (Dellinger et al. 2013), antimicrobial therapy should be started within the first hour of recognition of severe sepsis and blood cultures should be taken before antimicrobial therapy is initiated. This is essential to confirm infection and the responsible pathogens whilst not causing significant delay in antibiotic administration (Dellinger et al. 2013). If antibiotic therapy has already been commenced, blood cultures should ideally be taken immediately prior to the next dose, except in paediatric patients (DH 2007b).

Legal and professional issues

Competencies

Blood cultures should be collected by practitioners who have been trained in the collection procedure and whose competence has been assessed (DH 2007b). Practitioners must be competent and feel confident that they have the knowledge, skill and understanding to undertake blood culture sampling for microbiological analysis (NMC 2015).

Risk management

Contamination of a blood sample can lead to false-positive results which may in turn lead to inappropriate antibiotic therapy. This also has cost and resource implications (HPA 2014a). Contamination can be avoided by correctly decontaminating the patient's skin, adequate hand hygiene and decontamination of the bottle tops prior to obtaining a sample (Aziz 2011).

False negatives can occur due to inadequate sample volumes resulting in incorrect blood to media ratios and the administration of antimicrobials prior to taking the samples. False negatives result in present bacteria going undetected and therefore potentially being missed or untreated which has clear consequences for the patient (HPA 2014a).

Pre-procedural considerations

Equipment

Most blood culture systems involve two different collection bottles. Both bottles contain a particular medium that provides an optimal environment for bacterial growth. One bottle contains oxygen in the space above the medium for aerobic or oxygen-requiring bacteria and the other is suitable for anaerobic bacteria not requiring oxygen. The aerobic bottle should be filled first to avoid oxygen entering the anaerobic bottle (HPA 2014a).

The use of a needle to decant blood into the culture bottles is now largely redundant due to the wide use of closed, vacuumed blood collection systems (for example, the Bio-Merieux BacT/ALERT system which utilizes either a holder for venous access device sampling or a Luer adaptor safety winged device for peripheral sampling) (see Figure 10.6). This reduces the health and safety risk to the healthcare professional and the risk of culture contamination. Needle-free or safety systems should be used where possible (HSE 2013).

Volume of blood culture specimen collection

Care should be taken not to under- or overfill the bottles as it is difficult to accurately judge the sample volume with this method (Shore and Sandoe 2008). The volume of blood taken for a culture is also critical to ensure correct blood to liquid culture medium

ratio. A false-negative result could occur if an insufficient volume is introduced or if too much blood is introduced, due to the culture medium in the bottles being diluted (Higgins 2013). The liquid culture medium is a mixture of nutrients that supports microbial growth and inhibits phagocytosis and lysozyme activity (Shore and Sandoe 2008). This helps to determine if there are pathogenic micro-organisms present in the blood. As there are a number of systems in use, the manufacturer's instructions should be followed as to the total volume required for each bottle. Adult patients with clinically significant bacteraemias often have a low number of colony-forming units per millilitre of blood and a minimum of 10 mL per culture bottle is recommended (Dellinger et al. 2013).

Pharmacological support

Skin preparation products

Poor aseptic technique and skin decontamination can cause contamination of a blood culture with the patient's own skin flora, such as coagulase-negative staphylococci (Weston 2008). A combination of 2% chlorhexidine gluconate in 70% isopropyl alcohol is recommended as being effective for skin antisepsis (DH 2010, Loveday et al. 2014, Madeo and Barlow 2008). Chlorhexidine gluconate maintains a persistent antimicrobial function by disrupting the cell membrane and precipitating their contents, whilst the isopropyl alcohol quickly destroys micro-organisms by denaturing cell proteins (Inwood 2007). In order to achieve reduction and

inhibition of the micro-organisms living on the skin, gentle friction is required for 30 seconds and the solution should be allowed to dry to achieve good skin antisepsis and to expose the cracks and fissures of the skin to the solution (Loveday et al. 2014). The top of each blood culture collection bottle should also be cleaned with 2% chlorhexidine gluconate in 70% isopropyl alcohol (DH 2010, Higgins 2013).

Central venous access device-related infection

A CVAD presents a high risk of infection with an incidence of bacteraemia of between 4% and 8% (HPA 2014b). When it is suspected that the CVAD is the source of infection, a blood culture sample should ideally be obtained from each lumen of the vascular device, as well as obtaining a peripherally drawn sample (Dellinger et al. 2013, DH 2010, Gabriel 2008). Adequate hub cleansing with 2% chlorhexidine in 70% isopropyl alcohol is essential in reducing cross-contamination of the sample (DH 2010).

Blood cultures from a CVAD can identify colonization from either the device itself or the bloodstream (Penwarden and Montgomery 2002). To diagnose CVAD-related infections, comparison of the time it takes to achieve a positive result from both central and peripheral cultures is recommended (Catton et al. 2005). If a culture from the CVAD is positive much earlier than from the peripheral culture (>2 hours earlier) then it can be assumed that the vascular access device is the source of the infection with up to 96% sensitivity and 92% specificity (Bouza et al. 2005). Results of such analysis can guide whether removal of the CVAD is indicated.

Procedure guideline 10.6 Blood cultures: peripheral (winged device collection method)

Essential equipment

- Alcohol-based skin cleaning preparation (2% chlorhexidine in 70% isopropyl alcohol)
- Alcohol-based swab for blood culture bottle decontamination (2% chlorhexidine in 70% isopropyl alcohol)
- A set of blood culture bottles (anaerobic and aerobic)
- Vacuum-assisted collection system (some include a winged device for peripheral cultures)
- Non-sterile gloves
- Gauze swabs
- Appropriate document/form
- Clean tray or receiver
- Trolley

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub.	To reduce the risk of cross-infection and specimen contamination (DH 2010, C).
3 Clean any visible soiled skin on the patient with soap and water then dry.	To reduce the risk of contamination (DH 2010, C).

Procedure

4 Apply a disposable tourniquet and palpate to identify vein. Release tourniquet.	To improve venous access and choose appropriate vein (Witt 2011, E).
5 Clean skin with a 2% chlorhexidine in 70% isopropyl alcohol swab for 30 seconds and allow to dry for 30 seconds. Do not palpate site again after cleaning.	To enable adequate skin antisepsis and decontamination, and to prevent contamination from practitioner's fingers (DH 2010, C ; Inwood 2007, E).
6 Remove flip-off caps from culture bottles and clean with second 2% chlorhexidine in 70% isopropyl alcohol swab and allow to dry.	To reduce the risk of environmental contamination causing false-positive results (DH 2010, C).
7 Wash and dry hands again or use alcohol handrub and apply non-sterile gloves (sterile gloves are not essential).	To decontaminate hands having been in contact with the patient's skin to palpate vein and to prevent cross-infection. E

(continued)

Procedure guideline 10.6 Blood cultures: peripheral (winged device collection method) *(continued)*

Action	Rationale
8 Attach winged blood collection set into the appropriate vacuum holder for taking blood cultures.	To reduce risk of contamination and health and safety risk to practitioner (DH 2006a, C ; DH 2010, C).
9 Reapply tourniquet.	To improve venous access (Dougherty 2008, E).
10 Remove sheath covering needle at wings and perform venepuncture.	To obtain blood samples. E
11 If blood is being taken for other tests, collect the blood culture first. Inoculate the aerobic culture first.	To reduce the risk of contamination of culture bottles after inoculating other blood bottles. E
12 Attach aerobic bottle first, hold upright and use bottle graduation lines to accurately gauge sample volumes (at least 10 mL in each bottle or as recommended by manufacturer). Remove bottle and replace with anaerobic bottle, take same volume and remove bottle.	To ensure anaerobic bottle does not become contaminated with oxygen from the sample (Myers and Reyes 2011, E).
13 Release tourniquet and remove winged device, apply pressure to the venepuncture site.	To prevent bleeding at the site (de Verteuil 2011, E).

Post-procedure

14 Activate safety feature and discard winged collection set in sharps container.	To reduce risk of sharps injury (HSE 2013, C).
15 Remove gloves and wash/decontaminate hands.	To ensure correct clinical waste management and reduce risk of cross-infection (DH 2006a, C).
16 Apply appropriate dressing.	To cover the puncture site after checking the patient has no allergy to the dressing (de Verteuil 2011, E).
17 Label bottles with appropriate patient details while in the presence of the patient, ensuring the bar codes on the bottles are not covered or removed.	To ensure that the specimens from the right patient are delivered to the laboratory, the requested tests are performed and the results returned to the patient's records (NHSBT 2011, C ; NHSBT 2012, C ; NMC 2010, C ; NPSA 2007a, C).
18 Complete microbiology request form (including relevant information such as indications, site and time of culture).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
19 Arrange prompt delivery to the microbiology laboratory to process immediately (or incubate at 37°C).	To increase the chance of accurate organism identification (Higgins 2013, E).
20 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.7 Blood cultures: central venous access device**Essential equipment**

- Alcohol-based skin cleaning preparation (2% chlorhexidine in 70% isopropyl alcohol)
- Alcohol-based swab for blood culture bottle decontamination (2% chlorhexidine in 70% isopropyl alcohol)
- A set of blood culture bottles (anaerobic and aerobic)
- Vacuum-assisted collection system and tube holder for blood cultures
- Non-sterile gloves
- Gauze swabs
- Microbiological request form
- 10 mL syringe
- 0.9% sodium chloride flushing solution as per hospital policy
- Clean tray or receiver
- Trolley

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Apply gloves.	To reduce the risk of cross-infection and specimen contamination (DH 2010, C).

Procedure

3 Prepare a cleaned trolley and sterile intravenous or dressing pack.	To ensure a clean and suitable workplace. E
4 Clean the end of each lumen with 2% chlorhexidine in 70% isopropyl alcohol swab and allow to dry for 30 seconds (if continuous life-sustaining infusions are running, this may not be possible from this lumen, so an alternative lumen must be used).	To enable adequate antisepsis and decontamination of each lumen (Dellinger et al. 2013, C).
5 Remove flip-off caps from culture bottles and clean with 2% chlorhexidine in 70% isopropyl alcohol swab and allow to dry.	To reduce the risk of environmental contamination causing false-positive results (DH 2010, C).
6 Using a 10 mL syringe, take and discard at least 10 mL of blood prior to attaching blood culture bottles.	To remove any 0.9% sodium chloride or other drug residue that may be present in the lumen (Danckers and Fried 2013, E).
7 If blood is being taken for other tests, collect the blood culture first. Inoculate the aerobic culture first.	To reduce the risk of contamination of culture bottles after inoculating other blood bottles. E
8 Attach adaptor into holder and then attach vacuum-assisted collection system into hub of CVAD, insert blood culture bottle and puncture septum.	To initiate vacuum collection. E
9 Attach aerobic bottle first, hold upright, and use bottle graduation lines to accurately gauge sample volumes (at least 10 mL in each bottle or as recommended by manufacturer). Remove bottle and replace with anaerobic bottle.	To reduce the risk of a false-negative result due to insufficient volume or overdiluted culture medium (Higgins 2013, E).
10 Repeat steps 5–9 with each lumen if a multilumen device is <i>in situ</i> .	To accurately determine if the CVAD is the source of infection (Catton et al. 2005, E).
11 Remove and discard vacuumed collection holder in sharps container.	To reduce risk of sharps injury and ensure correct waste management (DH 2006a, C).
12 Flush with at least 10 mL 0.9% sodium chloride using a push-pause method and end with positive pressure.	To remove blood from lumen and maintain patency (Dougherty 2008, E).
Post-procedure	
13 Remove and dispose of gloves and wash/decontaminate hands.	To ensure correct clinical waste management and reduce risk of cross-infection (DH 2006a, C).
14 Label bottles with appropriate patient details, ensuring the bar codes on the bottles are not covered or removed.	To ensure correct patient and sample identity and to aid traceability within the laboratory. E
15 Complete microbiology request form (including relevant information such as indications, site and time of culture).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
16 Arrange prompt delivery to the microbiology laboratory to process immediately (or incubate at 37°C).	To increase the chance of accurate organism identification (Higgins 2013, E).
17 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Post-procedural considerations**Immediate care**

Blood cultures should be dispatched to the laboratory for immediate processing. If cultures cannot be processed immediately, they should be incubated at 37°C in order for bacterial growth to begin and to prevent deterioration in pathogenic micro-organism yield (Higgins 2013).

Ongoing care

Decisions on commencing, changing or adding antimicrobial therapy may need to be considered depending upon the patient's condition and history. Drug-resistant micro-organisms have highlighted the need for prudent control of antibiotic prescribing and usage. It is estimated that up to 40% of patients with moderate-

to-severe infections are given unnecessary or inappropriate antibiotics to treat the *in vitro* susceptibility of the pathogen that is subsequently cultured (Johannes 2008).

The possibility of false results should also be considered before commencing any therapy. A false negative may be due to disproportionate blood volume to culture medium, inadequate incubation time and/or antibiotic administration prior to taking the sample. If the results are positive, the possibility of contamination should be considered, especially if the bacterium is one that commonly causes contamination (Higgins 2013). Occasionally a blood culture will provide a positive result for *Staph. epidermidis* which is normally present on the skin and therefore can contaminate the sample due to poor technique (Higgins 2013). Decisions regarding appropriate choice of empirical therapy as well as the duration and dosage should be made in conjunction with advice from the microbiology team (Tacconelli 2009).

Antimicrobial drug assay

Definition

Therapeutic drug monitoring of blood serum ensures that there are sufficient levels of particular antimicrobial drugs to be therapeutically effective, whilst avoiding potentially toxic excess that may lead to adverse effects (Thomson 2004, Walker and Whittlesea 2012).

Related theory

The majority of drugs used in clinical practice have a wide therapeutic window and quantitative analysis of serum levels is unnecessary. However, there are certain drugs that require monitoring of serum concentration levels due to their narrow therapeutic index where toxicity is associated with persistently high serum concentrations, whilst therapeutic failure can result from low concentrations (Egan et al. 2012, Thomson 2004). Swallow et al. (2012) describe the use of saliva for testing drug levels. They suggest this is a reliable alternative to blood sampling and has been found to be particularly useful for children and babies.

Examples of drugs that need monitoring in clinical practice include lithium, digoxin, theophylline, phenytoin, ciclosporin and certain antibiotics (Higgins 2013). This section will focus on aminoglycoside antibiotics, such as gentamicin and amikacin, and glycopeptide antibiotics such as vancomycin as these are the most commonly monitored antimicrobial assays.

These drugs are excreted almost entirely by glomerular filtration and are potentially nephrotoxic and ototoxic. When aminoglycosides or glycopeptides are used as single modes of treatment, renal toxicity is estimated to be 5–10%, although this can increase to as much as 30% if both are used synergistically (Pannu and Nadim 2008).

- Nephrotoxicity involves the proximal tubules that are capable of regeneration; therefore adverse effects may be reversible over time (Hadaway and Chamallas 2003, Huth et al. 2011).
- Ototoxicity causes damage within the neuroepithelial cells of the inner ear, which can cause cochlear damage and/or vestibular impairment. These cells cannot be regenerated so the effects are irreversible (Huth et al. 2011). Ototoxicity occurs in 0.5–3% of patients and is usually associated with very high serum concentrations of the drugs (Pagkalis et al. 2011, Sha 2005).

Aminoglycoside antibiotics

Aminoglycosides such as gentamicin and amikacin are potent antibiotics, which are mainly used against aerobic, gram-negative bacteria and are often used synergistically against certain gram-positive organisms (Hammet-Stabler and Johns 1998). Administering extended dosing (single daily dosing) of aminoglycosides has been found to be associated with fewer adverse events and, because of their rapid 'concentration-dependent' action, the rate and extent of bacterial cell death are increased (Owens and Shorr 2009, Pagkalis et al. 2011). The timing of serum sampling will be determined by the patient's clinical manifestations, particularly renal function. Generally, for gentamicin, the post-dose level should be lower than 12 mg/L and the trough level should be lower than 2 mg/L (Walker and Whittlesea 2012).

Glycopeptide antibiotics

Vancomycin is the glycopeptide antibiotic most widely used for the treatment of serious infections caused by gram-positive pathogens, such as those suspected to be methicillin resistant (Jones 2006). Glycopeptides exhibit 'time-dependent' effects, meaning that their effectiveness increases with the duration of time that the antibiotic serum concentration is above the minimum inhibitory concentration (MIC) of susceptible pathogens (Owens and Shorr 2009).

The use and monitoring of vancomycin have increased due to the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) but the emergence of vancomycin-resistant *Staphylococcus aureus* has further complicated its clinical use (Roberts et al. 2011).

Determination of serum blood levels of vancomycin depends on the frequency of administration. If given intermittently (usually twice-daily doses), trough levels should be taken at set times, immediately before the administration of the next bolus dose (Jones 2006). An alternative method of administration is the continuous infusion of vancomycin providing higher and more sustained serum levels which may enhance the effect (Kitzis and Goldstein 2006). If given intermittently, the trough level should be between 5 and 15 mg/L, whilst continuous infusions aim to maintain serum concentrations at between 15 and 25 mg/L.

Evidence-based approaches

Rationale

The main criterion for monitoring serum drug concentration is to ensure that there is enough drug given for efficacy whilst avoiding concentrations associated with a significant risk of toxicity (Roberts et al. 2011).

Indications

Accurate and timely monitoring of microbial assay levels is indicated in patients receiving intravenous aminoglycoside or glycopeptide antibiotics:

- to ensure optimum therapeutic range
- to minimize high serum levels which may cause adverse side-effects of the drugs (particular caution should be exercised in patients who have renal impairment) (Roberts et al. 2011).

Contraindications

The samples should not be taken if there has been insufficient time lapse between dose administration and sample collection.

Principles of care

The initial dosage regimen should be appropriate for the clinical condition being treated, the patient's clinical characteristics (age, weight, renal function and so on) and concomitant drug therapy (Thomson 2004). The timing of the sample and interpretation of the results of analysis need consideration in relation to the dose given and the timing of previous dose administration.

Serum samples can be taken at two different times: the peak or the trough. A peak sample is collected at the drug's highest therapeutic concentration within the dosing period. The post-dose peak level timing will vary depending on the drug; ordinarily this is 1 hour after the completion of an infusion, although in the case of vancomycin, which has a slow distribution phase, it is recommended that the sample is taken at least 1–2 hours after the infusion ends (Tobin et al. 2002, Walker and Whittlesea 2012).

Trough levels are measured just prior to the administration of the next dose, that is, at the lowest concentration in the dosing period (Tobin et al. 2002). Therefore, trough levels are more commonly used because the level is more representative of how the different variables such as drug absorption and renal function affect the concentration within a predetermined timeframe. The results can then be used to adjust dosages to achieve the optimal response with the minimal toxicity.

Abnormally elevated serum levels may be obtained if the samples are taken from a CVAD through which the drug has been administered. This is more likely when residual drugs remain in the catheter if it has not been flushed correctly following administration of the drug or the first 5–10 mL of blood has not been discarded (Himberger and Himberger 2001). If a multilumen CVAD is *in situ*, a different lumen from the one used to administer the drug should be used to obtain the blood specimen.

Procedure guideline 10.8 Blood sampling: antimicrobial drug assay**Essential equipment**

- Appropriate blood sample bottles
- Vacuum-assisted blood collection system
- Non-sterile gloves and apron
- Clean tray or receiver
- Appropriate documentation/forms

Pre-procedure**Action**

- 1 Discuss indication for procedure with patient.
- 2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Apply gloves.

Rationale

- To ensure the patient understands the procedure and gives valid consent (NMC 2013, **C**).
- To reduce the risk of cross-infection and specimen contamination (Fraiese and Bradley 2009, **E**).

Procedure

- 3 For trough levels: following venepuncture (see Procedure guideline 10.1: Venepuncture), withdraw the volume of blood appropriate to the blood sample bottle using the vacuum-assisted collection system.
- 4 Clearly label blood sample bottle and appropriate form with 'pre-drug administration blood'.
- 5 Administer intravenous antibiotics as prescribed via the patient's established vascular access device.
- 6 If peak level required: within an allotted time after administration, repeat step 3. Clearly label blood sample bottle and appropriate form with 'post-drug administration blood'.
- 7 If CVAD used: the device must be flushed thoroughly before taking the blood sample. Take and discard enough blood to clear the device of any residual flushes solution or medications (usually 5–10 mL is sufficient), then attach vacuum-assisted collection system to take drug level sample. Indicate on blood sample bottle and appropriate form that sample is from a CVAD.

- To ensure the correct volume of blood is obtained and to reduce the safety risk to the practitioner (DH 2006a, **C**; DH 2010, **C**).
- To ensure there is no confusion between the pre-drug and post-drug serum level specimens. **E**
- To continue with patient's prescribed drug regimen. **E**
- To allow time for even distribution of the drug through the blood for peak blood levels to be achieved (Jones 2006, **E**).
- To reduce contamination by previously administered therapeutic agents and to allow appropriate interpretation of the results (NPSA 2007b, **C**; RCN 2010, **C**)

Post-procedure

- 8 Ensure microbiology request forms are completed correctly, including date, exact time and dosage of previously administered dose.
- 9 Arrange prompt delivery to the microbiology laboratory.
- 10 Document the procedure in the patient's records.

- To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).
- To allow for prompt analysis and timely adjustments to patient's drug therapy regimen if indicated. **E**
- To ensure timely and accurate record keeping (NMC 2010, **C**).

Post-procedural considerations**Ongoing care**

Changes in dosage regimens will depend upon interpretation of the results by the microbiology, medical and nursing team. Notably, high serum drug levels should prompt the microbiology team to telephone a result through to the medical team in charge of the patient's care, especially if this warrants withholding subsequent doses of the drug. A low drug serum level would instigate an increase in the dosage of the drug (Roberts et al. 2011). Any changes to the drug regimen should be communicated and clearly documented on the patient's prescription.

Documentation

In accordance with the principles of good record keeping, the date and time of when a trough and/or peak drug assay level is sent

to the laboratory should be documented clearly and promptly in the patient's notes, care plan and/or on the patient's drug chart (or antimicrobial flow charts as provided by the pharmacy department) (NMC 2010). This assists in communication and the dissemination of information between members of the interprofessional healthcare team.

Cerebrospinal fluid obtained by lumbar puncture**Definition**

Lumbar puncture is a medical procedure involving the withdrawal of CSF via a hollow spinal needle inserted into the lumbar

subarachnoid space, a technique first described by Quincke (1891). It may be used for either therapeutic or diagnostic purposes (Barker and Laia 2008).

Anatomy and physiology

The spinal cord lies within the spinal column, extending from the medulla oblongata to the level of the second lumbar vertebra. The adult spinal cord is 2 cm wide at the midthoracic region and 42–45 cm long (Jenkins and Tortora 2013) (Figure 10.9). Like the brain, the spinal cord is enclosed and protected by the meninges, that is, the dura mater, arachnoid mater and pia mater (Barker and Laia 2008). The dura and arachnoid mater are separated by a potential space known as the subdural space. The arachnoid mater and pia mater are separated by the subarachnoid space where the CSF continually circulates (Jenkins and Tortora 2013). Below the termination of the spinal cord, the subarachnoid space contains CSF, the filum terminale and the cauda equina (the anterior and posterior roots of the lumbar and sacral nerves) (Gruener and Biller 2008). So as to avoid damage to the spinal cord, it is imperative that lumbar puncture is performed at the lowest palpable intervertebral space (Figure 10.10). The higher the space, the greater the risk of spinal cord injury.

The spinal needle will have to pass through the following structures: skin, subcutaneous tissue, supraspinal ligament, interspinous ligament, ligamentum flavum, epidural space, dura mater and arachnoid mater.

Cerebrospinal fluid is formed primarily by filtration and secretion from networks of capillaries, called choroid plexuses, located in the ventricles of the brain. Eventually, absorption takes place through the arachnoid villi, which are finger-like projections of the arachnoid mater that push into the dural venous sinuses. CSF is a clear, colourless liquid with various functions and properties. In an adult, the total volume of CSF is 80–150 mL and is reabsorbed at a rate of 20 mL/hour or 480 mL/day (Jenkins and Tortora 2013). CSF constituents include:

- mineral salts
- glucose
- lactic acid
- protein (16–45 mg/dL)
- urea
- cations (Na^+ , K^+ , Ca^{2+} , Mg^{2+})
- anions (Cl^- , HCO_3^-)
- white blood cells (Jenkins and Tortora 2013).

There are three basic functions of CSF.

- *Mechanical protection*: acts as a shock absorber and buoys the brain, enabling it to 'float' in the cranial cavity.
- *Chemical protection*: ensuring an optimal chemical and ionic environment.
- *Circulation*: enabling an exchange of nutrients and waste products (Jenkins and Tortora 2013).

Related theory

Abnormalities of CSF

A red discoloration of the CSF is indicative of the presence of blood, which is an abnormal finding. If the presence of blood is caused by a traumatic spinal tap, the blood will usually clot and the fluid clears as the procedure continues. If the presence of blood is due to subarachnoid haemorrhage, no clotting will occur (Lindsay and Bone 2010).

Turbid or cloudy CSF is indicative of the presence of a large number of white cells or protein and is an abnormal finding. The causes of such turbidity include infection or the secondary infiltration of the meninges with malignant disease, for example leukaemia or lymphoma (Hoffbrand et al. 2006).

The presence of different types of blood cells in the CSF can be diagnostic of a variety of neurological disorders.

- Erythrocytes are indicative of haemorrhage.
- Polymorphonuclear leucocytes are indicative of meningitis or cerebral abscess.
- Monocytes are indicative of a viral or tubercular meningitis or encephalitis.
- Lymphocytes present in larger numbers are indicative of viral meningitis or infiltration of the meninges by malignant disease.
- The presence of leukaemic blast cells is indicative of infiltration of the meninges by leukaemia.
- Viral, bacterial or fungal cultures from the CSF sample are indicative of infection (Barker and Laia 2008).

Normal CSF pressure falls within a range of 10–15 cmH₂O (Lindsay and Bone 2010). Spinal pressure may be raised in the presence of cerebrovascular accident, a space-occupying lesion or bacterial meningitis (Barker and Laia 2008).

Evidence-based approaches

Rationale

A number of tests can be performed on CSF to aid diagnosis (Jenkins and Tortora 2013).

- *Culture and sensitivity*: identifying the presence of micro-organisms would confirm the diagnosis of bacterial/fungal meningitis or a cerebral abscess. The isolation of the causative organism would enable the initiation of appropriate antibiotic or antifungal therapy.
- *Virology screening*: isolation of a causative virus would enable appropriate therapy to be initiated promptly.
- *Serology for syphilis*: tests include the Wassermann reaction (WR), Venereal Disease Research Laboratory (VDRL) and *Treponema pallidum* immobilization (TPI) tests.
- *Protein*: the total amount of protein in CSF should be 15.45 mg/dL (154.5 µg/mL). Proteins are large molecules which do not readily cross the blood–brain barrier. There is normally more albumin (80%) than globulin in CSF as albumins are smaller molecules (Fischbach and Dunning 2004). Raised globulin levels are indicative of multiple sclerosis, neurosyphilis, degenerative cord or brain disease. However, raised levels of total protein can be indicative of meningitis, encephalitis, myelitis or the presence of a tumour (Hickey 2003).
- *Cytology*: central nervous system tumours or secondary meningeal disease tend to shed cells into the CSF, where they float freely. Examination of these cells morphologically after lumbar puncture will determine whether the tumour is malignant or benign (Fischbach and Dunning 2004).

Indications

A lumbar puncture and withdrawal of CSF, with or without the introduction of therapeutic agents, is performed for the following purposes.

- *Diagnosis*: CSF is normally a crystal clear, colourless and sterile liquid which resembles water. Analysis of the CSF for cells not normally present may be made to determine the presence of a pathological process (Jenkins and Tortora 2013). In addition, CSF pressure can be measured (Barker and Laia 2008).
- *Introduction of therapeutic agents*: a number of drugs do not cross the blood–brain barrier so in the treatment and prophylaxis of some malignant diseases such as leukaemia and lymphoma, cytotoxic drugs, namely cytarabine, methotrexate and, rarely, thiopeta, may be administered intrathecally (Coward and Cooley 2006, Hoffbrand et al. 2006, Scurr et al. 2005). Hydrocortisone may also be administered intrathecally.
- *Introduction of spinal anaesthesia for surgery*: spinal anaesthesia, first performed in 1899 by Corning, involves the injection of a local anaesthetic agent such as bupivacaine into the CSF, thus producing anaesthesia suitable for operations on the lower body (Yentis et al. 2009).
- *Introduction of radiopaque contrast medium*: used to provide radiopaque pictures (myelograms) of the spinal cord (Jenkins and Tortora 2013). Myelograms are useful in diagnosing spinal lesions and in helping to plan surgery by isolating the level of the lesion.

Contraindications

The procedure should not be undertaken in the following circumstances.

- In patients in whom raised intracranial pressure (ICP) is suspected or present due to the risk of ‘brain herniation’ (Belford 2005, Lindsay and Bone 2010).
- In patients with papilloedema, bacterial meningitis or deteriorating neurological symptoms, in whom raised ICP or an intracranial mass is suspected. In this situation, neuroimaging (CT or MRI scan) should be undertaken prior to lumbar puncture in order to avoid resultant potentially fatal brainstem compression, herniation or coning (Belford 2005). However, a normal CT scan does not always ensure that it is safe to perform a lumbar puncture so, until better non-invasive procedures to monitor ICP become available and are routinely used, the decision to proceed must be left to clinical expertise and judgement (Hickey 2003).
- Local skin infection may result in meningitis by passage of the bacteria from the skin to the CSF during the procedure. Cutaneous or osseous infection at the site of the lumbar puncture may be considered an absolute contraindication (Chernecky and Berger 2013).
- In patients who are unable to co-operate or who are too drowsy to give a history. Patient co-operation is essential to carry out a baseline neurological examination and to minimize the potential risk of trauma associated with this procedure (Barker and Laia 2008, Chernecky and Berger 2013).
- In patients who have severe degenerative spinal joint disease. In such cases difficulty will be experienced both in positioning the patient and in accessing between the vertebrae (Chernecky and Berger 2013).
- In those patients undergoing anticoagulant therapy or who have coagulopathies or thrombocytopenia (less than $50 \times 10^9/L$). These patients are at increased risk of bleeding and therefore coagulopathies and thrombocytopenia must be corrected prior to undertaking lumbar puncture (Lindsay and Bone 2010).

Principles of care

The principles of lumbar puncture are to gain access to the CSF of the patient whilst maintaining sterility and patient comfort throughout the procedure. For patients receiving intrathecal medication, it is essential that the correct agent is given. For diagnostic procedures, it is imperative that accurate measurements are taken and that the sample is handled and labelled correctly.

The role of the nurse in caring for a patient undergoing a lumbar puncture procedure may include helping to explain the procedure to the patient, preparing the patient, supporting both the patient and doctor/practitioner during the procedure and close follow-up monitoring (Barker and Laia 2008).

Method of lumbar puncture

The patient is positioned either sitting or lying with flexion of the lumbar spine. After cleaning the lumbar area with antiseptic solution, local anaesthetic (usually lidocaine) is infiltrated into the skin at the lowest palpable interspace. The spinal needle is introduced carefully and advanced slowly until there is a perceptible click as the needle tip passes through the dura mater. The stylet of the spinal needle is removed to observe for the free flow of CSF. If a cutting (Quincke type) needle is used, then the cutting edge of the needle should be aligned parallel to the direction of the dural fibres which run vertically (Barker and Laia 2008). No such precaution is necessary when using pencil-point (blunt-ended) needles. If opening pressure is to be measured, the patient must be in the lateral position and the manometer should be immediately connected to the hub of the spinal needle.

The amount of CSF withdrawn for sampling depends on the investigation required. In practice, approximately 5–10 mL of CSF is usually withdrawn, although investigations for cell count and gram stain can be performed using 1 mL (Barker and Laia 2008).

Legal and professional issues

Competencies

If a lumbar puncture is being undertaken to administer medication, for example for intrathecal chemotherapy administration, the practitioner performing the procedure must comply with the national guidance (DH 2008). Organizations must ensure that only appropriately trained staff are conducting lumbar punctures. In order to minimize risk to patients, the equipment used in the procedure has been altered to reduce the risk of incorrect drug administration and/or technique (DH 2012, NPSA 2011).

Risk management

Wrong route administration of intravenous or other chemotherapy into the intrathecal space is a Department of Health 'Never Event' and is therefore considered unacceptable and eminently preventable (DH 2012).

All needles, syringes and connectors utilized in intrathecal (spinal) boluses or lumbar puncture samples must not be able to connect to any other intravenous device. This must also include any

epidural, spinal and regional anaesthesia boluses or infusions (NPSA 2011).

Pre-procedural considerations

Equipment

Enhancements to the design of lumbar puncture needles can confer benefits to the patient in terms of reducing complications and also contribute to reducing drug errors. The newer 'non-cutting' needles such as the Sprotte and Whitacre types cause fewer post-dural puncture headaches (PDPH) than the older 'cutting' needles such as the Quincke type (Lavi et al. 2006). This is because the vertically aligned dural fibres are split and parted instead of being cut, thus allowing some degree of dural self-sealing. In the same manner, thinner gauge needles create less of a CSF leak and further reduce the occurrence of PDPH (NPSA 2011, Straus et al. 2006). It is important to be aware of alerts in relation to equipment problems such as an incorrect needle size supplied in certain packs (MHRA 2013).

Assessment and recording tools

Depending on the patient condition and the reason for the lumbar puncture, various observations and recording tools should be used. As a baseline, the patient's vital signs must be recorded before and after the procedure and documented on an observation chart. If the patient is being investigated for a neurological problem, then the inclusion of pre-procedural Glasgow Coma Scale (GCS) assessment is advised. In all cases, neurological observations, including GCS and pupillary response, should be recorded on a specialized neurological observation chart following the procedure. The patient should be monitored for headache and backache and the puncture site should be inspected, particularly if there have been fluctuations in the neurological observations (Hickey 2003).

Specific patient preparation

Preparation includes advising the patient to empty their bowels and bladder to ensure comfort during the correct flexed (knee-chest) position that the patient must assume during the procedure. This position is required to increase the space between adjacent vertebral spines to allow for the passage of the needle (Lindsay and Bone 2010).

Skin disinfection is of extreme importance to prevent serious spinal infection. Alcoholic chlorhexidine (0.5%) is the most effective solution in this regard, but must be allowed to air dry completely to prevent the neurotoxic chlorhexidine from coming into contact with neural tissue (Hebl 2006).

Procedure guideline 10.9 Lumbar puncture

Essential equipment

- Antiseptic skin-cleaning agents, for example chlorhexidine in 70% alcohol or isopropyl alcohol
- Selection of needles and syringes
- Sterile gloves
- Sterile dressing pack
- Lumbar puncture needles of assorted sizes
- Disposable manometer

- Three sterile specimen bottles. These should be labelled 1, 2 and 3
- Plaster dressing

Medicinal products

- Local anaesthetic, for example lidocaine 1%

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Patient should empty their bladder and bowels before procedure.

Rationale

- To ensure that the patient understands the procedure and gives valid consent (Barker and Laia 2008, **E**; NMC 2013, **C**).
- To ensure comfort (Barker and Laia 2008, **E**; Hickey 2003, **E**).

3 Assist patient into required position on a firm surface. <i>Either lying (Action figure 3):</i> <ul style="list-style-type: none"> • One pillow under the patient's head. • On side with knees drawn up to the abdomen and clasped by the hands. • Support patient to maintain this position. <i>Or sitting:</i> <ul style="list-style-type: none"> • Patient straddles a straight-backed chair so that their back is facing the doctor. • Patient folds arms on the back of the chair and rests head on them. 	To ensure maximum widening of the intervertebral spaces and thus easier access to the subarachnoid space (Lindsay and Bone 2010, E). To avoid sudden movement by the patient which would produce trauma (Barker and Laia 2008, E).
4 Continue to support, explain care and observe the patient throughout the procedure.	This position may be used for those patients unable to maintain the lying position. It allows more accurate identification of the spinous processes and thus the intervertebral spaces (Barker and Laia 2008, E ; Hickey 2003, E). To facilitate psychological and physical well-being (Barker and Laia 2008, E).
Procedure	
5 Wash hands with antibacterial detergent. Put on gloves and apron.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E).
6 Assist doctor/practitioner as required; doctor/practitioner will proceed to: Don a hat and mask, clean hands with antiseptic solution, don sterile apron and gloves.	To minimize the risk of cross-contamination (Gemmel et al. 2008, E).
7 Clean the skin with the antiseptic cleaning agent.	To ensure the removal of skin flora to minimize the risk of infection (Lindsay and Bone 2010, E).
8 Identify the area to be punctured and infiltrate the skin and subcutaneous layers with local anaesthetic.	To minimize discomfort from the procedure (Barker and Laia 2008, E).
9 Introduce a spinal puncture needle below the second lumbar vertebra and into the subarachnoid space.	This is below the level of the spinal cord but still within the subarachnoid space (Lindsay and Bone 2010, E).
10 Ensure that the subarachnoid space has been entered and attach the manometer to the spinal needle, if required.	To obtain a CSF pressure reading (normal pressure is 10–15 cm H ₂ O). This can only be measured if the patient is in a lateral position (Hickey 2003, E ; Lindsay and Bone 2010, E).
11 Obtain the appropriate specimens of CSF (approx. 10 mL) for analysis. Cell count and gram stain can be performed using 1 mL of fluid.	To establish diagnosis (Hickey, 2003, E). The first specimen, which may be bloodstained due to needle trauma, should go into bottle 1. This will assist the laboratory to differentiate between blood due to procedure trauma and blood due to subarachnoid haemorrhage (Chernecky and Berger 2013, E).
12 Ensure the specimens are labelled appropriately 1, 2 and 3 and sent with the correct forms to the laboratory.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
13 If intrathecal medication is to be instilled, drug and dose must be checked and administered safely according to national guidelines.	To ensure the correct drug and dosage of drug are safely administered (Coward and Cooley 2006, E ; DH 2008, C).
14 Withdraw the spinal needle once specimens have been obtained, appropriate pressure measurements taken and intrathecal medication administered.	To minimize the risks of the procedure (Barker and Laia 2008, E).
15 When the needle is withdrawn, apply pressure over the lumbar puncture site using a sterile topical swab.	To maintain asepsis and to stop blood and CSF flow (Hickey 2003, E).
16 When all leakage from the puncture site has ceased, apply a plaster dressing.	To prevent secondary infection (Barker and Laia 2008, E).
Post-procedure	
17 Make the patient comfortable. They should lie flat or the head should be tilted slightly downwards. Time to lie flat varies from hospital to hospital, but it is usually around 4 hours if there is no headache.	To avoid headache and decrease the possibility of brainstem herniation (coning) due to a reduction in CSF pressure (Barker and Laia 2008, E ; Hickey 2003, E).
18 Remove equipment and dispose of as appropriate.	To prevent the spread of infection and reduce risk of needlestick injury (DH 2006c, C).
19 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

(continued)

Procedure guideline 10.9 Lumbar puncture (continued)

Action	Rationale
20 Patient should be monitored for the next 24 hours with careful observation of the following. <ul style="list-style-type: none">• Leakage from the puncture site• Headache• Backache• Neurological observations/vital signs	Clear fluid may be a cerebrospinal leak (Barker and Laia 2008, E). Not unusual following lumbar puncture and may be due to loss of CSF. E As above. These may indicate signs of change in ICP (Hickey 2003, E). For further information on neurological observations and vital signs, see Chapter 11: Observations..
21 Encourage a fluid intake of 2–3 litres in 24 hours.	To replace lost fluid. Patient may have difficulty micturating due to procedure and supine position (Allan 2002, E ; Hickey 2003, E).

Action Figure 3 Position for lumbar puncture. Head is flexed onto chest and knees are drawn up.

Problem-solving table 10.3 Prevention and resolution (Procedure guideline 10.9)

Problem	Cause	Prevention	Suggested action
Pain down one leg during the procedure.	A dorsal nerve root may have been touched by the spinal needle.	Make sure the spinal needle is in the midline. Advance the needle slowly and stop as soon as CSF is obtained.	Inform doctor/practitioner, who will probably move the needle. Reassure patient.
Fluctuation of neurological observations: level of consciousness, pulse, respirations, blood pressure or pupillary reaction.	Herniation (coning) of the brainstem due to the decrease of ICP. Raised ICP is a contraindication to lumbar puncture.	Check that relevant neuroimaging has been reviewed prior to procedure.	Observe patient constantly for signs of alteration in ICP. The frequency may be decreased as patient's condition allows. Report any fluctuations in these observations to a doctor immediately (Barker and Laia 2008).

Post-procedural considerations

Immediate care
Patients will usually be nursed flat for a period of up to 4 hours in order to reduce the risk of post-spinal headache. There is no evidence that longer periods are useful (Ebinger et al. 2004). Follow-up care will include neurological observations, monitoring for issues such as difficulties with voiding, raised temperatures, headaches and discomfort. Analgesia and reassurance may be required (Allan 2002).

Ongoing care
If the procedure has been performed in an outpatient setting, the patient may be discharged home after 1–2 hours but with clear instructions to lie flat in transport and at home, and to report any

of the following: leakage from the site, headaches, backaches and neurological symptoms. Backache with leg weakness and bladder disturbance may be caused by a spinal haematoma (cauda equina syndrome) and is usually a surgical emergency (Chernecky and Berger 2013, Kennedy et al. 2000, Pikis et al. 2013).

Documentation
The procedure should be documented in the notes along with the record of informed consent. Any problems or immediate complications should be noted along with any treatment required. The sample bottles must be labelled correctly and sent to the laboratory.

Education of patient and relevant others
Patients should be informed about relevant signs of complications and be given verbal and written information prior to discharge.

Clear instructions should be given about side-effects and information on whom to call if side-effects occur.

Complications

Infection

Infection may be inadvertently introduced during the procedure. There is a greater risk in the presence of neutropenia (Hart 2006). Infection may be superficial or deep and may be caused by either skin commensals surviving on the patient or respiratory flora from the person performing the lumbar puncture. Deep infection includes the serious complications of meningitis and spinal abscess and will need urgent intravenous antibiotics after discussion with a microbiologist. Spinal abscess causing nerve root compression may also need urgent neurosurgical decompression. Adequate disinfection of the skin and the use of surgical face-masks will reduce the risk to the patient (Chernecky and Berger 2013, Schneider 2013).

Haemorrhage

Haemorrhage or localized bruising may be caused by a traumatic procedure or in the presence of thrombocytopenia or a coagulopathy (Barker and Laia 2008, Lindsay and Bone 2010). Haematoma formation may also become a surgical emergency if there is nerve root compression.

Herniation

Transtentorial or tonsillar herniation is possible if lumbar puncture is carried out in the presence of raised ICP (Belford 2005). This is a serious and life-threatening complication and so brain imaging studies should be done if raised ICP is suspected. Consultation with a neurologist may also be warranted.

Headache

Frequency of post-lumbar puncture headache varies amongst studies and between diagnostic and therapeutic procedures. The following risk factors have been identified: young age, female gender and the presence of headache before or at the time of the lumbar puncture (Chernecky and Berger 2013, Evans et al. 2000). Less certain risk factors include low Body Mass Index and previous experience of post-lumbar puncture headache (Evans et al. 2000). It is usually relieved by lying flat and, if ordered by the doctor or practitioner, a mild analgesic (Hickey 2003). Rehydration, pain relief and antiemetic medications can help in milder cases (Ahmed et al. 2006). If severe or prolonged, the headache may be treated with an epidural blood patch, usually after referral to an anaesthetist (Gruener and Biller 2008).

Backache

Backache after lumbar puncture may be due to either local bruising from the lumbar puncture needle or excessive spinal flexion for prolonged periods of time (i.e. during difficult procedures). It does not seem to be affected by different needle sizes nor by repeated attempts to gain CSF (Pan et al. 2004). In rare cases, backache may be suggestive of spinal haematoma or abscess, particularly if associated with leg weakness or bladder/bowel disturbance.

Leakage from puncture site

There may be a small amount of blood-stained oozing (Hickey 2003). The presence of clear fluid should be reported immediately to the doctor, especially if accompanied by fluctuation of other symptoms (level of consciousness, motor changes, problems voiding), as it may indicate a cerebrospinal fluid leak (Barker and Laia 2008).

Arachnoiditis

The combination of intrathecal methotrexate with radiotherapy may cause arachnoiditis (irritation of the meninges), cerebral atrophy and necrotizing encephalopathy (Vasey and Evans 2002).

Semen collection

Definition

Human male semen is collected for a variety of reasons; this chapter focuses on two of these. First, to facilitate semen analysis in the investigation of infertility and second, to procure and preserve sperm prior to interventions that carry the risk of future infertility. The physiology of semen is described, as are the ethics and legislation guiding the collection and storage of male gametes; key methods of procurement are outlined and finally the biopsychosocial process of the most common method of semen collection (self-masturbation and collection) is explained.

Anatomy and physiology

Two of the three key functions of the male reproductive system are to produce and deliver sperm to the female ova for fertilization; the third is to produce and secrete male sex hormones in order to maintain the male reproductive system (Jenkins and Tortora 2013, Mawhinney and Mariotti 2000).

Spermatogenesis takes place in the testes in a constant and continuous cycle throughout adult human male life. On average, 85 million sperm are made per testicle per day. Primary male germ cells are initially created in the outer wall of the germinal epithelium of the seminiferous tubules (Gilbert 2000). As the sperm cells mature, they move into the lumen of the tubule to begin a circuitous journey through the male reproductive system. On this journey, sperm cells are augmented with nutritional and biochemical supplements (Jeyendram 2003), resulting in a greyish-white viscous fluid (semen). Semen not only helps sperm to survive but also eases the transfer of sperm into the female reproductive tract and facilitates successful fertilization (Jenkins and Tortora 2013).

Components of normal semen

The volume of semen released per ejaculate varies between 2.3 mL and 4.99 mL. The average ejaculate is 3.4 mL.

- Fructose-rich fluid from the seminal vesicles (65–70%).
- Secretions from the prostate gland containing enzymes, citric acid, lipids and acid phosphatase (25–30%).
- 200–500 million sperm (2–5%).
- Secretions produced by the bulbourethral glands that aid the mobility of sperm in the vagina and cervix (1%) (Mandal 2010).

Semen is released into the female reproductive tract during the two-phase process of ejaculation (Mulhall 2013). Controlled by the central nervous system, ejaculation occurs when there is friction on the genitalia or other forms of sexual stimulation leading to impulses that are sent via the spinal cord to the brain. Phase 1 occurs when the vas deferens contracts to squeeze the sperm toward the base of the penis through the prostate gland and into the urethra. The seminal vesicles release their part of the semen that combines with the sperm (Mulhall 2013).

Phase 2 is when the muscles at the base of the penis and urethra contract. This forces the semen out of the penis. At this phase, the bladder neck contracts to prevent the backflow of the semen into the urinary tract (retrograde ejaculation if this occurs). The final components of semen join together in the posterior urethra and mix only after ejaculation (Mulhall 2013).

Evidence-based approaches

Rationale

Semen collection may be required for diagnostic and/or therapeutic purposes (Gerris 1999). Common reasons to collect semen include:

- to investigate the cause of infertility (Gerris 1999)
- to assess the success of a vasectomy or vasectomy reversal (Dohle et al. 2012)

- cryopreservation of semen prior to treatments that may affect fertility, i.e. cancer (NICE 2013, Royal College of Physicians 2007)
- prior to artificial insemination (Hammarberg et al. 2010)
- sperm donation (van den Broek et al. 2013).

Principles of care

Studies have shown that male infertility can cause extreme loss of self-esteem and impaired gender identity (Schmidt et al. 2005). There exists evidence on the importance of the relationship between body and mind in self-identity and perception (Greil et al. 2010) and that male infertility threatens the perception of masculinity (Gannon et al. 2004).

However, much of the infertility literature suggests that the focus has previously been on the female rather than male partner so best practice is now that couples (opposite sex or same sex) having difficulty conceiving should be seen together as decisions made in relation to investigations and treatment affect both partners (HFEA 2012). Access to evidence-based information should be made available to ensure informed decisions are made. Information can be given verbally and supplemented with written and/or audio-visual information (NICE 2013). The HFEA (2012) Code of Practice also recommends that three distinct types of counselling should be offered to both partners so they understand the implications and consequences of their actions in seeking treatment.

- Implication counselling – to understand the implications of proposed treatment.
- Support counselling – to give emotional support.
- Therapeutic counselling – to cope with the consequences of infertility (HFEA 2012).

For men and boys with cancer, semen collection as fertility preservation is common. Education and information should be given to inform their consent for cryopreservation. Practical issues of how sperm is collected, stored and managed in the event of death is essential prior to any cancer treatment (Pacey and Eiser 2011). Clinical judgement should be employed in the timing of this consultation, but doing so at the earliest opportunity is encouraged (Lee et al. 2006).

Whatever the reason for collecting semen, the donor should have adequate verbal and written information with time and counselling to consider the decision to collect and reflect on the consequences of donation and fully understand the process of how their semen will be collected.

Methods of semen collection

Masturbation

Collecting semen for sperm cryopreservation is generally obtained by masturbation. For many men, this may be an embarrassing or uncomfortable process (Williams 2010). It is critical that men understand how to collect semen and that they be offered a private and relaxing environment to do so.

For adolescent males, careful counselling, tactful and age-appropriate instructions are necessary, as these patients are at risk for emotional distress from this process (Crawshaw and Hale 2005). Parents should be included in discussions, although separate sessions with the adolescent are often useful. Unfortunately, no guidelines exist for the best approach to semen cryopreservation in the adolescent male, but individual institutional strategies are available (Leonard et al. 2004).

Electroejaculation

In some patients who have suffered a spinal cord injury, ejaculation by masturbation is not an option for sperm collection. In this case, the ejaculatory nerves can be electrically stimulated using

a low-voltage rectal probe. This is usually sufficient to produce a semen ejaculate, although the quality of the ejaculate is often less using this method compared to masturbation (Brackett et al. 2010).

Microepididymal sperm aspiration

Microepididymal sperm aspiration (MESA) is a surgical procedure for collection of sperm when the ejaculatory tubes are blocked or have been interrupted by a previous vasectomy (Nudell 1998). A surgical incision is made into the outer covering of the testis and the epididymis is exposed; expanded areas of the epididymis likely to contain sperm are incised and the sperm extracted (Nudell 1998).

Percutaneous epididymal sperm aspiration

Percutaneous epididymal sperm aspiration (PESA) is a variant of MESA; rather than an incision, needle aspiration is used to extract sperm from the epididymis. PESA can be performed under local anaesthesia, but less sperm is often collected using this approach (Esteves et al. 2013). Both MESA and PESA yield enough sperm for use with assisted reproductive methods but not enough for a standard insemination (Esteves et al. 2013, Nudell 1998).

Testicular sperm extraction (TESE)

For men who produce extremely small numbers of sperm, recovery of sperm from the epididymis may not be successful (Dabaja and Schlegel 2012). Testicular extraction and possibly tissue biopsy may be the best option for collecting sperm suitable for assisted reproductive techniques (ART). The outer covering of the testicle is pulled back so that seminiferous tubules can be visualized. An enlarged tubule is cut to permit sperm to flow from the tubule, where it can be aspirated (Schlegel 1999). Testicular tissue can be dissected in a culture dish and the released sperm collected for ART (Dabaja and Schlegel 2012, Gerris 1999). Some men with permanent azoospermia after chemotherapy can be successfully treated by TESE-intracytoplasmic sperm injection (ICSI) (Meseguer et al. 2003).

Anticipated patient outcomes

It would be expected that a diagnosis and/or analysis of results in relation to fertility treatments would be available to patients after semen collection had taken place. Cryopreserved semen will give the patient the opportunity to conceive after treatment for fertility-damaging treatment such as chemotherapy and/or radiotherapy.

Legal and professional issues

The 1990 Human Fertilisation and Embryology Act provided for the establishment of the Human Fertilisation and Embryology Authority (HFEA), the first statutory body of its type in the world. With the creation of the HFEA, the 1990 Act ensured the regulation, through licensing, of:

- the creation of human embryos outside the body and their use in treatment and research
- the use of donated gametes and embryos
- the storage of gametes and embryos.

The Act was radically amended in 2008 (Human Fertilisation and Embryology Act 2008) to ensure that the legislative framework was in line with radical technological, social and medical changes since its original publication. Amendments include:

- extending regulation to the creation and use of all embryos outside the human body, regardless of the processes used in their creation

- increasing the scope of legitimate embryo research activities, i.e. allowing hybrid embryos to be created for research purposes
- banning sex selection of offspring for non-medical reasons
- retention of a duty, when providing fertility treatment, to take account of the welfare of the child, but removal of the reference to 'the need for a father'
- recognizing same-sex couples as legal parents of children conceived through the use of donated sperm, eggs or embryos (Birk 2009).

Human Fertilisation and Embryology Authority

The HFEA is the independent regulator for the licensing and monitoring of fertility clinics and research involving human embryos in the UK. In accordance to the Human Fertilisation and Embryology Act (1990, 2008) and the European Union Tissues and Cells Directive (2004), the HFEA provides authoritative information for the public, in particular for people seeking treatment, donor-conceived people and donors. The HFEA also determines the policy framework for fertility issues, which are sometimes ethically and clinically complex.

European Union Tissues and Cells Directives

The European Union Tissues and Cells Directives, published in 2004 (EUTCD 2004), introduced common safety and quality standards for human tissues and cells across the European Union (EU). The purpose of the directive is to facilitate a safer and easier exchange of tissues and cells (including human eggs and sperm) between member states of the EU and to improve safety standards for European citizens.

Ethical considerations

Beyond the scientific processes in ART and cryopreservation, there are ethical considerations to consider in the collection, storage and use of semen (Gong et al. 2009). The legal ownership of sperm as unfertilized gametes varies from country to country (Pennings 2000). However, ethical principles must respect the interests and welfare of those who will be born as a result of semen collection as well as the health and welfare of the donor (Gong et al. 2009).

Consent

Counselling and gaining informed consent are an integral part of all patient activities. Prior to the collection of semen for any reason, it is essential that practitioners gain fully informed consent (NMC 2013). Consent is continuous throughout any patient episode and the practitioner must ensure that the patient is kept informed at every stage (Stuart and White 2012). For semen collection, this includes:

- informing the patient of the rationale for specimen collection
- what the procedure will involve
- ascertaining their level of understanding (especially if they need to be directly involved in the sampling technique)
- how long the results may take to be processed
- how the results will be made available
- information on how this may affect their care.

In the UK, if the donor is a child, i.e. under the age of 18 years, then the normal rules of gaining consent in this age group apply (Shaw 2001).

- When obtaining consent, the person gaining consent must establish whether the child is legally competent (has capacity) to give consent.
- All people aged 16 and over are presumed in law to have capacity unless there is evidence to the contrary.

- However, as with adults, it does not mean that all 16-year-olds have capacity, and competence must be assessed along the following lines.
 - Are they able to understand and retain the information pertinent to the decision about their care, i.e. the nature, purpose and possible consequences of undergoing and not undergoing the proposed investigations or treatment?
 - Are they able to use this information to consider whether or not they should consent to the intervention offered?
 - Are they able to communicate their wishes?

If the child is deemed not legally competent, consent will need to be obtained from someone with parental responsibility (Shaw 2001).

Pre-procedural considerations

Equipment

A sterile specimen container from the laboratory is required. Container lids must not be waxed cardboard or have plastic or rubber liners to maintain the quality of the sample. Contraceptive condoms are not suitable as the lubricants are spermicidal. Men who are unable to provide a sample on religious or moral grounds may use silastic condoms such as the seminal collection device (Brinsden 2005).

Recording tools

Labelling specimens

Prompt specimen analysis is only possible if specimens and their accompanying request forms are sent with specific, accurate and complete patient information. Incorrectly labelled or unlabelled specimens will be discarded (HSE 2003). The form should include as much information as possible as this allows the laboratory to select the most appropriate media inoculation for examination and result interpretation (Weston 2008). General labelling should be conducted accurately as discussed at the beginning of the chapter.

Specific patient preparation

It takes between 3 and 4 days for the sperm count to return to normal after ejaculation (Brinsden 2005, NCCWCH and NICE 2004) so patients should be advised that sexual intercourse or masturbation should not have taken place for 48 hours prior to semen collection. This will ensure that the semen will have an optimum count and motility (NCCWCH and NICE 2004). The patient should have ejaculated at least once between 48 hours and 7 days before collection. The patient should also be screened for the use of medicines and/or herbal remedies which may impact on sperm production or motility, such as St John's wort which has a mutagenic effect on sperm cells (Chernecky and Berger 2013).

Education

Patients who are to be treated with ICSI should undergo appropriate investigations to determine the diagnosis and enable informed discussion prior to the procedure. This will prepare the patient/couple for the potential implications of treatment. Genetic counselling and testing should be offered to men who have a specific or suspected genetic defect in relation to their infertility (NCCWCH and NICE 2004).

Patients who are undergoing treatments that may lead to infertility should be offered independent counselling to prepare them to cope with the possible physical and psychological implications of the treatment and its side-effects prior to commencing treatment (NCCWCH and NICE 2004, Wo and Viswanathan 2009).

Procedure guideline 10.10 Semen collection

Essential equipment <ul style="list-style-type: none">• Private room• Sterile specimen collection container supplied by laboratory• Tissues	
Pre-procedure	
Action	Rationale
1 Explain and discuss the procedure with the patient, giving clear, comprehensive instructions explaining what should and should not be done. Ask when he last had sexual intercourse or masturbated.	To ensure the patient understands the procedure and gives valid consent (Brinsden 2005, E ; NMC 2013, C). To ensure the sperm count will be at maximum levels (Brinsden 2005, E).
2 Ensure the patient has a private room.	To ensure privacy for the patient. E
Procedure	
3 Instruct the patient to only open the lid prior to ejaculation and replace it immediately after collection.	To minimize microbiological contamination (Brinsden 2005, E).
4 A fresh masturbated specimen must be collected in a sterile container.	To ensure optimum sample is obtained (Chernecky and Berger 2013, E).
Post-procedure	
5 Complete specimen form and label specimen container (including relevant information such as date and time of collection).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C).
6 Specimens must be transported to the laboratory as quickly as possible, within 1 hour of collection, and analysed within 3 hours.	To ensure optimum sample is obtained (Brinsden 2005, E ; Chernecky and Berger 2013, E).
7 The specimen must be kept at between 25°C and 37°C in a laboratory incubator.	To ensure optimum sample is obtained (Brinsden 2005, E).
8 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Post-procedural considerations

Immediate care

It is important that the patient has information to take away and has a contact number in case further questions arise. The patient should be informed when results are likely to be available and how they will be communicated (NICE 2013).

Ongoing care

Patients who are undergoing treatments that may lead to infertility should be offered independent counselling to help them cope with the possible physical and psychological implications of the treatment and its side-effects (NICE 2013).

Cervical uterine smear (pap smear)

Definition

The cervical smear is a test in which a specimen of cellular material is scraped from the cervix. The specimen is then stained and examined under a microscope by a cytologist to identify early cellular changes (Kumar and Clark 2012, Martin 2010).

Anatomy and physiology

The cervix is the narrow neck of the uterus and is located between the vagina and the uterus. It projects into the vagina and the cavity of the cervix is known as the cervical canal. The cervical canal's glands secrete a mucus that blocks the entry of sperm except in

the midcycle when a reduction in viscosity allows sperm to pass (Marieb and Hoehn 2010) (Figure 10.11).

Related theory

The intention of a smear test is to collect squamous epithelial cells and some endocervical cells from the transformation zone and squamocolumnar junction of the cervix (see Figure 10.11).

The sampling technique must take into consideration that the position of the squamocolumnar junction changes with age, contraception and parity (Higgins 2013, WHO 2006).

Evidence-based approaches

Rationale

The ideal time for obtaining a cervical smear is midcycle if the woman is premenopausal; this prevents contamination from menstrual flow and allows for accuracy of results (Higgins 2013, WHO 2006). It is not ideal to take a cervical smear if a woman is pregnant or immediately post-partum as results obtained can be misleading. The WHO suggests that if a woman is in the target age group and there are concerns about access to screening post-partum, then a cervical smear should be taken following childbirth after consent is obtained (WHO 2006).

In the UK, 80% of cervical smears are taken in the primary care setting and most are taken by practice nurses. Screening is recommended in the UK for all women between the ages of 25 and 64 years and is an investigation to confirm that the cervix is healthy and there are no abnormal changes to the cells; it is not a test for diagnosing cervical cancer (Higgins 2013, NHSCSP 2004). Human papillomavirus (HPV) testing was included in the current NHS cervical screening programme in April 2011. HPV testing does not require any other additional procedures in addition to the regular smear test. In practice, the residual smear sample is used to test for HPV and this is conducted in a laboratory (NHSCSP 2013).

Indications

- Women between the age of 25 and 64.

Contraindications

- During pregnancy.
- Immediately post-partum.

Method for cervical smears: liquid-based cytology

Liquid-based cytology (LBC) has been used in Europe and the USA since 1996. After extensive clinical trials in 2003 using LBC for cervical smears, the National Institute for Health and Clinical Excellence (NICE) recommended that LBC should replace the conventional cervical smear test by 2008 as part of the NHS cervical screening programmes. The change to LBC for smear taking has resulted in the reduction of reported 'inadequate smears', women's anxieties and the workload for primary care and laboratory personnel (Karnon et al. 2004, NHSCSP 2004).

Legal and professional issues

It is advised that the practitioner offers the patient the option of having a chaperone. The chaperone may be a person of the patient's choice who will accompany them throughout the procedure. The decision of the patient in regard to a chaperone should be documented (NMC 2012). Healthcare professionals conducting cervical smears should also be familiar with national guidance (NHSCSP 2004).

Governance

Smear tests are often performed by doctors and nurses. Training for cervical sample takers is designed to support the education and training of competent practitioners (NHSCSP 2006). Training should reflect current trends, developments and understanding of the cervical screening process in light of new recommendations (RCN 2013).

Risk management

It is essential that women are informed that the likelihood of an inadequate test is about 1–2% for LBC and 9% for conventional cytology (NHSCSP 2006).

Pre-procedural considerations

Equipment

There are several devices which are used in sampling the uterine cervix (Figure 10.12).

- *Vaginal speculum*: this is an instrument used during gynaecological examination to facilitate the visualization of the vagina and cervix. The speculum is introduced via the vagina and its cylinder with a rounded end shape allows easy passage. Once *in situ*, the speculum is opened, holding the vagina open and allowing the health professional to have access to the cervix and perform the cervical smear. Most speculums are now made of plastic and are single use, replacing those formerly made of metal, requiring sterilization after use. There are two categories of speculum: virgin and non-virgin. The latter is available in four sizes: small, medium, large and long. Special attention should be paid when selecting a speculum for use in women previously treated with pelvic radiotherapy or who are post-menopausal (Singh et al. 2013).
- *Wooden spatula (Aylesbury spatula)*: a wooden instrument used in smear screening to obtain a cervical sample, i.e. to take a representative cell sample from the cervix. It comes in different widths and should be chosen depending upon the condition of the os (NHSCSP 2006). Wooden spatulas are very popular due to their easy and cost-effective use.
- *Cervical broom*: these are plastic broom-shaped tools with a pyramidal arrangement of flexible flat 'teeth'. The longer 'central' tuft fits into the cervical os and must be rotated clockwise through a full circle five times. When used to take a conventional smear, this brush is an adequate and effective sampling device (NHSCSP 2006).
- *Endocervical brush*: a plastic instrument used to sample the endocervical canal which should never be used alone (Herzog and Cohn 2001) but always in conjunction with the spatula. The endocervical brush should be used after the spatula and its use is restricted to:
 - where there is difficulty in inserting the spatula into the external os (if the os is narrow or stenosed)
 - when the woman is being followed up for previous borderline nuclear changes in endocervical cells
 - for follow-up in previously treated endocervical glandular abnormality.

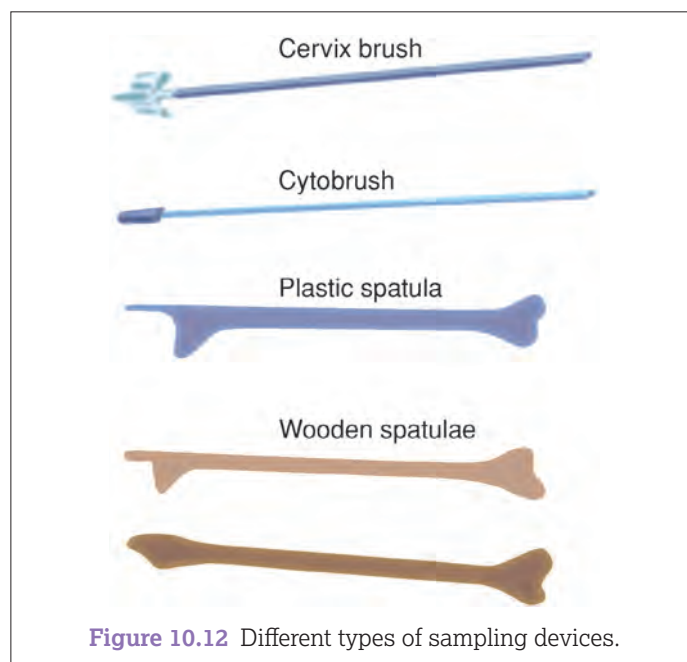

Figure 10.12 Different types of sampling devices.

The brush should be inserted into the cervical os with the lower bristles remaining visible, and rotated between half and a whole turn to reduce trauma (Insinga *et al.* 2004).

Cotton-tipped swabs are no longer recommended (NHSCSP 2006).

Cervical cytology on samples obtained using conventional smear-taking techniques is the current standard method of screening in the NHS cervical screening programme (NHSCSP).

The National Institute for Health and Clinical Excellence (2003) has recommended that LBC is used as the primary means of processing samples in the cervical screening programme in England and Wales. It achieves 'cleaner' preparations, which are generally easier to read. Its advantage is a reduction in inadequate samples and there may be gains in reducing borderline results and increasing sensitivity (NHSCSP 2004).

Whichever device is used, once the sample is taken it is vital that the cells collected are transferred onto a glass slide and preserved immediately or placed into the correct vial containing liquid preservative and fixative. Slides must not be placed in a refrigerator (Higgins 2013, NHSCSP 2006).

The environment is also important, with the following equipment required:

- height-adjustable couch
- angle-positioned light source which is ideally free standing for manoeuvrability (RCN 2013).

Specific patient preparation

The examination must be undertaken in a private room which cannot be entered during the examination. Adequate private changing facilities should also be available that are warm and comfortable. Where possible, face the examination couch away from the door to enhance privacy and dignity for the patient (RCN 2013).

The patient should be given the opportunity to empty her bladder prior to the examination. Ask the patient to undress and explain the position required on the couch. The most common position is prone or alternatively left lateral as it is comfortable and aids in the visualization of the cervix. Once the patient is ready, she should inform the practitioner. A modesty towel or covering should be supplied to enable the patient to partially cover herself (RCN 2013).

Education

Explain the procedure to the patient prior to commencing. It is good practice to offer the patient a demonstration of the speculum and to explain what part will be inserted into the vagina. Any possible side-effects such as spotting post examination should also be discussed prior to commencing the examination (RCN 2013).

Procedure guideline 10.11 Cervical uterine smear using a wooden spatula

Essential equipment

- Alcoholic handrub
- Light source
- An examination couch
- Disposable clean paper couch covers
- Various sized specula (disposable or reusable)
- Disposable clean gloves
- Wooden spatula or sampling device
- A glass slide with frosted edge
- A pencil for labelling slide
- Fixative solution
- Plastic slide container

- Specimen form and plastic specimen bag
- A container of warm water
- Box of tissue paper
- Clinical waste container
- Trolley
- Disposable apron
- Lubricant

Optional equipment

- A collecting container for Central Sterile Services (CSS) if reusable instruments are used

Pre-procedure

Action

- 1 Discuss benefits and limitations of screening and significance of smear results. Explain the purpose of the procedure and explain what will occur at each step.
- 2 Document the woman's clinical and screening history, specifically:
 - date of last menstruation
 - any abnormal bleeding
 - any unusual vaginal discharge
 - contraception
 - date of last cervical smear
 - any abnormal smear results
 - any treatment to the cervix.
- 3 Place all the equipment required for the procedure on the trolley.
- 4 Close room door or curtains and ask the woman to remove her underwear.

Rationale

To ensure that the woman understands that the procedure involves removing underwear and that the speculum will be inserted into her vagina, and consents to the procedure (NMC 2013, **C**). Allows the woman time to ask any questions. **E**

To ensure relevant history is recorded (NHSCSP 2006, **C**).

To facilitate the efficient taking of the smear. **E**

To provide privacy and comfort for the woman. **E**

Procedure

5 Turn the light source on and position at end of examination table.	To provide illumination of the cervix and increase the accuracy of the smear taking (NHSCSP 2004, C ; NHSCSP 2006, C).
6 Assist the woman into a supine position on the couch, with knees drawn up and legs parted. Keep her as covered as possible.	To facilitate easy access of the vaginal speculum and the taking of the cervical smear (NHSCSP 2004, C ; NHSCSP 2006, C ; WHO 2006, C).
7 Wash hands with antibacterial detergent and running hand-hot water. Ensure hands are dried with disposable paper hand towels.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E ; RCN 2012, C).
8 Apply gloves and apron.	To reduce the risk of contamination and cross-infection (Fraise and Bradley 2009, E ; RCN 2012, C).
9 Select the appropriate size speculum, from very small, small, medium, large including a long-bladed narrow speculum if the vagina is long or the cervix is lying posterior. The sterilized speculum can be warmed or cooled using clean tap water.	To promote patient comfort and reduce anxiety (NHSCSP 2006, C). If removed from a sterilizer, speculum may need to be cooled down, if cold then warmed up to reduce patient discomfort. It must be explained to the patient that the speculum has been sterilized but the water will not contaminate it. E
10 Apply lubricant to the speculum. Part the labia and, holding the speculum blades together sideways, slip the speculum into the vagina.	To insert the speculum and reduce patient discomfort (Fraise and Bradley 2009, E ; WHO 2006, C).
11 When the speculum is halfway into the vagina, turn it so that the handle is facing down.	To promote patient comfort and reduce contamination of the cervix with lubricants (NHSCSP 2006, C).
12 Gently open the blades of the speculum and look for the cervix. It may be necessary to move the speculum up or down until the entire cervix is visible.	To reduce patient discomfort and visualize the cervix (WHO 2006, C).
13 Once the cervix is visible, tighten the screw or lock the speculum in the open position so it remains in place. Adjustment of the light source may be required. Reassure the woman and allow time for her to relax.	To keep the speculum in the correct position and visualize the cervix (WHO 2006, C). To reduce patient discomfort and anxiety. E
14 Take the spatula and insert the long tip into the cervical os; rotate it through 360°.	To ensure an adequate cell sampling is obtained from the transformation zone (Higgins 2013, E ; WHO 2006, C).
15 Remove the spatula from the vaginal cavity then smear both sides of the spatula onto the glass slide using straight sweeps.	To ensure maximum collection of cells (WHO 2006, C).
16 Apply fixative immediately. <i>Either:</i> Spray fixative used at right angles to the slide and at a distance of 15–20 cm. <i>Or:</i> If immersing the slide in 95% ethanol, then leave for 5 minutes, remove from solution and allow to air dry. <i>Or:</i> If using 90% ethanol, then leave for 10–15 minutes, remove from solution and allow to air dry. <i>Or:</i> If using 'Cytofix' (95% industrial methylated spirit), apply a few drops to the slide and allow to dry for 5 minutes.	To preserve the specimen and ensure accurate results (Higgins 2013, E ; NHSCSP 2006, C ; WHO 2006, C).
17 If there are clinical signs of possible infection then a high vaginal swab is recommended prior to removal of speculum. (<i>If active infection is present, the cervical smear should be delayed until infection has been treated and resolved.</i>)	To ensure the swab is taken from the best site (Higgins 2013, E). A charcoal-impregnated swab is recommended if <i>Trichomonas</i> species are suspected as these organisms survive longer in this medium (Higgins 2013, E ; Mims 2004, E).
18 Place the swab into the medium.	To ensure specimen is correctly placed in the culture medium to ensure accuracy of results. E
19 If the screw is tightened, unscrew and gently pull the speculum out until the blades are clear of the cervix, then close blades and remove speculum, placing in clinical waste bin if disposable or into CSS container if reusable.	To prevent pinching the cervix or vaginal walls and to ensure safe disposal of contaminated equipment (Fraise and Bradley 2009, E ; NHSCSP 2006, C ; WHO 2006, C).
20 Cover the woman and offer tissue paper to wipe away any excess vaginal discharge.	To ensure dignity and privacy while promoting hygiene and comfort. E

(continued)

Procedure guideline 10.11 Cervical uterine smear using a wooden spatula (*continued*)

Action	Rationale
Post-procedure	
21 Dispose of the waste into clinical waste receiver.	Safe disposal of clinical waste (DH 2006a, C).
22 Assist the woman off the examination table and allow her to dress.	To ensure safety and promote dignity and privacy. E
23 Using a pencil, label the frosted end of the slide with woman's name, clinic number, date of birth and date sample taken. Using a black ballpoint pen, label the vaginal swab.	To ensure patient details are documented correctly on specimen. <i>Note that ballpoint pens do not work on glass slides.</i> E
24 Place the slide into transport container.	To prevent the slide from being damaged and ensure safe transportation of specimen to the laboratory for analysis. E
25 Remove gloves and dispose in clinical waste container.	Safe disposal of clinical waste (DH 2006a, C).
26 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

554

Procedure guideline 10.12 Cervical uterine smear using liquid-based cytology*Essential equipment*

- Alcoholic handrub
- Light source
- An examination couch
- Disposable clean paper couch covers
- Various sized specula (disposable or reusable)
- Disposable clean gloves
- Cervix brush
- A glass slide with frosted edge
- A pencil for labelling slide
- Fixative solution
- Plastic slide container

- Specimen form and plastic specimen bag
- A container of warm water
- Box of tissue paper
- Clinical waste container
- Trolley
- Disposable apron
- Lubricant

Optional equipment

- A collecting container for CSS if reusable instruments are used

Pre-procedure

Action	Rationale
Repeat steps 1–3 from Procedure guideline 10.11: Cervical uterine smear using a wooden spatula.	

Procedure

Repeat steps 4–12 from Procedure guideline 10.11, then:

13 Using the cervix brush, insert the central bristles into the endocervical canal so that the shorter, outer bristles fully contact the ectocervix.	To ensure accuracy of site sampled (NHSCSP 2004, C ; NHSCSP 2006, C).
14 Using pencil pressure, rotate the brush in a clockwise direction five times. <i>Note:</i> the plastic fronds of the brush are bevelled for rotation in a clockwise direction only.	To ensure good contact with the ectocervix and gather a high cellular yield (NHSCSP 2004, C ; NHSCSP 2006, C). Firm pressure is required to ensure the cells do not cling to the brush (NHSCSP 2004, C ; NHSCSP 2006, C).
<i>Either:</i> Using Thinprep, using a swirling motion, rinse the brush into the fixative vial; then push the brush into the base of the vial at least 10 times, forcing the bristles apart. Inspect the brush for any residual material and remove any remaining material by passing the brush over the edge of the fixative vial. Ensure that the material reaches the liquid. Then tighten the cap so that the material passes the torque line on the vial and give the vial a shake.	To ensure a usable amount of cellular material is collected (NHSCSP 2004, C ; NHSCSP 2006, C). To ensure the cellular material reaches the preservative solution (NHSCSP 2004, C ; NHSCSP 2006, C). To ensure that the cells do not cling to the device (NHSCSP 2004, C ; NHSCSP 2006, C).
<i>Or:</i> Using SurePath, remove head of the brush from the stem and place into the vial of fixative. Then screw lid on tightly and shake the vial. <i>Note:</i> it is essential that the sample is placed into the vial immediately in order to achieve fixation.	To ensure accurate preservation of cervical material (NHSCSP 2004, C ; NHSCSP 2006, C).

15 Gently pull the speculum out until the blades are clear of the cervix, then close blades and remove speculum, placing in clinical waste bin if disposable or into CSS container if reusable.	To prevent pinching cervix or vaginal walls and ensure safe disposal of contaminated equipment (NHSCSP 2006, C ; WHO 2006, C).
16 Cover the woman and offer tissue paper to wipe away any excess vaginal discharge.	To ensure dignity and privacy while promoting hygiene and comfort. E
Post-procedure	
17 Remove gloves and dispose of waste in clinical waste receiver.	Safe disposal of clinical waste (DH 2006a, C).
18 Assist the woman off the examination table and allow her to dress.	To ensure safety and promote dignity and privacy. E
19 Using a black ballpoint pen, label the vial with woman's name, clinic number and date of birth.	To ensure patient details are documented correctly. E <i>Note that ballpoint pens do not work on glass slides.</i> E
20 Place the vial into plastic specimen bag with the correctly labelled specimen form and send to laboratory.	To ensure safe handling and transportation of a biohazard (DH 2006a, C).
21 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.13 Cervical uterine smear using an endocervical brush

Essential equipment

- Alcoholic handrub
- Light source
- An examination couch
- Disposable clean paper couch covers
- Various sized specula (disposable or reusable)
- Disposable clean gloves
- Wooden spatula or sampling device
- Endocervical brush
- A glass slide with frosted edge
- Lubricant
- A pencil for labelling slide
- Fixative solution

To ensure patient details are documented correctly on specimen. <i>Note that ballpoint pens do not work on glass slides.</i> E
25 Place the slide into transport container.	To prevent the slide from being damaged and ensure safe transportation of specimen to the laboratory for analysis. E
26 Remove gloves and dispose in clinical waste container.	Safe disposal of clinical waste (DH 2006a, C).
27 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Problem-solving table 10.4 Prevention and resolution (Procedure guidelines 10.11, 10.12 and 10.13)

Problem	Cause	Prevention	Action
Inadequate sample.	Cervix has not been scraped firmly enough to obtain adequate epithelial cells (WHO 2006).	Ensure adequate pressure to obtain sample.	Repeat cervical smear.
	Sample on the spatula not completely transferred onto the slide or applied too thinly or thickly (Higgins 2013).	Ensure that the appropriate technique is utilized when transferring sample. Check that the sample has been transferred onto slide adequately before completion of the examination.	Repeat cervical smear.
	Fixative not applied immediately, allowing the sample to dry and causing the cells to become misshapen (WHO 2006).	Ensure fixative is applied in a timely manner.	Repeat cervical smear.
	Sample contaminated with lubricants, spermicide or blood (Higgins 2013).	Ensure sample is not contaminated by educating the patient not to use lubricants or spermicide prior to test.	Repeat cervical smear.
Unable to visualize the cervix.	Position of the patient or anatomical position of the cervix.	Adequate positioning of the patient.	Reposition the patient from the prone to the lateral position. Place a pillow under the buttocks or turn the speculum. Consider assistance from another sample taker or refer to colposcopy clinic if unable to visualize.

Post-procedural considerations

Immediate care

Ensure patient modesty is maintained throughout and directly after the examination. To maintain privacy and dignity, the nurse should leave the room while the patient gets undressed and dressed, and advise them to call when ready (RCN 2013).

Ongoing care

The results should be communicated to the patient and appropriate follow-up and/or referral to secondary services arranged where necessary. It is important that the healthcare professional considers how the patient may react if abnormal results are to be delivered and ensures necessary support (RCN 2013).

Documentation

The nurse should ensure that the request form has been adequately completed and that the samples are also labelled correctly and accurately. If other microbiological tests are conducted, ensure the correct forms are completed and the samples are labelled and document any findings and resulting actions (RCN 2013).

Education of patient and relevant others

It is not unusual for the patient to experience some spotting after the cervical smear. This must be explained to the patient to ensure she is aware and not to worry. The healthcare professional should promote health education programmes and encourage screening to those who are eligible such as accurate information and advice in the prevention of cervical cancer. Patient information leaflets are offered to patients to ensure they have the appropriate information (RCN 2013).

Specimen collection: swab sampling

Definition

Sterile swabs are commonly used in clinical practice to obtain samples of material from skin and mucous membranes. They are utilized to identify micro-organisms in suspected infection or as part of a screening programme to identify patients who may be carrying pathogens without displaying clinical signs or symptoms (Ferguson 2005). Swab cultures provide useful data to augment diagnostic and therapeutic decision making (Bonham 2009).

Related theory

Swabbing is aimed at quantitative or qualitative collection of bodily fluid or cutaneous material for the purpose of obtaining a specimen for microbiological analysis (Bowler et al. 2001, Kingsley 2001) and when properly performed, a swab is a simple, non-invasive and cost-effective method of culturing in clinical practice (Bonham 2009). Samples of infected material can be obtained from any accessible part of the body by using a sterile swab tipped with cotton wool or synthetic material (Hampson 2006).

Swabs for screening programmes

Meticillin-resistant *Staphylococcus aureus* is one of the most significant problematic organisms within healthcare (Weston 2008). Colonized and infected patients represent the most important reservoir of MRSA strains within hospitals (HPA 2014c). The transmission of MRSA and the risk of MRSA infection can only be effectively addressed if MRSA carriers are identified and treated to reduce this risk of transmission (DH 2006b). These screening control measures guide staff in the protection of patients from MRSA colonization and infection. Active screening of patients for MRSA carriage is performed based on a risk assessment approach to the use of isolation and cohorting facilities (Coia et al. 2006).

Obtaining swabs is a key component of an effective MRSA prevention programme and certain patient groups are deemed to be at higher risk of contracting serious MRSA infections: critical care,

burns, transplantation, cardiothoracic surgery, orthopaedic surgery, trauma, vascular surgery and renal patients (Coia et al. 2006).

The normal habitat of *Staphylococcus aureus*, including MRSA, is human skin, particularly the anterior nares (nose), axilla (armpit) and perineum (groin) (DH 2006b). The essential site to sample is the anterior nares (nose) as this is the most common carriage site for MRSA and most patients positive at other sites have positive results from nose samples (DH 2006b). Other samples can be taken from the following sites: skin lesions and wounds, vascular access device sites and other skin breaks, tracheostomies, catheter specimens of urine (CSU) and sputum from patients with a productive cough (Coia et al. 2006). The microbiological request form should clearly indicate that the samples are for MRSA screening to ensure that correct laboratory techniques are used and to avoid potential waste of resources.

Evidence-based approaches

Rationale

Indications

Taking a swab is indicated:

- if there are clinical signs of infection which may manifest as symptoms such as pain, redness, inflammation, heat, pus and odour
- if a patient shows signs of systemic infection or has a pyrexia of unknown origin (PUO)
- as part of a screening programme.

Contraindications

- As routine use (unless part of a screening regimen).
- On chronic wounds which will be colonized with skin flora.

Principles of care

Although swabs are relatively simple to use, absorbency of infected material is variable and adequate material collection that is representative of pathogenic changes, for example to wounds, is often dependent upon correct sampling technique (Gould and Brooker 2008). Swab specimens should be collected using an aseptic technique with sterile swabs, with the principal aim of gathering as much material as possible from the site of infection/inflammation. Care should be taken to avoid contamination with anything other than sample material such as surrounding tissue, which will be contaminated with other pathogens such as skin flora (Weston 2008).

If an infected area is producing copious amounts of pus or exudate, a specimen should be aspirated using a sterile syringe because swabs tend to absorb excess overlying exudate, resulting in an inadequate specimen (Gilchrist 2000). If the area to be swabbed is relatively dry, for example nasal or skin swabs, the tip of the swab can be moistened with sterile 0.9% sodium chloride which makes it more absorbent and increases the survival of pathogens (Weston 2008).

Obtaining a swab should be considered in conjunction with a comprehensive nursing assessment. This could include observation of localized infection such as inflammation or discharge from a wound during a dressing change.

Practitioners should know what type of pathogenic micro-organisms they are testing, for example whether a bacterial or viral infection is suspected, as this will determine which swab is the most appropriate. Advice should be sought from the microbiology laboratory prior to taking a swab to ensure appropriate and resource-effective sampling or specimen collection. For example, whilst viruses cause the majority of throat infections, group A streptococcus is the main bacterial cause of sore throats and therefore, if suspected, a swab with bacterial transport medium would need to be used rather than one containing viral transport medium (HPA 2014d).

Legal and professional issues

Competencies

Obtaining specimens for microbiological analysis is a key component in the patient’s assessment and subsequent nursing care. Therefore, practitioners must be competent and feel confident that they have the knowledge, skill and understanding to obtain and correctly process samples for specimen collection (RCN 2012).

Pre-procedural considerations

Equipment

Commercially available transport media offer a cheap and effective method to enable the culture of both aerobic and anaerobic micro-organisms (Bowler et al. 2001). Wound swabbing most frequently

involves the use of a cotton- or alginate-tipped swab (Bowler et al. 2001), although these have been found to inhibit the detection of certain bacteria (Faoagali 2010). Despite being more expensive, flocked nylon swabs now provide a sensitive collection method for culture, rapid, near patient testing and molecular detection of a variety of bacteria and viruses. This is because of their ability to absorb cells then release them effectively to increase the sensitivity of detection of infecting microbes (Faoagali 2010). If unsure, the practitioner should liaise with the microbiology laboratory to clarify which is the most suitable swab for a particular investigation or type of specimen. See Figure 10.4.

Specific patient preparation

It may be necessary to position the patient in order to obtain the required sample.

558 Procedure guideline 10.14 Swab sampling: ear

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.	To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, E ; RCN 2012, E).
3 Ensure no antibiotics or other therapeutic drops have been used in the aural region 3 hours before taking the swab.	To prevent collection of such therapeutic agents which may mask pathogenic organisms and invalidate the specimen (Hampson 2006, E).
Procedure	
4 Remove the swab from outer packaging and place at the entrance of the auditory meatus as shown in Action figure 4 . Rotate gently once.	To avoid trauma to the ear and to collect secretions/suitable specimen material (Mims 2004, E).
Post-procedure	
5 Remove cap from plastic transport tube.	To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (HPA 2014c, C).
6 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.	To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (Ferguson 2005, E).
7 Remove gloves and apron and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
8 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
9 Arrange prompt delivery to the microbiology laboratory or refrigerate at 4–8°C.	To achieve optimal conditions for analysis (HPA 2014c, C).
10 Document the procedure in the patient’s records.	To ensure timely and accurate record keeping (NMC 2010, C).

Action Figure 4 Area to be swabbed when sampling the outer ear.

Procedure guideline 10.15 Swab sampling: eye**Essential equipment**

- Non-sterile gloves
- Apron
- Appropriate documentation/form
- Sterile bacterial or viral swab (with transport medium)

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Seek advice from the microbiology laboratory as to the correct culture medium and swab required.	Different culture media and swabs are required for bacteria, viruses and chlamydia (Shaw et al. 2010, E).
3 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.	To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, E ; RCN 2012, E).

Procedure

4 Remove swab from outer packaging.	To ensure collection of specimen material (Mims 2004, E).
5 Ask patient to look upwards.	To prevent corneal damage (Shaw et al. 2010, E).
6 Hold the swab parallel to the cornea and gently rub the conjunctiva in the lower eyelids from nasal side outwards.	To ensure that a swab of the correct site is taken and to avoid contamination by touching the eyelid (Shaw et al. 2010, E).
7 <i>If for chlamydia specimen:</i> apply slightly more pressure when swabbing.	To obtain as many organisms as possible from the follicles and to sweep organisms away from the lower punctum (Shaw et al. 2010, E).
8 If both eyes are to be swabbed, label swabs 'right' and 'left' accordingly.	To prevent the wrong swab being placed in the wrong culture medium (Shaw et al. 2010, E).

Post-procedure

9 Remove cap from plastic transport tube.	To avoid contamination of the swab (HPA 2014c, C).
10 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.	To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (Ferguson 2005, E).
11 Remove gloves and apron and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
12 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
13 Arrange prompt delivery to the microbiology laboratory.	To achieve optimal conditions for analysis (HPA 2014c, C).
14 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.16 Swab sampling: nose**Essential equipment**

- Non-sterile gloves
- Apron
- Sterile bacterial or viral swab (with transport medium)

Optional equipment

- 0.9% sodium chloride
- Appropriate documentation/form

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.	To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, E ; RCN 2012, E).

Procedure

3 Remove swab from outer packaging.	To ensure collection of specimen material (Mims 2004, E).
4 Ask patient to tilt head backwards.	To optimize visualization of area to be swabbed (Gould and Brooker 2008, E).

(continued)

Procedure guideline 10.16 Swab sampling: nose (continued)

Action	Rationale
5 Moisten swab with sterile saline.	To prevent discomfort to the patient as the nasal mucosa is normally dry and organisms will adhere more easily to a moist swab (Hampson 2006, E).
6 Insert swab inside the anterior nares with the tip directed upwards and gently rotate (Action figure 6).	To ensure that an adequate specimen from the correct site is obtained and to avoid damage to the delicate epithelium (Gould and Brooker 2008, E).
7 Repeat the procedure with the same swab in the other nostril.	To optimize organism collection. E
Post-procedure	
8 Remove cap from plastic transport tube.	To avoid contamination of the swab (HPA 2014e, C).
9 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.	To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (Ferguson 2005, E).
10 Provide the patient with a tissue if required.	For patient comfort (Higgins 2013, E).
11 Remove gloves and apron and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
12 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
13 <i>If sample taken for screening:</i> state clearly on the microbiology request form, for example for MRSA screening.	To ensure only these organisms are being analysed, so the result will only indicate their presence or absence, and sensitivities (Weston 2008, E).
14 Arrange prompt delivery to the microbiology laboratory.	To achieve optimal conditions for analysis (HPA 2014e, C).
15 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

**Action Figure 6** Area to be swabbed when sampling the nose.**Procedure guideline 10.17 Swab sampling: penis****Essential equipment**

- Non-sterile gloves
- Apron
- Sterile bacterial or viral swab (with transport medium)
- Appropriate documentation/form

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).

- 2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.

To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, **E**; RCN 2012, **E**).

Procedure

- 3 The patient should not have passed urine for at least 1 hour.

To ensure a representative sample from the area being swabbed (HPA 2014f, **C**).

- 4 Remove swab from outer packaging.

To ensure collection of specimen material (Mims 2004, **E**).

- 5 Retract prepuce.

To obtain maximum visibility of area to be swabbed (HPA 2014f, **C**).

- 6 Pass the swab gently through the urethral meatus and rotate gently.

To collect a specimen of discharge or secretions (HPA 2014f, **C**).

Post-procedure

- 7 Remove cap from plastic transport tube.

To avoid contamination of the swab (HPA 2014f, **C**).

- 8 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.

To avoid contamination of the swab and to maintain viability of the sampled material during transportation (Ferguson 2005, **E**).

- 9 Remove gloves and apron and wash/decontaminate hands.

To reduce risk of cross-infection (Loveday et al. 2014, **C**; Sax et al. 2007, **E**).

- 10 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).

To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).

- 11 Arrange prompt delivery to the microbiology laboratory (within 4 hours).

To increase the chance of accurate organism identification and to ensure the best possible conditions for laboratory analysis (HPA 2014f, **C**).

- 12 Document the procedure in the patient's records.

To ensure timely and accurate record keeping (NMC 2010, **C**).

Procedure guideline 10.18 Swab sampling: rectum

Essential equipment

- Non-sterile gloves
- Apron
- Appropriate documentation/form
- Sterile bacterial or viral swab (with transport medium)

Pre-procedure

Action

Rationale

- 1 Explain and discuss the procedure with the patient.

To ensure the patient understands the procedure and gives valid consent (NMC 2013, **C**).

- 2 Ensure a suitable location in which to carry out the procedure.

To maintain patient privacy and dignity (Hampson 2006, **E**).

- 3 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.

To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, **E**; RCN 2012, **E**).

Procedure

- 4 Remove swab from outer packaging.

To ensure collection of specimen material (Mims 2004, **E**).

- 5 Pass the swab, with care, through the anus into the rectum and rotate gently.

To avoid trauma and to ensure that a rectal, not an anal, sample is obtained. **E**

- 6 *If specimen is for suspected threadworm:* take swab from the perianal area.

Threadworms lay their ova on the perianal skin (Hampson, 2006, **E**).

Post-procedure

- 7 Remove cap from plastic transport tube.

To avoid contamination of the swab (HPA 2014c, **C**).

- 8 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.

To avoid contamination of the swab and to maintain viability of the sampled material during transportation (Ferguson 2005, **E**).

(continued)

Procedure guideline 10.18 Swab sampling: rectum (continued)

Action	Rationale
9 Remove gloves and apron and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
10 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
11 Arrange prompt delivery to the microbiology laboratory.	To achieve optimal conditions for analysis (HPA 2014c, C).
12 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

562

Procedure guideline 10.19 Swab sampling: skin**Essential equipment**

- Non-sterile gloves
- Apron
- Appropriate documentation/form
- Sterile bacterial or viral swab (with transport medium)

Optional equipment

- Scalpel blade/U blade (for trained practitioners only)

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.	To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, E ; RCN 2012, E).

Procedure

3 Remove swab from outer packaging.	To ensure collection of specimen material (Mims 2004, E).
4 <i>For cutaneous sampling (for screening, for example groin):</i> moisten swab with sterile saline and roll one swab along the area of skin along the inside of the thighs closest to the genitalia.	Organisms adhere more easily to a moist swab (Hampson 2006, C).
5 <i>For suspected fungal infection:</i> skin scrapings should be obtained. Take a scalpel blade and, with the affected area of skin stretched taut between two fingers, gently scrape the skin with a piece of dark paper underneath. Do not cause bleeding.	To identify superficial fungi that inhabit the outer layer of the skin (Mackie 2003, E). To visualize amount of sample and to allow easier transfer. E

Post-procedure

6 <i>Either:</i> <i>For swab specimen:</i> (a) Remove cap from plastic transport tube. (b) Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.	To avoid contamination of the swab (HPA 2014c, C). To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (Ferguson 2005, E). To allow samples to be processed appropriately in the laboratory. E
<i>Or:</i> <i>For skin scrapings:</i> (a) Transfer scrapings into sterile container.	
7 Remove gloves and apron and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
8 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
9 Arrange prompt delivery to the microbiology laboratory (keep at room temperature).	To achieve optimal conditions for analysis (HPA 2014c, C).
10 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.20 Swab sampling: throat**Essential equipment**

- Non-sterile gloves
- Apron
- Sterile bacterial or viral swab (with transport medium)
- Light source
- Tongue spatula
- Appropriate documentation/form

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.

Rationale

To ensure the patient understands the procedure and gives valid consent (NMC 2013, **C**).

To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, **E**; RCN 2012, **E**).

Procedure

- 3 Remove swab from outer packaging.
- 4 Ask patient to sit upright facing a strong light, tilt head backwards, open mouth and stick out tongue.
- 5 Depress tongue with a spatula.
- 6 Ask patient to say 'Ah'.
- 7 Quickly but gently roll the swab over any area of exudate or inflammation or over the tonsils and posterior pharynx (**Action figure 7**).
- 8 Carefully withdraw the swab, avoiding touching any other area of the mouth or tongue.

To ensure collection of specimen material (Mims 2004, **E**).

To ensure maximum visibility of the area to be swabbed and avoid contact with the oral mucosa (Gould and Brooker 2008, **E**).

The procedure may cause the patient to gag. The spatula prevents the tongue moving to the roof of the mouth, which would contaminate the specimen (Hampson 2006, **E**).

Assists with depression of the tongue and prevents patient from feeling the gag reflex (Keir et al. 2007, **E**).

To obtain the required sample (Weston 2008, **E**).

To prevent contamination of the specimen with the resident flora of the oropharynx (Weston 2008, **E**).

Post-procedure

- 9 Remove cap from plastic transport tube.
- 10 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.
- 11 Remove gloves and apron and wash/decontaminate hands.
- 12 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).
- 13 Arrange prompt delivery to the microbiology laboratory.
- 14 Document the procedure in the patient's records.

To avoid contamination of the swab (HPA 2014c, **C**).

To avoid contamination of the swab and maintain the viability of the sampled material during transportation (Ferguson 2005, **E**).

To reduce risk of cross-infection (Loveday et al. 2014, **C**; Sax et al. 2007, **E**).

To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).

To achieve optimal conditions for analysis (HPA 2014c, **C**).

To ensure timely and accurate record keeping (NMC 2010, **C**).

Action Figure 7 Area to be swabbed when sampling the throat.

Procedure guideline 10.22 Swab sampling: wound*Essential equipment*

- Non-sterile gloves
- Apron
- Sterile bacterial or viral swab (with transport medium)

Optional equipment

- 0.9% sodium chloride
- Appropriate documentation/form
- Dressing pack containing sterile gloves, cleansing solution and dressing (post sampling procedure)

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.	To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, E ; RCN 2012, E).
3 Remove current dressing, if applicable.	To expose wound in preparation for swabbing. E
4 Remove gloves and decontaminate hands. Open sterile dressing pack, decant sterile swab and don sterile gloves.	To reduce the risk of cross-infection (RCN 2012, E) and prepare equipment for sampling (Fraise and Bradley 2009, E).

Procedure

5 Remove swab from outer packaging.	To ensure collection of specimen material (Mims 2004, E).
6 Rotate the swab tip over a 1 cm ² area of viable tissue, at or near the centre of the wound for 5 seconds, applying enough pressure to express tissue fluid from the wound bed.	Expressed tissue fluids are likely to contain the true infecting organisms and less likely to contain surface contaminants (Kingsley 2003, E).
7 If the wound is dry, the tip of the swab should be moistened with 0.9% sodium chloride.	To make the swab more absorbent and to increase survival of pathogens present prior to culture (Weston 2008, E).
8 If pus is present, it should be aspirated using a sterile syringe and decanted into a sterile specimen pot.	To yield the optimum number of micro-organisms present within the wound (Weston 2008, E).

Post-procedure

9 Remove cap from plastic transport tube.	To avoid contamination of the swab (HPA 2014c, C).
10 Carefully place swab into plastic transport tube, ensuring it is fully immersed in the transport medium. Ensure cap is firmly secured.	To avoid contamination of the swab and to maintain the viability of the sampled material during transportation (Ferguson 2005, E).
11 Redress the wound, if applicable, as per patient care plan.	To redress the wound. E
12 Remove gloves and apron, discard all clinical waste and wash/decontaminate hands.	To reduce risk of cross-infection (Loveday et al. 2014, C ; Sax et al. 2007, E).
13 Complete microbiology request form (including relevant information such as exact site, nature of specimen and investigation required).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
14 Arrange prompt delivery to the microbiology laboratory (keep at room temperature).	To achieve optimal conditions for analysis (HPA 2014c, C).
15 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Post-procedural considerations**Immediate care**

Commercially available transport media maintain the viability of both aerobic and anaerobic micro-organisms (Bowler et al. 2001). Specimens should be sent immediately to the laboratory or no later than 2 hours following collection (Bonham 2009). For specimens that cannot be transferred to the laboratory within 2 hours, storage at room temperature is considered to be appropriate for the maintenance of aerobic and anaerobic micro-organisms (Bowler et al. 2001). Advice should be sought from the microbiology laboratory if practitioners are unsure of the storage requirements for the sample.

Documentation

Relevant and detailed information such as clinical presentation, signs and symptoms of infection, and the site and nature of the swab should be indicated on the sample and microbiology request form (Ferguson 2005). This allows the microbiology laboratory to select the most appropriate processing technique and assist in differentiating organisms which would normally be expected at a particular site from those causing infection (Weston 2008).

In accordance with the principles of good record keeping, the date and time when a swab is sent to the laboratory should be documented clearly and promptly in the patient's notes and care plan (NMC 2010). This should be done alongside documentation of the clinical nursing assessment, particularly in relation to significant findings that have prompted the collection of the sample such as observation of inflammation or discharge at the site. This assists in communication and the dissemination of information between members of the interprofessional healthcare team.

Specimen collection: urine sampling**Definition**

Urine samples are intended to identify any organisms causing infection within the urinary tract. Urinalysis is the tests that involve microbiological, chemical, microscopical and physical examination of the urine (Higgins 2013). Urinary tract infections (UTIs) result from the presence and multiplication of bacteria in one or more structures of the urinary tract with associated tissue invasion (HPA 2014j).

Related theory

Protection against infection is normally given by the constant flow of urine and regular bladder emptying, which prevent the colonization of micro-organisms (HPA 2014j). The urethra is colonized with naturally occurring flora but urine proximal to the distal urethra is normally sterile. As urine passes through the urethra, some of these micro-organisms are flushed through and normal urine will naturally contain a small number of bacteria. Therefore, the presence of bacteriuria is insignificant in the absence of clinical symptoms of an infection (Weston 2008).

Urinary tract infections account for up to 20% of all overall hospital-acquired infections. This is the second largest group of infections in the healthcare setting (HPA 2014j). The majority of the 20% are generally catheter-related infections with only 2–6% actual UTIs (HPA 2014j). UTIs in adults are common, particularly in women due to the short female urethra and its close proximity to the perineum, but age, sex and predisposing factors are other important considerations (HPA 2014j).

Evidence-based approaches

Rationale

Urine sample requests for Microscopy, Culture and Sensitivity (MC&S) constitute the largest single category of specimens examined in microbiological laboratories. The main value of urine culture is to identify bacteria and their sensitivity to antibiotics (Higgins 2013).

Urine sampling should be considered in combination with clinical assessment and urinalysis to avoid unnecessary sample processing which has time and cost implications for the microbiology laboratory (Simerville et al. 2005, Thomas 2008). A clinical assessment would involve examination of the odour, turbidity and colour, whether there are obvious signs of haematuria and pain particularly around the suprapubic area (Dulczak and Kirk 2005). Urinalysis may reveal a high pH, the presence of blood or positivity to leucocyte esterase (an enzyme released by white blood cells) or nitrite, all of which indicate a high probability of bacteriuria (Higgins 2013).

Indications

Obtaining a urine specimen is indicated:

- when there are clinical signs and symptoms to indicate a UTI
- if there are signs of a systemic infection or in patients with a PUO
- on development of new patient confusion as toxicity from infection can cause alterations in mental status or impairments in cognitive ability (Pellowe 2009).

Principles of care

Urine may be collected using a midstream urine (MSU) clean-catch technique or from a catheter using a sterile syringe to access the sample port (HPA 2014j). To minimize the contamination of

a specimen by bacteria, which may be present on the skin, the perianal region or the external genital tract, good hand and genital hygiene should be encouraged. Therefore, patients should be encouraged to wash their hands prior to collecting a clean-catch midstream urine specimen and to clean around the urethral meatus prior to sample collection (Higgins 2013).

The principle for obtaining a midstream collection of urine is that any bacteria present in the urethra are washed away in the first portion of urine voided and therefore the specimen collected more accurately represents the urine in the bladder. A study conducted by Jackson et al. (2005) using a urinary collection device showed a reduction in contamination from different MSU techniques. However, a study in pregnant women found that there was no difference between MSU, clean-catch or morning samples with regard to potential contamination (Schneeberger et al. 2013).

Catheter-associated urinary tract infections (CAUTI)

The presence of a urinary catheter, and the duration of its insertion, are contributory factors in the development of a UTI. For every day the catheter remains *in situ*, the risk of bacteriuria is 5% so that 50% of patients catheterized for longer than 7–10 days will have bacteriuria (Pellowe 2009). Although often asymptomatic, 20–30% of patients with bacteriuria will develop a CAUTI and 1–4% will develop a bacteraemia, which has significant implications for patient morbidity, increased hospital stay and increased cost (HPA 2014j). Bacteriuria in patients who are catheterized for more than 30 days is up to 100%, although the patient may be asymptomatic (HPA 2014j).

In order to minimize CAUTIs, catheters should only be inserted where absolutely necessary and should not be placed for the management of urinary incontinence except in exceptional circumstances when all other management methods have been unsuccessful. Additional techniques such as closed catheter systems, antimicrobial coated catheters and routine catheter changes every 2–4 weeks should be considered to reduce the risks of a CAUTI (Hooton et al. 2010).

Pre-procedural considerations

Equipment

Specimen jars for urine collection must be sterile to ensure no contamination occurs which may lead to an incorrect diagnosis and treatment. The jars must close securely to prevent leakage of the sample and have a CE marking (HPA 2014j). See Figure 10.3.

Specific patient preparation

When collecting a MSU, the patient must pass a small amount of urine before collecting the specimen. This reduces the risk of contamination of the specimen with naturally occurring micro-organisms/flora within the urethra. Periurethral cleansing is recommended although the need for this has been questioned in both men and women as its effectiveness has been debated (HPA 2014j, Prandoni et al. 1996, Saint and Lipsky 1999).

Procedure guideline 10.23 Urine sampling: midstream specimen of urine: male

Essential equipment

- Cleaning solution (e.g. soap and water, 0.9% sodium chloride or disinfectant-free solution)
- Sterile specimen container (with wide opening)
- Non-sterile gloves
- Apron
- Appropriate documentation/forms

Pre-procedure

Action

- 1 Discuss need and indication for procedure with patient.

Rationale

To obtain valid consent (NMC 2013, C).

2 Fully explain the steps of the procedure.	The patient needs to fully understand the procedure in order to avoid inadvertent contamination of specimen and optimize the quality of the sample (Higgins 2008a, E).
3 Ensure a suitable, private location.	To maintain patient privacy and dignity (Gilbert 2006, E).
Procedure	
4 Ask patient to wash hands with soap and water.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
5 <i>If practitioner's assistance required:</i> wash hands with bactericidal soap or decontaminate physically clean hands with alcohol rub and don apron.	To prevent cross-contamination (Fraise and Bradley 2009, E ; RCN 2012, C).
6 Ask patient to retract the foreskin and clean the skin surrounding the urethral meatus with soap and water, 0.9% sodium chloride or a disinfectant-free solution.	To optimize general cleansing and minimize contamination of specimen with other organisms. E Disinfectant solutions may irritate the urethral mucous membrane (Higgins 2013, E).
7 Ask patient to begin voiding first stream of urine (approx. 15–30 mL) into a urinal, toilet or bedpan.	To commence the flow of urine and avoid contamination of specimen with naturally occurring micro-organisms/flora within the urethra (HPA 2014j, C).
8 Place the wide-necked sterile container into the urine stream without interrupting the flow.	To prevent contamination of specimen and ensure the collection of the midstream urine which most accurately represents the urine in the bladder (HPA 2014j, C).
9 Ask the patient to void his remaining urine into the urinal, toilet or bedpan.	For patient to comfortably continue passing urine (HPA 2014j, C).
10 Transfer specimen into sterile universal container.	For despatch to the laboratory (HPA 2014j, C).
11 Allow patient to wash hands.	To maintain personal hygiene. E
Post-procedure	
12 Label sample and complete microbiological request form including relevant clinical information, such as signs and symptoms of infection, antibiotic therapy.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
13 Dispatch sample to laboratory immediately (within 4 hours) or refrigerate at 4°C.	To ensure the best possible conditions for microbiological analysis and to prevent micro-organism proliferation (HPA 2014j, C).
14 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.24 Urine sampling: midstream specimen of urine: female

Essential equipment

- Cleaning solution (e.g. soap and water, 0.9% sodium chloride or disinfectant-free solution)
- Sterile specimen container with wide opening (CE marked)
- Non-sterile gloves
- Appropriate documentation/forms
- Apron

Pre-procedure

Action	Rationale
1 Discuss need and indication for procedure with patient.	To obtain valid consent (NMC 2013, C).
2 Fully explain the steps of the procedure.	The patient needs to fully understand the procedure in order to avoid inadvertent contamination of specimen and optimize the quality of the sample (Higgins 2008b, E).
3 Ensure a suitable, private location.	To maintain patient privacy and dignity (Gilbert 2006, E).

Procedure

4 Ask patient to wash hands with soap and water.	To reduce risk of cross-infection (Fraise and Bradley 2009, E).
5 <i>If practitioner's assistance required:</i> wash hands with bactericidal soap or decontaminate physically clean hands with alcohol rub and don apron.	To prevent cross-contamination (Fraise and Bradley 2009, E ; RCN 2012, C).

(continued)

Procedure guideline 10.24 Urine sampling: midstream specimen of urine: female (*continued*)

Action	Rationale
6 Ask patient to part the labia and clean the urethral meatus with soap and water, 0.9% sodium chloride or a disinfectant-free solution.	To optimize general cleansing and to minimize other organisms contaminating the specimen. E Disinfectant solutions may irritate the urethral mucous membrane (Higgins 2013, E).
7 Use a separate swab for each wipe and wipe downwards from front to back.	To prevent cross-infection and perianal contamination (Weston 2008, E).
8 Ask patient to begin voiding first stream of urine (approx. 15–30 mL) into a toilet or bedpan whilst separating the labia.	To commence the flow of urine and avoid contamination of specimen with naturally occurring micro-organisms/flora within the urethra (HPA 2014j, C).
9 Place the wide-necked sterile container into the urine stream without interrupting the flow.	To prevent contamination of specimen and to ensure the collection of the midstream urine which most accurately represents the urine in the bladder (HPA 2014j, C).
10 Ask the patient to void her remaining urine into the toilet or bedpan.	For patient to comfortably continue passing urine (HPA 2014j, C).
11 Transfer specimen into sterile universal container.	For dispatch to the laboratory (HPA 2014j, C).
12 Allow patient to wash hands.	To maintain personal hygiene. E
Post-procedure	
13 Label sample and complete microbiological request form including relevant clinical information, such as signs and symptoms of infection, antibiotic therapy.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
14 Dispatch sample to laboratory immediately (within 4 hours) or refrigerate at 4°C.	To ensure the best possible conditions for microbiological analysis and to prevent micro-organism proliferation (HPA 2014j, C).
15 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.25 Urine sampling: catheter specimen of urine (CSU)*Essential equipment*

- Sterile gloves
- Apron
- Syringe
- Non-traumatic clamps
- Appropriate documentation/forms
- Universal specimen container
- Alcohol-based swab

Optional equipment

- Non-sterile gloves

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Ensure a suitable, private location.	To maintain patient privacy and dignity (Gilbert 2006, E).
3 Prepare equipment and place on sterile trolley.	To prepare equipment for use. E

Procedure

4 <i>If no urine visible in catheter tubing:</i> wash/decontaminate physically clean hands with alcohol rub, don apron and apply non-sterile gloves prior to manipulating the catheter tubing.	To minimize the risk of cross-infection (Pellowe 2009, E ; RCN 2012, C).
5 Apply non-traumatic clamp a few centimetres distal to the sampling port.	To ensure sufficient sample has collected to allow for accurate sampling (Higgins 2013, E).
6 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol rub and don gloves.	To prevent cross-contamination (Fraise and Bradley 2009, E ; RCN 2012, C).
7 Wipe sampling port with 2% chlorhexidine in 70% isopropyl alcohol and allow drying for 30 seconds.	To decontaminate sampling port and prevent false-positive results (DH 2007a, C).

8 <i>If using needle and syringe:</i> using a sterile syringe and needle, insert needle into port at an angle of 45° and aspirate the required amount of urine, then withdraw needle. <i>Or in a needle-less system:</i> insert syringe firmly into centre sampling port (according to manufacturer's guidelines), aspirate the required amount of urine and remove syringe.	To enable safe inoculation of urine specimen and to minimize the risk of penetration of the wall of the catheter tubing (Hampson 2006, E). Reduces the risk of sharps injury (DH 2006, C ; European Biosafety Network 2010, C).
9 Transfer an adequate volume of the urine specimen (approx. 10 mL) into a sterile container immediately.	To avoid contamination and to allow for accurate microbiological processing (HPA 2014j, C).
10 Discard needle and syringe into sharps container.	To prevent the risk of needlestick injury. E
11 Wipe the sampling port with an alcohol wipe and allow to dry.	To reduce contamination of access port and to reduce risk of cross-infection (DH 2007a, C).
Post-procedure	
12 Unclamp catheter tubing.	To allow drainage to continue. E
13 Dispose of waste, remove apron and gloves and wash hands.	To ensure correct clinical waste management and reduce risk of cross-infection (DH 2006a, C).
14 Label sample and complete microbiological request form including relevant clinical information, such as signs and symptoms of infection, antibiotic therapy.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
15 Dispatch sample to laboratory immediately (within 4 hours) or refrigerate at 4°C.	To ensure the best possible conditions for microbiological analysis and to prevent micro-organism proliferation (HPA 2014j, C).
16 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.26 Urine sampling: sampling from an ileal conduit

Essential equipment

- Sterile trolley
- Sterile dressing pack (with gloves)
- Urinary catheter (not larger than 14 Fr)
- Apron
- Universal specimen container
- Clean stoma appliance
- Appropriate documentation/forms
- Sterile water or 0.9% sodium chloride

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Ensure a suitable, private location.	To maintain patient privacy and dignity (Gilbert 2006, E).
3 Ensure patient is in a comfortable position (sitting up, supported by pillows) and that stoma is easily accessible.	For patient comfort and to allow access to the stoma. E
4 Prepare equipment and place on sterile trolley.	To prepare equipment for use. E

Procedure

5 Wash hands with bactericidal soap and water and dry or decontaminate physically clean hands with alcohol rub. Don non-sterile gloves.	To prevent cross-contamination (Fraise and Bradley 2009, E ; RCN 2012, C).
6 Remove the appliance from stoma. Decontaminate hands, apply gloves and place sterile towel/pad under stoma.	To absorb any spillage from the stoma. E
7 Clean around the stoma with sterile water or 0.9% sodium chloride from the centre outwards.	Cleaning of the area reduces the risk of introducing surface pathogens into the ileal conduit. E
8 Apply gentle skin traction to allow the stoma opening to be more visible.	To avoid catheter coming into contact with external surface of the stoma. E
9 Insert catheter tip gently into the stoma to a depth of 2.5–5 cm only.	Gentle handling reduces the risk of ileal perforation and is more comfortable for the patient. E
10 Allow approximately 10 mL of drain through into a sterile specimen container.	To avoid contamination and to allow for accurate microbiological processing (HPA 2014j, C).

(continued)

Procedure guideline 10.26 Urine sampling: sampling from an ileal conduit (*continued*)

Action	Rationale
11 Remove the catheter and discard.	As catheter is no longer required. E
12 Change gloves, attend to stoma and apply new stoma appliance.	To ensure patient comfort. E
Post-procedure	
13 Dispose of waste, remove apron and gloves and wash/decontaminate hands.	To ensure correct clinical waste management and reduce risk of cross-infection (DH 2006a, C).
14 Label sample and complete microbiological request form including relevant clinical information, such as signs and symptoms of infection, antibiotic therapy.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
15 Dispatch sample to laboratory immediately (within 4 hours) or refrigerate at 4°C.	To ensure the best possible conditions for microbiological analysis and to prevent micro-organism proliferation (HPA 2014j, C).
16 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

570

Procedure guideline 10.27 Urine sampling: 24-hour urine collection**Essential equipment**

- Clean urine collection containers (e.g. wide-necked pot)
- Large urine containers with label attached for patient details
- Appropriate documentation/forms

Optional equipment

- Written patient instruction sheet

Pre-procedure

Action	Rationale
1 Discuss need and indication for procedure with patient.	To obtain valid consent (NMC 2013, C).
2 Fully explain the steps of the procedure, emphasizing the importance of not discarding any urine within the 24-hour period (provide written information if needed).	The patient needs to fully understand the procedure in order to avoid inadvertent contamination of specimen and optimize the quality of the sample. E

Procedure

3 Ask patient to void urine and discard this specimen.	To establish the exact start time of the 24-hour period. E
4 All urine passed in the next 24 hours from this appointed time should be collected in a clean urine collection container.	To ensure the specimen is representative of the variables of altering body chemistry within the 24 hours (Thomson 2002, E).
5 <i>If catheter in situ:</i> completely empty catheter bag and hourly chamber (if applicable) or attach new catheter bag. Attach label indicating start time of 24-hour urine collection.	To clearly indicate to all practitioners the 24-hour collection period. E
6 If applicable, transfer urine from collection container into large specimen container.	To ensure specimen is collected in a suitable container for safe transportation to the laboratory. E

Post-procedure

7 Label sample and complete request form.	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
8 Dispatch sample to laboratory as soon as possible after completion of the 24-hour period.	To allow accurate laboratory processing and analysis (Higgins 2013, E).
9 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Post-procedural considerations**Immediate care**

Urine is a very good culture medium so any bacteria present at the time of collection will continue to multiply in the specimen container. Rapid transport or special measures to ensure

preservation of the sample are essential for laboratory diagnosis. The specimens should be transported and processed within 4 hours (HPA 2014j). Therefore, specimens should be processed immediately as delays of more than 2 hours at room temperature between collection and examination will yield unreliable results, suggesting falsely raised bacteriuria. If a delay was to occur the

sample should be stored in a designated sample refrigerator (Higgins 2013).

Where delays in processing are unavoidable, specimens should be refrigerated at 4°C or a boric acid preservative, which holds the bacterial population steady for 48–96 hours, should be utilized. Facilities with semi-automated urine analysers should ensure that they have been validated and follow the manufacturer's and local guidance (HPA 2014j).

Specimen collection: faecal sampling

Definition

Faecal specimens are primarily obtained for microbiological analysis to isolate and identify pathogenic bacterial, viral or parasitic organisms suspected of causing gastrointestinal infections or in patients with diarrhoea of potentially infectious aetiology (Higgins 2008b). Faecal specimens may also be obtained for other non-microbiological testing to detect the presence of other substances, such as occult blood or as part of the national screening programme for colorectal cancer (NHS BCSP 2008).

Related theory

There are a number of enteric pathogens normally present within the gastrointestinal (GI) tract, along with resident flora, that play an important role in digestion and in forming a protective, structural and metabolic barrier against the growth of potentially pathogenic bacteria (Kelly et al. 2005). Pathogenic agents that disrupt the balance within the GI tract manifest in symptoms such as prolonged diarrhoea, bloody diarrhoea, nausea, vomiting, abdominal pain and/or fever. Bacteria in faeces are representative of the bacteria present in the GI tract, so the culture of a faecal sample is necessary for identification of GI tract colonization (Lautenbach et al. 2005).

Laboratory investigations are requested for bacterial infections such as *Salmonella*, *Campylobacter*, *Helicobacter*, *Shigella*, *Escherichia coli* and *Clostridium difficile*, viral infections such as norovirus and rotavirus, and parasitic pathogens such as protozoa, tapeworms and amoebiasis (HPA 2014g, Weston 2008).

Diarrhoea can be defined as an unusual frequency of bowel actions with the passage of loose, unformed faeces and may be associated with other symptoms such as nausea, abdominal cramping, fever and malaise. It may be attributable to a variety of bacterial, viral or parasitic pathogens and may be associated with antibiotic use, food or travel-related agents (HPA 2014g, HPA 2014h). Prompt collection of a faecal sample for microbiological investigation is essential in determining the presence and identification of such agents.

Clostridium difficile

Clostridium difficile (*C. diff*) is recognized as a major healthcare-acquired infection causing diarrhoea associated with antibiotic use and environmental contamination globally. It is an anaerobic, gram-positive bacterium that produces spores that are resistant to many disinfectants and can survive in harsh environmental conditions for prolonged periods (Soyfoo and Shaw 2008). It has a significant impact upon patient morbidity and mortality and the signs and symptoms range from mild, self-limiting diarrhoea to severe, life-threatening conditions (HPA 2014g, Lessa et al. 2012). Those most at risk are older patients, immunocompromised patients and those who have had a recent course of antibiotics.

Antimicrobials, particularly broad-spectrum antibiotics, alter the normal gut flora, allowing *C. diff* to proliferate and become pathogenic in the absence of other organisms. This leads to the production of toxins that irritate and cause mucosal damage of the intestinal tract (Lessa et al. 2012).

The diagnosis of *C. diff* is through faecal sampling for culture and toxin analysis on patients who develop diarrhoea or who are

admitted to healthcare institutions with unexplained diarrhoea. The control of antimicrobial drugs and improved infection control practices can limit or reduce the incidence of infection (HPA 2014g, Lessa et al. 2012). The use of faecal microbiota transplantation in the treatment of patients with recurrent infection has also shown positive results in the management of *C. diff* but this technique is not currently widely used and can be controversial (Kelly et al. 2012).

Evidence-based approaches

Rationale

Timely and accurate identification of patients with infective diarrhoea is crucial in individual management of colonization and within the context of effective infection control management. Obtaining the specimen provides important diagnostic information that can be used to decide how to manage the patient's condition and the mode of treatment (HPA 2014g, HPA 2014h). Prompt diagnosis can influence aspects of care such as isolation and cohort nursing of infected patients, infection control procedures, environmental decontamination and antibiotic prescribing (DH 2007b).

Indications

Collection of a faecal specimen is indicated:

- to identify an infective agent in the presence of chronic, persistent or extended periods of diarrhoea
- if patients are systemically unwell with symptoms of diarrhoea, nausea and vomiting, pain, abdominal cramps, weight loss and/or fever
- to investigate diarrhoea occurring after foreign travel
- to identify parasites, such as tapeworms (Pellatt 2007)
- to identify occult (hidden) blood if rectal bleeding is suspected (Pellatt 2007)
- in the presence of diarrhoea associated with prolonged antibiotic administration
- for symptomatic contacts of individuals with certain organisms (e.g. *E. coli* O157) where an infection can have serious clinical sequelae (HPA 2014g).

Contraindications

- As routine testing.
- In the absence of diarrhoea in suspected infective colonization.

Principles of care

A sample should be obtained as soon as possible after the onset of symptoms, ideally within the first 48 hours of illness, as the chance of successfully identifying a pathogen diminishes once the acute stage of the illness passes (Weston 2008). The specimen should be obtained using a clean technique in order to avoid inadvertent contamination (HPA 2014g).

Pre-procedural considerations

Assessment and recording tools

Collecting a faecal sample should be considered in conjunction with a comprehensive nursing assessment. This includes the observation of faeces for colour, presence of blood, consistency and odour (Pellatt 2007). The most widely used assessment tool is the Bristol Stool Chart (Lewis and Heaton 1997), which categorizes faeces into seven classifications (types) based upon the appearance and consistency. Samples sent to the microbiology laboratory for analysis of suspected *C. difficile* should be classified as Type 6/7 on the Bristol Stool Chart (HPA 2014h).

In addition to other associated symptomatology such as vomiting, fever, myalgia or abdominal pain, an accurate history should also include the onset, frequency and duration of diarrhoea, and other information such as history of foreign travel or potential food poisoning.

Procedure guideline 10.28 Faecal sampling

Essential equipment

- A clinically clean bedpan or disposable receiver
- Sterile specimen container (CE marked) (with integrated spoon) (see Figure 10.2)
- Non-sterile gloves
- Apron
- Appropriate documentation/forms

Pre-procedure

Action

- 1 Discuss need and indication for procedure with patient.
- 2 Wash hands with bactericidal soap and water, or decontaminate physically clean hands with alcohol-based handrub. Don apron and gloves.

Rationale

- To ensure the patient understands the procedure and gives valid consent (NMC 2013, **C**).
- To reduce the risk of cross-infection and specimen contamination (Fraise and Bradley 2009, **E**; RCN 2012, **C**).

Procedure

- 3 Ask patient to defaecate into a clinically clean bedpan or receiver.
- 4 *If the patient has been incontinent:* a sample may be obtained from bedlinen or pads: try to avoid contamination with urine.
- 5 Using the integrated 'spoon', scoop enough faecal material to fill a third of the specimen container (or 10–15 mL of liquid stool).
- 6 Apply specimen container lid securely.

- To avoid unnecessary contamination from other organisms (Kyle 2007, **E**).
- Urine would cause contamination of the sample (Higgins 2008b, **E**).
- To obtain a suitable amount of specimen for laboratory analysis. **E**
- To prevent risk of spillage. **E**

Post-procedure

- 7 Dispose of waste, remove apron and gloves, and wash hands with soap and water.
- 8 Examine the specimen for features such as colour, consistency and odour. Record observations in nursing notes/care plans.
- 9 *In cases of suspected tapeworms:* segments of tapeworm are easily seen in faeces and should be sent to the laboratory for identification.
- 10 Label sample and complete microbiology request form (including relevant information such as onset and duration of diarrhoea, fever or recent foreign travel).
- 11 Dispatch sample to the laboratory as soon as possible or refrigerate at 4–8°C and dispatch within 12 hours.
- 12 *In cases of suspected amoebic dysentery:* dispatch the sample to the laboratory immediately.
- 13 *In cases of prolonged diarrhoea, especially in the presence of a fever:* dispatch the sample to the laboratory immediately.
- 14 Document the procedure in the patient's records.

- To reduce risk of cross-infection (DH 2006a, **C**). Soap and water must be used as alcohol-based handrubs are ineffective for *C. diff* (DH 2007b, **C**).
- To complete a comprehensive nursing assessment (Pellatt 2007, **C**).
- Unless the head is dislodged, the tapeworm will continue to grow. Laboratory confirmation of the presence of the head is essential (Gould and Brooker 2008, **E**).
- To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, **C**; Weston 2008, **E**).
- To increase the chance of accurate organism identification and to ensure the best possible conditions for laboratory analysis (Higgins 2013, **E**).
- The parasite causing amoebiasis must be identified when mobile and survives for a short period only. Therefore, faeces should remain fresh and warm (Kyle 2007, **E**).
- Due to the risk of *C. diff* and to ensure prompt diagnosis and initiation of appropriate infection control measures (DH 2007b, **C**).
- To ensure timely and accurate record keeping (NMC 2010, **C**).

Post-procedural considerations

Immediate care

A faecal sample should be transported to the laboratory and processed as soon as possible because a number of important pathogens, such as *Shigella*, may not survive changes in pH and temperature once outside the body (HPA 2014g). If there is an

anticipated delay in despatching the sample to the laboratory, it should be refrigerated at 4–8°C and processed within 12 hours (HPA 2014g).

Ongoing care

The result of specimen analysis will determine the patient's ongoing care. The involvement of the microbiology and infection

control teams is essential to ensure prudent and safe treatment and nursing care. This should include:

- effective handwashing techniques to minimize the transmission of organisms
- implementation of Standard Precautions (gloves and aprons)
- nursing patients with unexpected or unexplained diarrhoea in isolation or cohorted with other infected patients (DH 2007b)
- thorough environmental decontamination (DH 2007b)
- prudent antibiotic prescribing (DH 2007a).

Education of patient and others

Patients should be provided with information and involved in their care as much as they choose to be (NMC 2015). Confirmation of an infection diagnosis should be relayed to patients and their families alongside information on management strategies (such as antibiotic therapy, the use of PPE, reasons for isolation and visiting restrictions). The provision of written information, such as leaflets, may also be useful.

Specimen collection: respiratory tract secretion sampling

Definition

Obtaining a specimen from the respiratory tract is important in diagnosing illness, infections and conditions such as tuberculosis and lung cancer (Guest 2008). A sample can be obtained invasively or non-invasively and the correct technique will enable a representative sample to identify respiratory tract pathology and to guide treatment.

Related theory

Excessive respiratory secretions may be due to increased mucus production in cases of infection, impaired mucociliary transport or a weak cough reflex (Hess 2002). Lower airway secretions that are not cleared provide an ideal medium for bacterial growth. Suitable microbiological analysis in diagnosing infection will depend upon (HPA 2014k):

- the adequacy of lower respiratory tract specimens
- avoidance of contamination by upper respiratory tract and oral flora
- use of microscopic techniques and culture methods
- current and recent antimicrobial therapy.

Evidence-based approaches

Rationale

The main aim of sputum/secretion collection is to provide reliable information on the causative agent of bacterial, viral or fungal infection within the respiratory tract and its susceptibility to antibiotics for guiding treatment (Ioanas et al. 2001).

Indications

A respiratory tract secretion specimen is indicated:

- when there are clinical signs and symptoms of a respiratory tract infection, such as a productive cough, particularly with purulent secretions
- if there are signs of systemic infection or in patients with a PUO of $>38^{\circ}\text{C}$ (Perry 2007).

The presence of sputum, especially when discoloured, is commonly interpreted to represent the presence of bacterial infection and as an indication for antibiotic therapy. However, purulence primarily occurs when inflammatory cells or sloughed mucosal epithelial cells are present, and can result from either viral or bacterial infection (Johnson et al. 2008). One strategy for limiting or

targeting antimicrobial prescribing is to send a respiratory tract specimen for microbiological analysis to either demonstrate that a substantial infection is not present or to identify an organism for which antimicrobial treatment is deemed necessary.

The accuracy of microbiological analysis can depend on the quality of the specimen obtained as well as the time taken for transportation and the method by which it is stored and transported (Perry 2007).

Methods of non-invasive and semi-invasive sampling

A sufficient quality of sputum will yield a representative sample and early morning sputum samples are preferred as they contain pooled overnight secretions in which pathogenic bacteria are more likely to be concentrated (Philomina 2009).

Obtaining a sputum sample

Sputum is a combination of mucus, inflammatory and epithelial cells, and degradation products from the lower respiratory tract (Dulak 2005). It is never free from organisms since material originating from the lower respiratory tract has to pass through the pharynx and the mouth, which have commensal populations of bacteria (Thomson 2002). However, it is important to ensure that material sent to the microbiology laboratory is of sputum rather than a saliva sample, which will contain squamous epithelial cells and be unrepresentative of the underlying pulmonary pathology.

Sputum produced as a result of infection is usually purulent and a good sample can yield a high bacterial load (Weston 2008). For patients who are self-ventilating, co-operative, able to cough, expectorate and follow commands, a sputum sample is a suitable collection method. In cases of suspected *Mycobacterium tuberculosis*, three sputum specimens are required as the release of the organism is intermittent, before the pathogenic organisms can be isolated (Damani 2012). See Figure 10.1 and Procedure guideline 10.29: Sputum sampling.

Nasopharyngeal samples

Nasopharyngeal suctioning is a viable alternative for patients who are obtunded or whose cough is weak (Dulak 2005). Sampling techniques to obtain specimens from the nasopharynx are semi-invasive but can be used on patients who are self-ventilating. They are indicated in suspected viral infections such as respiratory syncytial virus (RSV), influenza and parainfluenza. The main aim is to collect epithelial cells from the posterior nasopharynx and a sample can be obtained using nasal washing or vacuum-assisted aspiration (see Procedure guideline 10.30: Nasopharyngeal wash: syringe method). This method can yield a more reliable sample because the normal flora present in the oropharynx are bypassed (Philomina 2009).

Invasive sampling techniques

Intubated patients who are unable to clear secretions independently or who require more accurate specimen collection may need a more invasive technique to obtain a sample. Invasive techniques obtain secretions directly from the lower airway and are designed to avoid contamination by upper airway colonization, which may lead to misinterpretation of cultures (Ioanas et al. 2001).

Vacuum-assisted aspirate via endotracheal tube

Endotracheal suctioning is frequently used as a diagnostic method and for obtaining specimens in intubated patients with suspected pulmonary infection. This technique bypasses the upper respiratory airways and provides an accurate microbiological result. Suctioning aids the clearance of secretions by the application of negative pressure through a sterile flexible suction catheter or a closed suction system. A sterile sputum trap is attached to the suction catheter at one end, whilst the other end is attached to the suction tubing to collect the sample (Figure 10.13).

Bronchoalveolar lavage (BAL)

Bronchoalveolar lavage is a reliable and accurate technique that provides a good diagnostic yield in cases of pulmonary infection,

Figure 10.13 Types of vacuum-assisted sputum traps.

particularly invasive fungal infections and malignancies (Knox and Meinke 2009). BAL specimens are particularly useful in immunocompromised patients with diffuse pneumonia (Brooks et al. 2010). This method is used to clear secretions and to obtain washings for the retrieval of cellular and non-cellular components of the epithelial surface of the lower respiratory tract (HPA 2014k). Endotracheal aspiration can eliminate some of the contamination problems of expectorated sputum.

Flexible fiberoptic bronchoscopy is a relatively safe and well-tolerated means by which to obtain BAL fluid (Knox and Meinke 2009). A flexible bronchoscope is inserted through the endotracheal tube (ETT) and advanced distally into a subsegmental bronchus. The area selected for sampling is based upon a correspondent area of infiltration on a chest X-ray or by visualization of a subsegment containing purulent secretions (Ioanas et al. 2001). A volume of sterile 0.9% sodium chloride (normally 20–30 mL) is then instilled through a port on the bronchoscope and suctioned back through another port into a sterile sputum trap. The procedure is repeated 3–5 times and the samples are then dispatched to the laboratory for microscopy and microbiological analysis.

Legal and professional issues

Competencies

Practitioners must be competent and feel confident that they have the knowledge, skill and understanding to undertake respiratory tract secretion sampling for microbiological analysis (NMC 2015). For more advanced skills of specimen collection such as suctioning, the practitioner should receive training and be assessed on their knowledge and understanding of the technique and potential adverse effects that may occur, such as hypoxia, cardiovascular instability and mucosal trauma (Thomson 2000). Bronchoalveolar lavage is normally performed by a member of the medical team who has received specialist training and has been deemed competent in the skill.

Pre-procedural considerations

Equipment

The use of vacuum-assisted and invasive suctioning techniques requires a comprehensive assessment of clinical indication and safety considerations. These include the following.

Table 10.6 Catheter sizes and suction pressures

Patient age	Catheter size (French)	Suction pressure (mmHg)
Premature infant	6	80–100
Infant	8	80–100
Toddler/preschooler	10	100–120
School age	12	100–120
Adolescent/adult	14	120–150

- The use of an appropriately sized, single-use, multi-eyed suction catheter which causes less tracheal mucosal trauma (NHSQIS 2007). If suctioning through an ETT, the suction catheter diameter should be half the diameter or less which prevents occlusion of the airway and avoids generation of large negative intrathoracic pressures (Thomson 2000) (Table 10.6).
- The use of the lowest effective suction pressure that is high enough to clear secretions whilst avoiding trauma to the bronchial mucosa.
- Ensuring suction duration time of <10 seconds to decrease the risk of adverse side-effects (NHSQIS 2007).

Procedures that involve suctioning present a risk of suction-induced hypoxaemia, hypertension, cardiac arrhythmias and other problems that warrant patient monitoring, in particular oxygen saturation and cardiac monitoring (Thomson 2000).

Pharmacological support

Adequate analgesia is a key consideration in ensuring that an effective sputum expectoration technique can be achieved. For example, pre-procedural analgesia should be given time to be effective, and wounds need to be supported to maximize inhalation and minimize pain (Guest 2008).

Nebulization of 0.9% sodium chloride and/or mucolytic agents, such as N-acetylcysteine, may need to be administered to help loosen tenacious secretions and to elicit an effective cough (Rajiv 2007).

Non-pharmacological support

Collaboration with the physiotherapy team may assist in obtaining a good-quality sample (Hess 2002). For sputum sampling, physiotherapeutic modalities implemented may include appropriate positioning, active cycle of breathing, deep breathing and effective coughing techniques (HPA 2014k).

Specific patient preparation

Patient position is important in optimizing secretion sampling. Patients should be sat upright or on the edge of the bed, if able, or in a high semi-Fowler position (head elevated to 30–45°) in bed supported by pillows (Dulak 2005).

The quality and quantity of secretion production and mucociliary clearance depend on systemic hydration. Patient hydration can boost sputum production to enable a good sample (Dulak 2005). This can be further enhanced with sufficient airway humidity and nebulization.

Procedure guideline 10.29 Sputum sampling

Essential equipment

- Universal container
- Apron
- Non-sterile gloves

Optional equipment

- Nebulizer
- Appropriate documentation/form
- Eye protection (e.g. goggles/visor)

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Fully explain the steps of the procedure.	The procedure requires the patient to fully understand and co-operate in order to optimize the quality of the sample (Dulak 2005, E).
3 Position patient upright in a chair or in a semi- or high Fowler position, supported as necessary with pillows.	For comfort and to facilitate optimum chest/lung expansion. E
4 <i>If secretions thick/tenacious or having difficulty clearing secretions:</i> administer nebulization therapy and/or enlist help of the physiotherapist.	To loosen secretions and assist in techniques that will optimize sputum sample collection (Hess 2002, E).
5 Wash hands with bactericidal soap/decontaminate physically clean hands with alcohol rub. Don apron, gloves and eye protection.	To reduce the risk of cross-infection or splash injury to practitioner and specimen collection (Damani 2012, E).

Procedure

6 Ask patient to take three deep breaths in through their nose, exhale through pursed lips and then force a deep cough.	Deep breathing helps loosen secretions and a deep cough will ensure a lower respiratory tract sample is obtained (Dulak 2005, E).
7 Ask patient to expectorate into a clean container and secure lid.	To prevent contamination. E

Post-procedure

8 Dispose of waste, remove apron, gloves and eye protection and wash/decontaminate hands.	To ensure correct clinical waste management and reduce the risk of cross-infection (DH 2006a, C).
9 Label sample and complete microbiology request form (including relevant information such as indication for sample and current/recent antimicrobial therapy).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
10 Dispatch to the laboratory as soon as possible within 4 hours.	To increase the chance of accurate organism identification (Higgins 2013, E).
11 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Procedure guideline 10.30 Nasopharyngeal wash: syringe method**Essential equipment**

- Universal container
- 5 mL syringe or wide-bore bladder syringe
- Sterile tubing cut to approximately 2–3" (e.g. size 8 Fr NG tube or cut off tip from a suction catheter if using a 5 mL syringe)
- 3–5 mL 0.9% sodium chloride
- Viral transport medium (VTM) (if required by laboratory)
- Apron
- Non-sterile gloves
- Eye protection (e.g. goggles/visor)
- Appropriate documentation/form
- Sterile water-soluble lubricant

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure the patient understands the procedure and gives valid consent (NMC 2013, C).
2 Position patient upright in a chair or in a semi- or high Fowler position, supported as necessary with pillows.	For comfort and to facilitate optimum specimen collection. E
3 Wash hands with bactericidal soap/decontaminate physically clean hands with alcohol rub. Don apron, gloves and eye protection.	To reduce the risk of cross-infection, splash injury to practitioner and specimen collection (Damani 2012, E).

(continued)

Procedure guideline 10.30 Nasopharyngeal wash: syringe method (continued)

Action	Rationale
Procedure	
4 Fill syringe with 3–5 mL of 0.9% sodium chloride and attach tubing to syringe tip.	To facilitate instillation of 0.9% sodium chloride high into the patient's nostril. E
5 Ask patient to tilt their head backwards slightly whilst sitting upright.	To promote the flow of 0.9% sodium chloride into the nostril. E
6 Dip the end of the catheter into the water-soluble lubricant.	To facilitate comfortable passing of the catheter. E
7 Carefully insert tubing into nostril and quickly instil 0.9% sodium chloride into one nostril while holding the second nostril closed.	To facilitate optimal recovery of epithelial cells. E
8 Aspirate fluid while withdrawing and rotating the tube to dislodge cells and secretions. NB: Recovery must occur rapidly or instilled fluid will drain down the throat.	To obtain desired nasopharyngeal specimen. E
9 <i>Either:</i> Where appropriate, patient may tilt head forward and gently push the fluid out of the nostril into a sterile container. <i>Or:</i> <i>If aspirated:</i> inject aspirated specimen from syringe into suitable dry, sterile container or one containing viral transport medium, according to virology laboratory requirements.	Patients may find this method more comfortable. E To ensure a good-quality specimen and to prevent cross-contamination. E
10 Repeat procedure with other nostril and inject specimen into the same container (Action figure 10).	A combined specimen will promote optimal yield of micro-organisms. E
Post-procedure	
11 Remove apron, gloves and eye protection. Dispose of waste and wash/decontaminate hands.	To ensure correct clinical waste management and reduce the risk of cross-infection (DH 2006a, C).
12 Label sample and complete microbiology request form (including relevant information such as indication for sample and current/recent antimicrobial therapy).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
13 Dispatch to the laboratory as soon as possible within 4 hours.	To increase the chance of accurate organism identification (Higgins 2013, E).
14 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

Action Figure 10 Nasopharyngeal wash: syringe method.

Procedure guideline 10.31 Nasopharyngeal wash: vacuum-assisted aspirate method**Essential equipment**

- Suction pump (wall or portable)
- Sterile suction catheter (see Table 10.6 for appropriate size)
- Sterile sputum trap
- Viral transport medium (if required by laboratory)
- Apron
- Sterile gloves
- Eye protection (e.g. goggles/visor)
- Appropriate documentation/form
- Sterile water-soluble lubricant

Pre-procedure**Action****Rationale**

Procedure guideline 10.31 Nasopharyngeal wash: vacuum-assisted aspirate method (continued)

Action	Rationale
Post-procedure	
14 Dispose of waste, remove apron, gloves and eye protection and wash/decontaminate hands.	To ensure correct clinical waste management and to reduce the risk of cross-infection (DH 2006a, C).
15 Label sample and complete microbiology request form (including relevant information such as indication for sample and current/recent antimicrobial therapy).	To maintain accurate records and provide accurate information for laboratory analysis (NMC 2010, C ; Weston 2008, E).
16 Dispatch to the laboratory as soon as possible within 4 hours.	To increase the chance of accurate organism identification (Higgins 2013, E).
17 Document the procedure in the patient's records.	To ensure timely and accurate record keeping (NMC 2010, C).

578

Post-procedural considerations**Immediate care**

Many organisms responsible for infection of the lower respiratory tract do not survive well outside the host, so specimens should be dispatched to the laboratory immediately and processed within 2 hours (Gould and Brooker 2008). If there is an anticipated delay in despatching the sample to the laboratory, it should be refrigerated at 4–8°C and sent as soon as possible (HPA 2014k).

Documentation

The date and time when a sputum sample is sent to the laboratory should be documented clearly and promptly in the patient's notes and care plan (NMC 2010). This should be done alongside documentation in relation to significant findings that have prompted the collection of the sample, such as a description of the type and colour of sputum/secretions and method used to obtain the sample.

Specimen collection: pleural fluid**Definition**

Specimens of pleural fluid for microbiological analysis are obtained by thoracocentesis to assist in the diagnosis of infection in fluid that has accumulated within the inner and outer (visceral and parietal) layers of the pleural cavity such as parapneumonia, empyema and tuberculosis (Barnes et al. 2005). In the context of microbiological analysis, thoracocentesis is the insertion of a needle into the pleural space to obtain a fluid sample for diagnostic testing (Rushing 2006).

Anatomy and physiology

See Chapter 9: Respiratory care.

Related theory

Pleural fluid is generated from pleural vessels as a result of negative intrapleural pressure. It exits via the parietal pleural lymphatic system. Pleural effusions occur when there is an accumulation of fluid within the pleural cavity, which implies either an increased production of fluid that exceeds the capacity of lymphatic removal and/or obstruction of drainage of the pleural space (Pendharkar and Tremblay 2007).

Analysis of pleural effusion fluid is obtained via thoracocentesis, which determines the cause of the effusion. Effusion occurs when factors that influence the formation and absorption of fluid are altered either systematically, for example in cirrhosis or congestive heart failure (transudate effusions), or locally, for example in infection or malignancy (exudate effusions). Pleural fluid in a patient with undiagnosed exudative effusions should be cultured

for bacteria (aerobic and anaerobic), mycobacteria and fungi (Barnes et al. 2005).

Infection of pleural fluid caused by bacteria, viruses or fungi may originate in the pleura or translocate from another site. Micro-organisms can infiltrate the pleural space by various routes: directly in cases of empyema, primary tuberculous focus rupturing into the pleural cavity, from an adjacent area of pneumonia, thoracic surgery or drainage, chest trauma or by transdiaphragmatic spread from intra-abdominal infection (HPA 2014i).

Pleural fluid is a clear, straw-coloured fluid that contains a small number of white blood cells (WBC) but no red blood cells (RBC) or micro-organisms (HPA 2014i). In cases of suspected infection, it appears cloudy due to the presence of micro-organisms and/or increased WBC (Barnes et al. 2005). Differential WBC counts assist further in the diagnosis of infection because increased numbers of neutrophils indicate bacterial infection, whereas an increased number of lymphocytes is indicative of malignancy or tuberculosis (Conner et al. 2003). Other changes include decreased glucose levels, increased protein or albumin levels and disturbances in lactate level.

Evidence-based approaches**Rationale**

Detection of micro-organisms in fluids that are normally sterile indicates significant infection (HPA 2014i). Pleural fluid may be sent to the microbiology laboratory for bacterial culture to identify the cause of an effusion, isolate pathogenic micro-organisms and establish susceptibility to antimicrobial therapy.

Indications

Obtaining a specimen of pleural fluid is indicated in patients with:

- bacterial pneumonia with radiological suggestion of significant pleural effusions
- systemic infection with pyrexia, severe pleuritic pain and leucocytosis
- suspected tuberculous focus with clinical signs or radiological evidence of significant pleural effusions (HPA 2014i).

Methods of pleural fluid collection

Diagnosis of infection is established by the microbiological analysis of pleural fluid obtained by thoracocentesis using a strict aseptic technique, including meticulous skin antisepsis (Barnes et al. 2005).

Following clinical assessment and possible radiological guidance, local anaesthetic is infiltrated into the area of intended thoracocentesis. A needle is advanced superiorly to the ribs to avoid neuromuscular bundle damage and to reduce the risk of causing a pneumothorax (Pendharkar and Tremblay 2007). Fifty

to 100 mL of fluid are drawn, transferred into a sterile container and sent to the laboratory for analysis.

The samples can initially be observed for characteristics such as colour and turbidity, and gram stains allow for direct observation of bacteria under a microscope. When bacterial infection of pleural fluid is suspected, a specimen should be drawn and inoculated directly into aerobic and anaerobic blood culture bottles (Pendharkar and Tremblay 2007).

Specimens should be dispatched to the laboratory immediately and liaison with the laboratory is essential to enable efficient processing of the sample. If there are any delays, the sample should be refrigerated at 4°C (HPA 2014i).

Endoscopic investigations

Definition

Occasionally patients will be required to undergo further invasive diagnostic procedures such as an endoscopy. An endoscopy is the direct visual examination of the GI tract (Figure 10.14) which may include gastroscopy or colonoscopy. Endoscopy allows the practitioner to evaluate the appearance of the visualized mucosa for the purpose of diagnosis and therapeutic procedures (Smith and Watson 2005).

Gastroscopy

Definition

A gastroscopy or oesophagogastroduodenoscopy (OGD) is a procedure in which a long flexible endoscope is passed through the mouth, allowing the doctor or nurse endoscopist to look directly at the mucosal lining of the oesophagus, stomach and proximal duodenum. The endoscope is generally less than 10 mm in diameter but a larger scope may be required for therapeutic procedures where suction channels are required (Smith and Watson 2005) (see Figure 10.14).

Anatomy and physiology

See Figure 10.15.

Oesophagus

The oesophagus is a muscular thin-walled tube approximately 25 cm long and about 2 cm in diameter. It is located behind

Figure 10.14 Endoscopy. *Source:* Reproduced with permission from the patient information website of Cancer Research UK (www.cancerresearchuk.org/cancerhelp).

Figure 10.15 Anatomy of the lower gastrointestinal tract. RUQ, right upper quadrant; LUQ, left upper quadrant; RLQ, right lower quadrant; LLQ, left lower quadrant.

the trachea and in front of the vertebral column. It begins at the inferior end of the laryngopharynx and ends at the stomach. There are two sphincters within the oesophagus: the upper or hypopharyngeal sphincter and the lower gastro-oesophageal or cardiac sphincter. The upper moves food from the pharynx to the oesophagus and the lower the food passing into the stomach. The oesophagus has three layers, the mucosa, submucosa and the muscularis, with the innermost layer consisting of stratified squamous epithelium (Jenkins and Tortora 2013).

Stomach

The stomach connects the oesophagus and the small intestine or duodenum. It is a J-shaped dilated portion of the alimentary tract and one of its functions is a holding reservoir and mixing chamber. It is also located between the epigastric, umbilical and left hypochondriac regions of the abdomen. It is divided into four regions: the cardia, fundus, body and pyloric part. Distally, the pyloric sphincter is located between the stomach and the duodenum. The stomach has three muscle layers to allow for gastric motility to move the contents adequately whereas other parts of the alimentary tract only have two muscle layers (Jenkins and Tortora 2013).

Duodenum

The duodenum is part of the small intestine. It is approximately 25 cm long and 3.5 cm in diameter and is the shortest region. It begins at the pyloric sphincter of the stomach and joins the jejunum. Both the pancreas and the gallbladder release secretions into the duodenum (Jenkins and Tortora 2013).

Evidence-based approaches

Rationale

A gastroscopy is undertaken to investigate symptoms originating from the upper GI tract such as reflux and dysphagia. The doctor or nurse endoscopist uses direct vision to diagnose, sample and document changes in the upper GI tract.

Indications

- Dysphagia.
- Odynophagia.
- Achalasia.
- Unresponsive reflux disease.
- Gastric and peptic ulcers.
- Haematemesis and melaena.
- Suspected carcinoma.
- Oesophageal or gastric varices.
- Monitoring Barrett's oesophagus disease.

Contraindications

- Fractured base of skull.
- Metastatic adenocarcinoma.
- Some head/neck tumours.
- Thrombocytopenia.
- Symptoms that are functional in origin.

Legal and professional issues

Nurse endoscopists

In some centres nurse endoscopists work alongside medical endoscopists undertaking endoscopy. In 1995, the British Society of Gastroenterology supported the development of non-medical endoscopists. The nurse endoscopist must work within their own professional boundaries and complement the medical endoscopist teams (BSG 2005, Smith and Watson 2005). It has also been shown that nurse endoscopists perform procedures at a high standard and adhere to international standards. Most patients also had no specific preference for doctor or nurse endoscopist and expressed high patient satisfaction (Tursi 2013, van Putten et al 2012). It is essential that all practitioners are adequately trained in the administration of conscious sedation, and are aware of its side-effects and reversal agents. Conscious sedation is used to relax the patient, minimize pain during the procedure and improve procedural efficiency (Choi 2012). Clinical units must also limit the possibility of overdose, particularly with midazolam, as highlighted by the NPSA (2008b).

Consent

It is essential that valid consent is obtained as previously discussed in this chapter prior to any investigation. This is important as conscious sedation may be utilized during this procedure.

Governance

It is a priority that an organization providing endoscopic services has clear identifiable policies and procedures. Bidirectional communication must be open between the department, organizational board and national bodies to ensure that appropriate care is delivered. Monitoring processes must be in place to identify potential clinical or organizational risks and there must be a clear reporting mechanism.

Risk management

The organization must ensure that relevant policies and procedures are in place to reduce risk. Responding to national alerts and guidance is essential as well as implementing relevant evidence. In 2008, the NPSA issued an alert regarding the use of midazolam during conscious sedation. It was found that some patients were receiving an overdose of midazolam with a subsequent over-reliance on the use of flumazenil as a reversal agent.

Pre-procedural considerations

Equipment

To conduct a gastroscopy, a flexible side- or end-viewing endoscope is required. The endoscope allows visualization of the oesophagus, stomach and proximal duodenum (MacKay et al.

2010, Smith and Watson 2005). Access to resuscitation equipment is also essential if conscious sedation is going to be administered (BSG 2007).

Assessment and recording tools

A medical and nursing history and assessment must be undertaken to identify any care needs or concerns that may be significant, in particular the patient's current drug therapy, drug reactions or allergies, any organ dysfunctions such as cardiac and/or respiratory disease and previous or current illnesses. It is also important to be aware of any coagulopathies as samples of tissue or biopsy may need to be taken during the procedure. This can be pre-empted by reviewing blood results prior to the gastroscopy. A set of observations including temperature, pulse, blood pressure, respiration rate and oxygen saturations should also be taken to identify any pre-procedural abnormalities and provide a baseline. If the patient has diabetes, a blood glucose level should also be checked (BSG 2003, BSG 2007, MacKay et al. 2010, Smith and Watson 2005).

Pharmacological support

Prior to the procedure, a local anaesthetic spray may be used on the back of the throat. In some cases conscious sedation may be administered. This technique involves the administration of a benzodiazepine such as midazolam in small doses. Doses must be titrated for elderly patients or those with co-morbidities such as cardiac or renal failure (BNF 2014). Oxygen therapy should also be administered for patients at risk of hypoxia or those requiring sedation. Generally 2 litres per minute is adequate for most circumstances to maintain oxygen saturation levels and prevent hypoxaemia (BSG 2003, BSG 2007).

Specific patient preparation

The patient must fast for at least 4–8 hours prior to the gastroscopy to ensure that the stomach is relatively empty. Clear fluids may be taken up to 2 hours before, but local guidelines must be followed. This increases the visual field for the endoscopist and also minimizes the risk of aspiration if the patient vomits (Kang and Hyun 2013, Saied et al. 2012). If the patient has undergone previous gastric surgery, this fasting time may be longer, dependent on the type of surgery, to ensure gastric emptying (Ahn et al. 2013). The nurse can also assist by getting the patient to lie on their left side on the trolley (Smith and Watson 2005). If a sedative is used, it is essential that the patient is monitored with pulse oximetry and observed for any respiratory depression. Nursing staff can observe and record oxygen saturations and respiratory rate. ECG monitoring may only be required if a patient is at risk of cardiac instability during the procedure (BSG 2003).

Post-procedural considerations

Immediate care

Physiological monitoring must continue in the immediate recovery period. Supplemental oxygen and oxygen saturations may be required, especially if a sedative has been used. The patient should avoid drinking or eating for an hour after the use of the throat spray to minimize the risk of aspiration. Once stable, awake and reviewed by the team, the patient may be discharged or transferred to another department (BSG 2003, BSG 2007).

Ongoing care

It is recommended that patients who have been sedated with an intravenous benzodiazepine do not drive a car, operate machinery, sign legal documents or drink alcohol for 24 hours (BSG 2003). This is irrespective of whether their sedation has been reversed with flumazenil. The patient must be accompanied home if they have been given a sedative. The accompanying adult should stay with the patient for 12 hours at home if they live alone. It is important to remember that aspiration pneumonia may develop

hours or days later and the patient should be informed to report any symptoms such as temperatures or breathing difficulty (BSG 2003, BSG 2007, Smith and Watson 2005).

Documentation

Any samples should be clearly documented with the appropriate forms as previously discussed in this chapter. All drugs administered, complications and/or findings should be documented.

Complications

Respiratory depression

If oversedation occurs, respiratory function will be affected. It is essential that close monitoring occurs during and after the procedure. A reversal agent may be required such as flumazenil for midazolam (BSG 2003, NPSA 2008b, Smith and Watson 2005).

Perforation

Although rare, it is possible that perforation of the oesophagus, stomach or duodenum may occur. Further medical and/or surgical intervention will be required to manage this potential complication (Borgaonkar et al. 2012, Smith and Watson 2005).

Haemorrhage

Where biopsy samples have been taken, this may increase the risk of post-procedural bleeding. Further intervention may be required to stop the bleeding. Patients should be advised to seek medical assistance if there are signs of bleeding following discharge, which include the presence of fresh blood in the sputum and melaena (Chernecky and Berger 2013).

This will be dependent on the specific aetiology of the bleed, for example whether it is from varices when variceal band ligation may be required (Borgaonkar et al. 2012, SIGN 2008, Smith and Watson 2005).

Colonoscopy

Definition

A colonoscopy is conducted by inserting a colonoscope through the anus into the colon. It provides information regarding the lower GI tract and allows a complete examination of the colon. The colonoscope is similar to the endoscope used in gastroscopy. Its length ranges from 1.2 to 1.8 metres. It is the most effective method of diagnosing rectal polyps and carcinoma (MacKay et al. 2010, Smith and Watson 2005, Swan 2005, Taylor et al. 2009).

Anatomy and physiology

The large intestine is about 1.5 metres long. It begins at the ileum and ends at the anus. The four major structures are the caecum, colon, rectum and anal canal (Jenkins and Tortora 2013). See Figure 10.15.

Caecum

The caecum is about 6 cm long and opens from the ileum and ileocaecal valve (Jenkins and Tortora 2013).

Colon

The colon consists of three parts. The ascending colon runs from the caecum and joins the transverse colon and the hepatic flexure. The transverse colon is in front of the duodenum where it joins the descending colon at the splenic flexure. The descending colon travels down toward the middle of the abdomen where it joins the sigmoid colon which is S-shaped and becomes the rectum (Jenkins and Tortora 2013).

Rectum and anal canal

The rectum is approximately 20 cm long and is a dilated section of the colon. It joins the anal canal which is approximately 2–3 cm long (Jenkins and Tortora 2013).

Evidence-based approaches

Rationale

A colonoscopy is performed to investigate specific symptoms originating from the lower GI tract such as bleeding. The endoscopist uses direct vision to diagnose, sample and document changes in the lower GI tract (MacKay et al. 2010, Taylor et al. 2009).

Indications

- Screening of patients with family history of colon cancer, a serious but highly curable malignancy.
- Determining the presence of suspected polyps.
- Monitoring ulcerative colitis.
- Monitoring diverticulosis and diverticulitis.
- Active or occult lower gastrointestinal bleeding.
- Unexplained bleeding or faecal occult blood specifically in patients >50 years.
- Abdominal symptoms, such as pain or discomfort, particularly if associated with weight loss or anaemia.
- Chronic diarrhoea, constipation or a change in bowel habits.
- Surveillance of inflammatory bowel disease.
- Population screening for colorectal carcinoma.
- Palliative supportive treatments such as stent insertion.

Contraindications

- Upper gastrointestinal bleeding.
- Acute diarrhoea.
- Recent colon anastomosis.
- Toxic megacolon.
- Pregnancy (Chernecky and Berger 2013).

Legal and professional issues

Competencies and consent

Competencies and consent will be the same as those discussed in the section on 'Gastroscopy', above.

Risk management

The NPSA (2009) highlighted the risks in relation to bowel preparation and actions required to minimize these. Harm to patients has occurred where oral bowel preparations were prescribed to those with definite contraindications; however, the majority of the incidents were related to the administration of the bowel preparations (56%) (Connor et al. 2012). The NPSA (2009) report identified that one death and 218 patient safety incidents resulting in moderate harm were related to the use of oral bowel preparations where contraindications were not considered or assessed.

Pre-procedural considerations

Equipment

A colonoscope is a flexible endoscope which generally uses fibreoptics to allow direct visualization of the rectum and colon (Chernecky and Berger 2013, MacKay et al. 2010, Smith and Watson 2005).

Pharmacological support

Bowel preparation agents, such as senna tablets and Citramag, are given to the patient to take 1 day before the colonoscopy to clear the bowel and minimize faecal contamination (Connor et al. 2012). A sedative and possibly an analgesic are usually administered before the procedure. This involves the administration of a benzodiazepine such as midazolam and an opioid such as fentanyl or pethidine which have been prescribed. Doses must be titrated for elderly patients or those with co-morbidities such as cardiac or renal failure. An antispasmodic may also be given. Oxygen therapy should also be administered during sedation. Generally 2 litres per minute is adequate for most circumstances to maintain

oxygen saturation levels and prevent hypoxaemia (BSG 2003, BSG 2007, MacKay et al. 2010, Riley 2008, Swan 2005).

Specific patient preparation

A medical and nursing history and assessment must be undertaken to identify any care needs or concerns that may be significant. In particular, this should cover the patient's current drug therapy, drug reactions or allergies, any organ dysfunctions such as cardiac and/or respiratory disease, and previous or current illnesses. It is also important to be aware of any coagulopathies as samples of tissue or biopsy may need to be taken during the procedure. This can be pre-empted by reviewing blood results prior to the colonoscopy (Chernecky and Berger 2013).

To complete a successful colonoscopy, the bowel must be clean so that the physician can clearly view the colon. Most patients will require a bowel preparation. It is very important that the patient is given clear written instructions for bowel preparation well in advance of the procedure. Without proper preparation, the colonoscopy will not be successful and the test may have to be repeated. The patient must be individually assessed before being supplied the bowel preparation and the potential contraindications considered as below.

Contraindications to bowel preparation

- Gastrointestinal obstruction, perforation, ileus or gastric retention.
- Severe acute inflammatory bowel disease.
- Toxic megacolon.
- A reduction in consciousness level.
- Allergies or hypersensitivity to bowel preparation.
- The inability to swallow.
- Ileostomy (Connor et al. 2012).

The choice of bowel preparation must consider the advantages and disadvantages of each product, the tolerability, efficacy and possible side-effects. If the patient feels nauseated or vomits while taking the bowel preparation, they are advised to wait 30 minutes before drinking more fluid and start with small sips of solution. Some activity such as walking or a few cream crackers may help decrease the nausea (Connor et al. 2012, Smith and Watson 2005, Swan 2005).

Two days prior to the colonoscopy, specific light foods may be eaten, such as steamed white fish, and others avoided, such as high-fibre foods. On the day before the colonoscopy, breakfast from the approved food groups may be eaten while drinking plenty of clear fluids. The period of bowel cleansing generally should not be longer than 24 hours. On the day of the procedure, patients can drink tea/coffee with no milk 4 hours before and water up to 2 hours before. Some patients who are at risk of hypovolaemia and dehydration may need to be admitted to hospital for prehydration (Connor et al. 2012, MacKay et al. 2010, Smith and Watson 2005, Swan 2005).

A set of observations including temperature, pulse, blood pressure, respiration rate and oxygen saturations should also be taken to identify any pre-procedural abnormalities and provide a baseline. If the patient has diabetes, a blood glucose level should also be checked (BSG 2003, BSG 2007, Connor et al. 2012, Smith and Watson 2005).

Post-procedural considerations

Immediate care

Physiological monitoring and care post sedation should be the same as those for gastroscopy. However, larger doses of sedative and opioids may have been used so further observation is required. The patient may feel some cramping or a sensation of having gas, but this quickly passes on eating and drinking. Bloating and distension typically occur for about an hour after the examination until the air is expelled. Unless otherwise instructed,

the patient may immediately resume a normal diet, but it is generally recommended that the patient waits until the day after the procedure to resume normal activities (BSG 2007, MacKay et al. 2010).

Ongoing care

If a biopsy was taken or a polyp was removed, the patient may notice light rectal bleeding for 1–2 days after the procedure; large amounts of bleeding, the passage of clots or abdominal pain should be reported immediately.

Complications

Polypectomy syndrome

When an endoscopic mucosal resection (EMR) or an endoscopic submucosal dissection (ESD) is conducted, a thermal injury to the bowel wall may occur. The patient may present with localized tenderness and pyrexia. Generally conservative management is adequate, but it is essential to monitor their condition as they may go on to develop a perforation (MacKay et al. 2010).

Perforation

During the procedure, the greatest risk or possible complication is bowel perforation; this may be apparent during the procedure but it can present 3–4 days after the procedure. This occurs in 1 in 1000 cases (MacKay et al. 2010, Smith and Watson 2005). If a snare polypectomy was conducted, the incidence of perforation is 0.1–0.3%. The incidence rises to 5% following an EMR (MacKay et al. 2010, Smith and Watson 2005). The nurse monitoring the patient after colonoscopy should be familiar with potential signs and symptoms such as unresolved abdominal pain, rigidity and/or bleeding. If a perforation occurs, surgical intervention is likely to be required (MacKay et al. 2010, Smith and Watson 2005, Suissa et al. 2012).

Haemorrhage

On average, haemorrhage occurs in 3 in 1000 procedures but the incidence and complication rates may be higher where a procedure involves a polypectomy. MacKay et al. (2010) state that the incidence post polypectomy should be <1% and 0.5–6.0% following EMR. The post-procedure monitoring by the nurse again includes observing for signs and symptoms of bleeding (MacKay et al. 2010, Smith and Watson 2005). Depending on the severity of the bleed, it may be managed conservatively or in haemodynamically unstable patients embolization may be required (MacKay et al. 2010, Suissa et al. 2012).

Cystoscopy

Definition

Cystoscopy examines the inside of the urethra and bladder using a cystoscope and is one of the most widely used invasive urological investigations. It gives direct visualization of the urethra and bladder for both males and females but it is especially important in males as the urethra is much more complex (Fillingham and Douglas 2004, Rodgers et al. 2006).

Anatomy and physiology

Urethra

The urethra extends from the external urethral orifice to the bladder (Jenkins and Tortora 2013).

Male urethra

The male urethra is approximately 20 cm long and provides a common pathway for urine, semen and reproductive organ secretions. The three parts of the male urethra are the prostatic urethra, membranous urethra and spongy or penile urethra. Originating at the urethral orifice of the bladder, the prostatic urethra passes through the prostate gland (Figure 10.16). The narrowest

and shortest part of the urethra is the membranous urethra, originating from the prostate gland and extending to the bulb of the penis. The penile urethra ends at the urethral orifice (Jenkins and Tortora 2013).

Female urethra

The female urethra is located behind the symphysis pubis and opens at the external urethral orifice (Figure 10.17). It is approximately 4 cm long (Jenkins and Tortora 2013).

Evidence-based approaches

Rationale

A cystoscopy is undertaken to gain direct visualization of the urethra and the bladder to aid diagnosis of urological complications and diseases such as bladder cancer (Fillingham and Douglas 2004).

Indications

- Bladder dysfunction.
- Unexplained haematuria.
- Diagnosis of bladder cancer.
- Staging of bladder cancer.
- Obstruction or strictures.
- Dysuria.

Contraindications

- Confirmed urinary tract infection.

Pre-procedural considerations

Equipment

A cystoscope may be flexible or rigid. A rigid cystoscope is utilized in the operating theatre where the patient is anaesthetized. The flexible cystoscope can be used in the outpatient setting with local anaesthesia. The flexible cystoscope is useful for patients who require more regular examinations for follow-up after bladder cancer treatment (Fillingham and Douglas 2004).

Specific patient preparation

It is essential that the patient does not have a UTI as the organism responsible for the infection may be spread into the bloodstream during the procedure. If the patient is having a general anaesthetic, they will have to fast prior to the procedure, dependent on anaesthetic instruction. Prior to the procedure, patients undergoing a local anaesthetic can usually eat and drink as normal and should empty their bladder prior to the procedure (Fillingham and Douglas 2004). It may be necessary for some patients to be treated with antibiotics before the procedure to reduce the risk of infection (AUA 2012).

Post-procedural considerations

Immediate care

Dependent on the type of procedure, recovery will vary. After a general anaesthetic, the patient will be recovered by recovery nursing staff. In the outpatient setting, physiological observations may be required. Nursing staff should monitor for signs of haematuria, infection, urinary retention and excessive pain in the abdomen or urethral area. It is also possible that the patient may experience bladder spasms which can be minimized with prescribed analgesics. Oral fluids should be encouraged (Chernecky and Berger 2013).

Ongoing care

It is common for the patient to experience some burning sensations whilst passing urine for a few days. It is advised that the patient drink plenty of water post procedure to flush the bladder and reduce the risk of infection. Any signs of excessive bleeding should be reported to the medical team (Chernecky and Berger 2013, Fillingham and Douglas 2004).

Complications

Infection

There is a risk of urinary infection in approximately 5% of cystoscopies performed. If an infection were to occur, relevant prescribed antimicrobial therapy may be required (Rodgers et al. 2006).

Liver biopsy

Definition

Liver biopsy involves percutaneous puncture using a biopsy needle and removal of a small piece of the liver (Al Knawy and Shiffman 2007).

Anatomy and physiology

The liver is the heaviest organ in the body. It weighs approximately 1.4 kg and is highly vascular. It is incompletely covered by a layer of peritoneum and enclosed in a thin inelastic capsule. There are two main lobes in the liver: the large right lobe and

the smaller left lobe which is wedge shaped. The caudate and quadrate lobes are on the posterior surface and are continuations of the left lobe (Jenkins and Tortora 2013).

Functions of the liver

The liver has many functions including:

- *carbohydrate metabolism* and contributing to maintenance of blood glucose levels
- *lipid metabolism*
- *protein metabolism*: converting ammonia into urea
- *drug and hormone processing*: detoxifying the body
- *activation of vitamin D*
- *excretion of bilirubin*
- *phagocytosis* of some bacteria and aged blood cells
- *storage* of some vitamins, iron, copper and glycogen (Jenkins and Tortora 2013).

584

Evidence-based approaches

Rationale

A liver biopsy is an invaluable tool for diagnosing or monitoring conditions affecting the liver, such as cirrhosis, inflammation or hepatitis of various causes and some metabolic liver disorders. The risks, although small, must be weighed against the potential benefits (Al Knawy and Shiffman 2007, Tannapfel et al. 2012).

Indications

- Diagnosis of cirrhosis.
- Diagnosis of cancer both primary and secondary.
- Miliary tuberculosis.
- Amyloidosis.
- Viral hepatitis for grading, staging and exclusion of co-morbidities.
- Diagnosis of autoimmune diseases affecting the liver.
- Grading and staging of chronic hepatitis B or C.

Contraindications

- An unco-operative or confused patient.
- Severe purpura.
- Coagulation defects.
- Prolonged clotting time.
- Increased bleeding time.
- Severe jaundice.
- Under 3 years of age.
- Current right lower lobe pneumonia.
- Current pleuritis (Al Knawy and Shiffman 2007, Tannapfel et al. 2012).

Methods of liver biopsy

There are a variety of methods for conducting a liver biopsy. A retrospective study by Manolakopoulos et al. (2007) found that the ultrasound-assisted approach was as safe as the ultrasound-guided approach and both obtained adequate samples. The ultrasound-guided technique is considered the standard (Tannapfel et al. 2012).

Percussion palpation approach

This method is also known as the blind approach where the liver is palpated in order to determine the position required for the liver biopsy.

Image-guided approach

Image guidance may be conducted using ultrasound, CT or MRI but the preferred method is ultrasound. The ultrasound method utilizes continuous ultrasound or site marking immediately prior to the procedure (Al Knawy and Shiffman 2007).

Ultrasound-assisted approach

The ultrasound is utilized immediately prior to the procedure and a mark is left on the skin indicating the puncture site. It is also known as the 'X marks the spot' technique. This technique has been shown to yield larger tissue samples, require fewer needle passes and have a decreased biopsy failure rate than the non-ultrasound-assisted approach (Di Teodoro et al. 2013).

Ultrasound-guided approach

The ultrasound is utilized throughout the procedure where the liver and biopsy needle are viewed in real time. This method is simple, reasonably fast, inexpensive and safer than other methods. In 1% of the cases significant complications have been reported with a mortality of 0.1% (Tannapfel et al. 2012).

Transjugular liver biopsy

When the percutaneous approach is contraindicated due to coagulopathy, vascular tumours, ascites or failed percutaneous attempts, the transjugular technique is indicated and is a safer approach (BSG 2004). The biopsy needle is inserted via the hepatic vein and this approach avoids the peritoneum and liver capsule (Keshava et al. 2008).

Pre-procedural considerations

Equipment

Aspiration or suction type needle

There are a few varieties of aspiration or suction type needles such as the Jamshidi, Klatskin and Menghini (Figure 10.18). The Menghini needle has a retaining device to minimize the risk of the sample being aspirated into the syringe and is the most commonly used. It is 6 cm long and approximately 1.4 mm wide.

Cutting type needles

The Tru-Cut and Vim-Silverman needle utilizes a cutting sheath to obtain the specimen. It is advanced approximately 2–3 cm into the liver and a sample of 1–2 cm with a diameter of 1 mm is collected. These needles are associated with a low failure rate but they also have a higher complication rate (Karamshi 2008).

Automated spring-loaded needle biopsy guns

Automated spring-loaded needle biopsy guns automatically trigger and insert the needle. These generally only require one hand to operate, allowing the clinician to use the other hand for visual guidance such as the use of ultrasound (Karamshi 2008).

Pharmacological support

Medications should be reviewed by medical and nursing staff and arrangements made by the medical team for alternative

Figure 10.18 Liver biopsy needles.

anticoagulant and diabetic medication if necessary. A local anaesthetic such as lidocaine 2% is infiltrated into the area where the biopsy is to be taken. In some cases where the patient is extremely anxious, conscious sedation may be considered (Al Knaawy and Shiffman 2007).

Specific patient preparation

Nursing staff should take a nursing history, reviewing social and medical history and determining allergy status. Up to 7 days prior to the procedure, the referring medical team must ensure that a full blood count, clotting screen and biochemistry have been taken. Nursing staff should review bloods as part of their pre-procedure assessment. If a patient is currently taking an anticoagulant such as warfarin, a clotting sample must be taken within 24 hours of the procedure.

A baseline set of physiological observations must be undertaken. If conscious sedation is used, the patient must be nil by mouth and they must have patent intravenous (IV) access (Royal College of Radiologists 2006). The patient is usually in the supine position with the right side as close to the edge of the bed as possible. The left side may be supported by a pillow. The patient's right hand is positioned under their head and their head turned to the left. Oxygen therapy may be required if there are pre-existing conditions or when conscious sedation is used. The patient may be asked to hold their breath at the end of expiration so nursing staff should explain this prior to the procedure (Karamshi 2008).

Post-procedural considerations

Immediate care

Immediately following the procedure, the patient must lie on their right side for 3 hours and remain on bedrest for a total of 6 hours. They may be able to go to the toilet after 3 hours. Physiological observations are required every 15 minutes for the first hour, every 30 minutes for the following 2 hours and then the frequency can be reviewed by the Registered Nurse (Chernecky and Berger 2013, Karamshi 2008). Any abnormality must be reported to the medical team immediately. The nurse should also observe the puncture site and abdomen for signs of bleeding and ensure that pain is adequately controlled. Pain is the most common problem reported by patients which can develop within 3 hours after the procedure, so recording the pain score and analgesia may be required. Severe pain must always be reported to the medical team as it may be an indicator of a bleed or bile leak (Karamshi 2008). The patient may also require emotional care throughout and after the procedure (Karamshi 2008).

Ongoing care/education

A post-procedure information sheet should be given to the patient identifying possible complications and instructions on what to do if any symptoms occur (Royal College of Radiologists 2006).

Complications

Haemorrhage

An inadvertent puncture of an intrahepatic or extrahepatic blood vessel can lead to haemorrhage manifesting within 4 hours. However, it is normal to lose approximately 5–10 mL of blood from the surface of the liver after the biopsy. Conservative management with blood products may be appropriate but surgical intervention may also be required to treat haemorrhage (Chernecky and Berger 2013, Karamshi 2008).

Peritonitis

An inadvertent puncture of the bile duct which consequently results in bile leaking into the peritoneal cavity can lead to peritonitis. Treatment may range from antimicrobial therapy to surgical and/or critical care intervention dependent on the severity (Chernecky and Berger 2013, Karamshi 2008).

Pneumothorax

An inadvertent puncture of the pleura can lead to a pneumothorax. If this occurs, urgent medical intervention is required. A formal chest drain may be necessary to relieve the pneumothorax (Chernecky and Berger 2013, Denzer et al. 2007).

Radiological investigations: X-ray

Definition

An X-ray is a short-wavelength electromagnetic radiation that passes through matter and is used in diagnostic radiology and radiotherapy (Martin 2010).

Evidence-based approaches

Rationale

The general X-ray department performs a wide range of examinations, many of which require no patient preparation in advance and can often be performed on the day of the request. In accordance with the Ionizing Radiation Regulations (1999), to ensure radiation safety, there is a requirement for radiographers to justify, optimize and limit radiation dosage to a patient.

Indications

Diagnostic X-rays are performed to diagnose medical conditions such as damage to the skeletal structures and organ dysfunction, for example chest X-rays for respiratory complications.

Contraindications

The Ionizing Radiation (Medical Exposure) Regulations (2000) (Regulations 6 and 7) prohibit any medical exposure from being carried out which has not been justified and authorized, and provides an optimization process to ensure that doses arising from exposures are kept as low as reasonably practicable (ALARP).

In accordance with the *Medical and Dental Guidance Notes* (2002) for women known or likely to be pregnant, where the examination has been justified on the basis of clinical urgency and involves irradiation of the abdomen, operators must optimize the technique to minimize irradiation of the fetus (IPEM 2002). Radiography of areas remote from the fetus, for example chest, skull or hand, may be carried out safely at any time during pregnancy as long as good beam collimation and proper shielding equipment are used.

Legal and professional issues

The Ionizing Radiation (Medical Exposure) Regulations (2000) set out the legal roles and responsibilities of all duty holders related to medical exposures to X-rays.

In accordance with the Ionizing Radiation (Medical Exposure) Regulations (IR(ME)R) (2000), the completed request form for a medical exposure must be clear and legible and the following information must be supplied.

- Unique patient identification – to include at least three identifiers from name, date of birth, hospital number or NHS number.
- Sufficient details of the clinical problem to allow the IR(ME)R practitioner to justify the medical exposure, and indication of examination thought to be appropriate.
- If applicable, information on the patient's possible pregnancy status.
- Signature uniquely identifying the referrer as it is important that the referrer is qualified to order an X-ray.

Blank request cards, pre-signed by a referrer, are a breach of the Regulations and any entries on the request form made by others

should be checked and initialled by the referrer prior to signing the form.

Competencies

Non-medical 'referrers'

The IR(ME)R (2000) require employers to only accept requests for X-ray or nuclear medicine investigations from approved and authorized 'referrers'. When the referrer is not a trained medical doctor or dentist, the Regulations further require that the referrer has received appropriate information, instruction and training in radiation protection, and the scope and range of investigations for which they are authorized to request must be documented. All 'referrers' must be made aware of the appropriate referral criteria for such investigations as set down by each individual's organization in its IR(ME)R procedures and protocols.

Risk management

Radiation protection is based on the three principles of justification, optimization and limitation. The procedure must be justified and of net benefit to the patient. Optimization ensures that exposure to the patient, staff and public shall be as low as reasonably possible (ALARP). The limitation is essential to ensure that dose equivalent to staff and members of the public does not exceed the dose limits (IR(ME)R 2000).

Pre-procedural considerations

Pharmacological support

For some types of X-ray such as the barium swallow or enema, the patient is usually required to drink the contrast or have it administered via an enema, and a series of X-ray pictures is taken at various intervals. Afterwards the patient will be advised to drink plenty of fluids to clear their system of the contrast as quickly as possible (Chernecky and Berger 2013).

Specific patient preparation

The radiology department will inform the patient of any requirements prior to the booked procedure, such as being nil by mouth. For most examinations, the patient will be asked to remove some of their clothing and change into a hospital gown, to ensure that no artefacts (any feature in an image which misrepresents the object in the field of view) (McRobbie 2007) are caused in the area of clinical interest on the X-ray image. It is advisable for the patient not to wear jewellery at the time of the appointment as in most cases this will have to be removed, again to prevent the presence of artefacts on the image. For all X-rays the patient will be required to keep still to prevent any blurring of the images. Some procedures are performed on inspiration/expirations, and the patient will be given the appropriate breathing instruction by the operator performing the procedure (Chernecky and Berger 2013).

Magnetic resonance imaging

Definition

Magnetic resonance imaging provides cross-sectional images of the body. The patient lies inside the bore of a very strong magnet, typically 1.5 tesla, although 3 tesla scanners are becoming increasingly prevalent. Protons in the body's water molecules spin or 'precess' when exposed to such a strong magnetic field. Radio waves are transmitted into the patient at the same frequency at which the protons are precessing and the patient transmits a signal that is detected by a receiver coil (Chernecky and Berger 2013, Weishaupt et al. 2006). This signal contains specific information or 'weighting' about the individual tissues that can be mapped to form a two- or three-dimensional image (Weishaupt et al. 2006).

Evidence-based approaches

Rationale

Soft tissue structures such as the brain, spinal cord, musculoskeletal system, liver and pelvic structures are particularly well demonstrated using MRI. Although MRI is often targeted to particular areas of the body, it is also possible to scan the whole body with scan times ranging from 20 to 60 minutes. MRI is increasingly being used as a tool in radiotherapy treatment planning (Prestwich et al. 2012) and has begun to be used to guide interventional procedures, e.g. breast biopsies (O'Flynn et al. 2010). MRI does *not* use ionizing radiation and can therefore be used for repeated examinations. The magnetic field is always present so strict safety procedures are necessary to protect staff and patients (Shellock and Spinazzi 2008).

Indications

- Scanning of the brain to assess stroke, tumour, meningeal disease.
- Spinal pathology is particularly well demonstrated, including intervertebral disc pathology, tumour, infarction, spinal dysraphism, infection and degenerative diseases.
- Differentiation and characterization of benign versus malignant pathology in the liver.
- MRI is highly sensitive for imaging of the breast.
- MRI is the gold standard for assessment of pelvic malignancy and pelvic anatomy (Royal College of Radiologists 2012).

Contraindications

Patients with non-MRI-compatible implanted devices, such as cardiac pacemakers and cochlear implants, must not be scanned. Other implanted devices, for example stents, must be confirmed as MR safe prior to scanning.

Magnetic resonance imaging tends not to be used for acute trauma, for which CT is usually the preferred imaging modality, or for primary whole-body staging of malignancies, although a role for whole-body MRI is increasingly being proposed in some areas for non-oncological and oncological diagnostic purposes (Lambregts et al. 2011, Lin et al. 2012).

Pre-procedural considerations

Assessment and recording tools

A pre-MRI checklist is undertaken for all patients to identify risks from implanted devices which may be harmful to the patient or may severely degrade the image quality (Shellock and Spinazzi 2008).

Pharmacological support

The patient may require intravenous access for contrast injection, most often of a gadolinium-based contrast agent. This is used to enhance areas of suspected pathology, to define tumour bulk or to improve the efficacy of the scan by delineation or characterization of a pathological process (Runge et al. 2009). These contrast agents may be contraindicated in patients with poor renal function and therefore recent blood results to demonstrate adequate renal function will usually be required before contrast administration (Baert and Knauth 2009). It is also routine practice in some centres to administer antispasmodic agents prior to abdominal or pelvic scans to reduce bowel peristalsis and improve image quality. Claustrophobia can also be an issue and in some cases patients may require an oral sedative to relax them during the procedure. In severe claustrophobia or when scanning young children or individuals with learning difficulties, general anaesthetic may be necessary.

Non-pharmacological support

The scanner is very noisy so it is mandatory that patients are given ear protection during the scan. If the patient feels claustrophobic there are strategies to manage this, such as:

- adapting the patient's position
- changing the scanning technique

- using blindfolds or mirrors
- relaxation therapy (Chernecky and Berger 2013).

Specific patient preparation

Apart from safety checking, for most scans there is no preparation but for certain body scans the patient may have to abstain from food but may drink clear (non-caffeine) fluids to ensure their bladder does not fill too quickly, resulting in movement artefacts (Chernecky and Berger 2013).

Patients must be able to lie very still, usually lying on their back for significant time periods. Patient comfort is paramount so patients requiring pain relief should continue with pain medication as normal.

Computed tomography

Definition

Computed tomography images are created when radiation passes through a patient and is absorbed in varying degrees by the body tissue. Multislice data are acquired as a three-dimensional block in a matter of seconds and digitally displayed in coronal, sagittal or axial planes (Fishman and Jeffrey 2004).

Evidence-based approaches

Rationale

Multislice CT has excellent image resolution and is used for diagnosis, staging and monitoring treatment response in the oncology setting, as well as being a research tool. Soft tissues as well as bone and lung anatomy are all seen well on CT scans. Routinely patients are given intravenous contrast medium which perfuses the body tissues and enhances the blood vessels and lesions (Husband and Reznick 2010).

Computed tomography does use radiation but protocols are optimized to give the best image with the lowest dose. Also, the number of body areas scanned and the intervals between scans are closely monitored in accordance with IR(ME)R regulations.

Indications

Computed tomography can image all parts of the body and is used for:

- pre-treatment staging
- interval scans to monitor treatment
- follow-up post treatment
- diagnosis and assessment of complications:
 - bowel obstructions and perforation
 - pulmonary embolism
 - stroke, cerebral bleeds
- perfusion CT (Chernecky and Berger 2013).

Contraindications

- Pregnancy: CT is not recommended unless clinical benefit outweighs radiation risk.
- Patients with poor renal function or those having iodine therapy may have CT without intravenous contrast.
- Previous CT within short timeframe unless clinically urgent.
- Patients who are unable to lie down in order to pass through the machine (Royal College of Radiologists 2010).

Pre-procedural considerations

Assessment and recording tools

Patients complete a questionnaire prior to CT in order to assess their suitability for CT and IV contrast. Intravenous contrast contains iodine, so patients with an iodine allergy, an allergy to shellfish or previous history of reaction to IV contrast should have a non-IV contrast CT.

Pharmacological support

The patient is cannulated for the intravenous injection of iodine-based contrast medium to enhance the blood vessels and bodily organs. During the injection it is normal for the patient to transiently feel warm over their whole body and to experience a metallic taste at the back of the throat, and some patients feel nauseous. CT examinations such as CT pulmonary angiograms demand contrast to flow at a fast rate and therefore a large-gauge cannula (20 G) is required. CT-compatible ports and PICCs may also be used (Thomsen et al. 2009).

Non-pharmacological support

Although CT is a fast imaging technique (5–20 seconds), some patients are very concerned about being claustrophobic during scanning but with kind careful explanation, most manage to be scanned.

Specific patient preparation

Patients are prepared for CT by drinking an oral contrast, usually water, which shows the digestive tract. This serves to hydrate the patient which is beneficial post IV contrast and also acts as a negative contrast agent in the digestive tract. Patients refrain from eating for 2 hours prior to CT in order to allow them to drink easily and to reduce nausea post IV contrast medium (Thomsen et al. 2009). IV access must be established prior to the CT scan to facilitate injection of the IV contrast. Radiopaque objects such as jewellery must be removed (Chernecky and Berger 2013).

Patients lie on the CT scan couch and pass through the doughnut-shaped machine. The examination is painless and the majority of patients tolerate the examinations well. Small children require general anaesthetic for CT (Thomsen et al. 2009). Emergency equipment must be available if IV contrast or a general anaesthetic is used (Chernecky and Berger 2013).

Post-procedural considerations

Immediate care

If any monitoring leads were moved prior to the CT, they should be replaced immediately. Some patients may experience side-effects which should be observed for after the administration of a contrast. These may include headache, nausea and vomiting. If an allergic reaction occurs this must be treated and the allergy status of the patient amended. The patient must then be informed that they have had an allergic reaction (Chernecky and Berger 2013).

Overview

The following observations will be discussed: pulse, blood pressure, respiration, peak flow, temperature, urinalysis, blood glucose, central venous pressure and neurological observations. For each observation discussed, we provide a definition, the rationale, legal and professional issues, procedural guidelines and a guide to problem solving.

Observations

Definitions

The term 'observation' refers to the physical assessment of a patient, including assessment of wounds, intravenous therapy, wound drains, pain and vital signs collection and specialized assessments such as neurological observations (Zietz and McCutcheon 2006). 'Vital signs' are traditionally used in the context of the collection of a cluster of physical measures, such as pulse, respiration, temperature and blood pressure, and more recently pulse oximetry.

Evidence-based approaches

Rationale

The taking of patient observations forms a fundamental part of the assessment process. The interpretation of the data from the assessment is vital in determining the level of care a patient requires, providing an intervention or treatment and preventing a patient deteriorating from an otherwise preventable cause (Wheatley 2006) (see Chapter 2: Assessment and discharge).

Indications

Observations are usually undertaken:

- to act as a baseline to help determine the patient's usual range (Bickley and Szilagyi 2009)
- to assist in recognizing if a patient's condition is deteriorating or indeed improving (Kisiel and Perkins 2006).

Principles of care

Adult patients in acute hospital settings should have:

- observations taken when they are admitted or initially assessed (including on transfer to a ward setting from critical care or transfer from one ward to another)
- a clearly documented plan which identifies which observations should be taken and how frequently subsequent observations should be done. This plan should take into consideration:
 - the diagnosis
 - plan for patient's treatment
 - any co-morbidities which may affect their health (NICE 2007a).

All patients in hospital should have their observations taken at least once every 12 hours, unless specified otherwise by senior staff (NICE 2007a).

Methods of measuring, recording and documenting observations

To assist with the identification of critically ill patients and those at risk of deterioration, physiological scoring systems were introduced (DH 2000, Wheatley 2006), referred to as 'track and trigger systems'. Examples include the National Early Warning System (NEWS) (RCP 2012) (Figure 11.1), medical emergency team (MET) scoring and patient-at-risk team (PART) score (DH 2001, Hodgetts et al. 2002). These scoring systems rely on nursing staff performing basic patient observations, that is, respiratory rate, heart rate, blood pressure, temperature and fluid balance (Wheatley 2006) and informing medical staff/critical outreach team of deviations from normal.

Data entry in terms of entering a patient's score can be recorded on:

- a paper medical record system
- a clinical documentation system with 'computers on wheels' workstation, or
- a clinical documentation system with a tablet PC/hand-held device affixed to the vital signs monitor.

Hand-held devices have been reported to contribute to the management of vulnerable patient groups. These devices have been shown to improve accuracy and timeliness in the recording of vital signs when the activity is delegated to non-registered healthcare support workers such as technicians (Wager et al. 2010). Hand-held computer methods have demonstrated speed and accuracy of charting when compared to the traditional pen/paper method where incorrect entries or omissions have been reported to occur (Prytherch et al. 2006).

Early warning systems help ward nurses to improve and focus their recognition of patients who may need further support and monitoring (DH 2000). As there are several track and trigger scoring systems in use, including locally adapted versions, it is important that time is taken to accurately calculate an individual patient's vital sign parameters in relation to the individual tool.

Currently no track and trigger system is validated for use across all diagnoses (Kyriacos et al. 2011). There is concern with the use of NEWS, in the assessment of patients with brain dysfunction, due to the use of 'alert, verbal, pain, unresponsive (AVPU)' components (Teasdale 2012). Within the field of haematology, emphasis is placed on the increase in referrals to critical outreach teams when using a system that has not been modified for a specific patient population (Teasdale 2012). It is also suggested that any track and trigger system should be used as an adjunct to identifying patients developing critical illness (Mulligan 2010). In order to avoid 'alarm fatigue', any early warning system escalation levels should be used in conjunction with clinical judgement and a holistic assessment rather than being relied on as an absolute measure of the patient's condition (Critical Care Stakeholders Forum and National Outreach Forum 2007).

Critical care outreach teams are now available in many hospitals following the recommendation of a review of the critical care services in England (DH 2000). Where such teams exist, they must be informed of any patients who are deteriorating or at risk of deteriorating, so that they can provide support to ward staff, assess the patient and avert critical care admissions (DH 2000).

A tool that assists with structuring and standardizing communication when reporting concern is the Situation-Background-Assessment-Recommendation (SBAR) tool (Figure 11.2). SBAR is an easy-to-remember, concrete mechanism useful for framing any conversation, especially critical ones, requiring a clinician's immediate attention and action. It gives an easy and focused way to set expectations for what will be communicated and how, between members of the team. This is essential for developing teamwork and fostering a culture of patient safety (Woodhall 2008). For an example of how to use the SBAR tool in clinical practice, refer to the Institute for Innovation and Improvement website (2008).

Anticipated patient outcomes

Physiological observations are extremely important in recognizing if a patient's condition is deteriorating or indeed improving (Kisiel and Perkins 2006).

Legal and professional issues

Nurses are accountable and responsible for providing optimum care for their patients. The Nursing and Midwifery Council's (NMC) *The Code* provides the main source of professional accountability for nurses (NMC 2015). It is essential that nursing staff objectively examine the information gathered from

Figure 11.1 NEWS – National Early Warning Scoring System (Royal College of Physicians 2012). In some settings, patients will have an impaired level of consciousness as a consequence of sedation, e.g. following surgical procedures. Thus, the assessment of consciousness level and the necessity to escalate care should be considered in the time-limited context of the appropriateness of the consciousness level in relation to recent sedation. For patients with known hypercapnic respiratory failure due to chronic obstructive pulmonary disease (COPD), recommended British Thoracic Society target saturations of 88–92% should be used. These patients will still ‘score’ if their oxygen saturations are below 92 unless the score is ‘reset’ by a competent clinical decision maker and patient-specific target oxygen saturations are prescribed and documented on the patient’s chart and in the clinical notes. All supplemental oxygen, when administered, must be prescribed. *Reproducing this chart:* please note that this chart must be reproduced in colour, and should not be modified or amended. *Source:* Reproduced with permission from the Royal College of Physicians. assessments and observations, including the patient’s baseline, as well as any information previously recorded (Crouch and Meurier 2005).

For nurses’ own professional accountability and for the achievement of safe, effective and proficient care of the patient, it is essential that nurses are able to discuss (using physiological rationale) the potential reasons for the observations they have recorded (Kisiel and Perkins 2006). Professional accountability demands more than nurses just undertaking observations. It is about nurses being able to interpret them and then to take appropriate action (Kisiel and Perkins 2006).

Observations should be taken by staff who have undergone the appropriate training regarding the procedure, not only so that they are able to perform the procedure correctly and accurately but also, crucially, so they are able to act on and understand the clinical relevance of the results (NICE 2007a). The degree of training should be suitable to the level of care that the practitioner is providing and the equipment they are using (NICE 2007a). However, all staff should have competencies in relation to measuring, monitoring, interpretation and when to respond promptly (NICE 2007a).

Pre-procedural considerations

Equipment

All practitioners need to be aware of the strengths and limitations of the devices they are using and need to have adequate training

on the use of all equipment. They must ensure that the devices are validated, checked, maintained and recalibrated regularly according to the manufacturer’s instructions (NICE 2011a). In addition to this, the device should only be used as the manufacturer intends; the user needs to know how it works normally, be able to use it effectively and safely (MHRA 2006).

Prior to the procedure, check when the device was last serviced. All devices, manual or automated, are only accurate if they are working and used correctly. Most trusts have the devices checked annually and the date documented on the device and staff should check this and report when it is due for servicing (Woodrow 2004).

Pulse (heart rate)

Definition

The pulse is a pressure wave that is transmitted through the arterial tree with each heart beat following the alternating expansion and recoil of arteries during each cardiac cycle (Marieb and Hoehn 2010). A pulse is strongest in the arteries closest to the heart, becomes weaker in the arterioles and disappears in the capillaries altogether (Tortora and Derrickson 2011). A pulse can be palpated in any artery that lies close to the surface of the body. The radial artery at the wrist is easily accessible and therefore the radial pulse is frequently used, but there are several other

clinically important arterial pulse points, such as the carotid, femoral and brachial plexus (Marieb and Hoehn 2010, Tortora and Derrickson 2011) (Figure 11.3).

Anatomy and physiology

In health, the arterial pulse is one of the measurements used to assess the effects of activity, postural changes and emotions on the heart rate. In ill health, the pulse can be used to assess the effects of disease, treatments and response to therapy. Each time the heart beats, it pushes blood through the arteries. The pumping action of the heart causes the walls of the arteries to expand and distend, causing a wave-like sensation which can then be felt as the pulse (Marieb and Hoehn 2010).

The pulse is measured by lightly compressing the artery against firm tissue and counting the number of beats in a minute. The pulse is palpated to note the following:

- rate
- rhythm
- amplitude.

Rate

A person's pulse rate can be influenced by several factors including age, gender, exercise, pyrexia, medications, hypovolaemia, stress, positioning, pathology, hormones and electrolytes (Field 2008, Kozier et al. 2008). The approximate range is illustrated in Table 11.1.

Figure 11.3 Pulse points. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

The pulse may vary depending on posture. For example, the pulse of a healthy man may be around 66 beats per minute when he is lying down; this increases to 70 beats per minute when sitting up and 80 beats per minute when he suddenly stands (Marieb and Hoehn 2010).

The pulse rate of an individual with a healthy heart tends to be relatively constant. However, when blood volume drops suddenly or when the heart has been weakened by disease, the stroke volume declines and cardiac output is maintained only by increasing the rate of the heart beat.

Cardiac output (CO) is the amount of blood pumped out by each ventricle in 1 minute. It is the product of heart rate (HR) and stroke volume (SV). Stroke volume is defined as the volume of

blood pumped out by one ventricle with each beat. Using normal resting values for HR (75 beats/minute) and SV (70 mL/beat), the average adult cardiac output can be calculated:

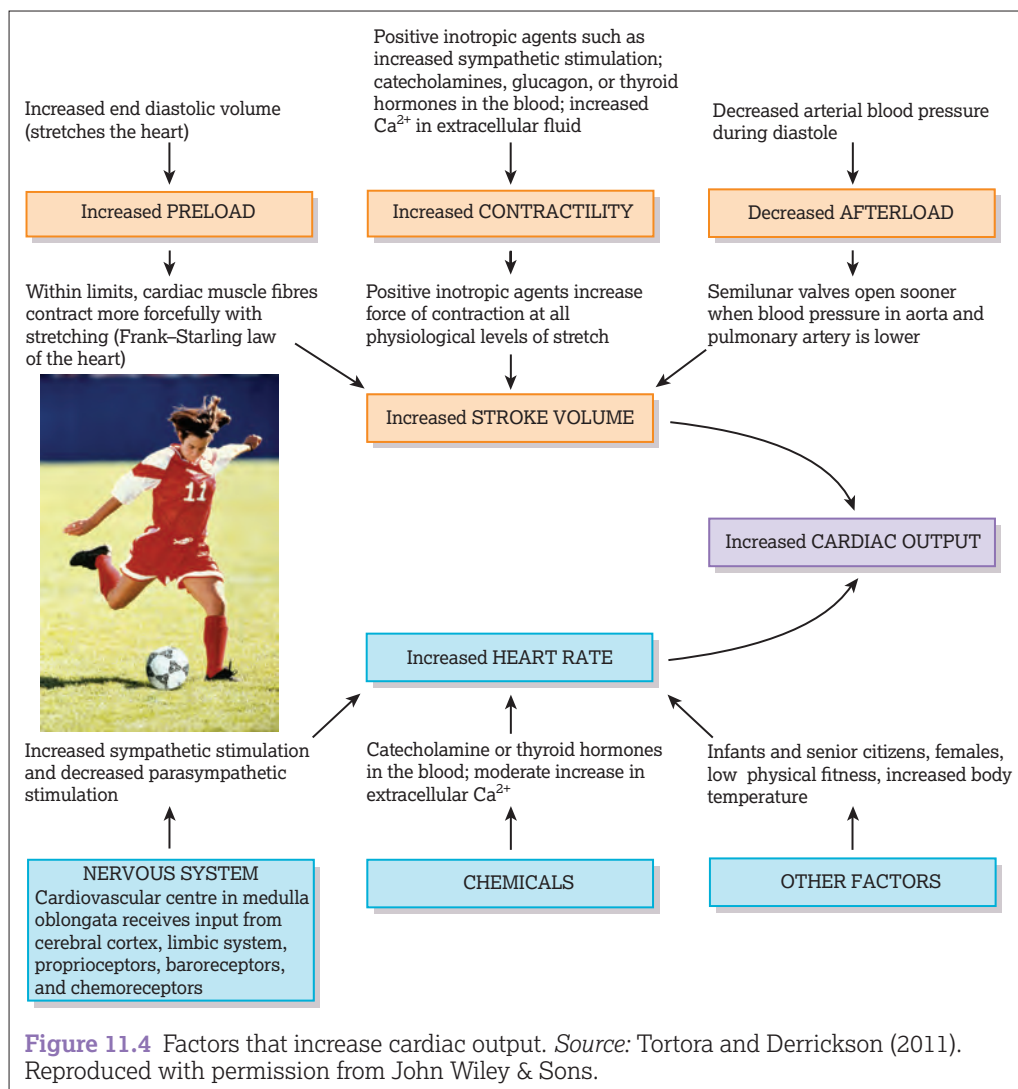

$$\begin{aligned}\text{CO} &= \text{HR} \times \text{SV} = 75 \text{ beats/min} \times 70 \text{ mL/beat} \\ &= 5250 \text{ mL/min} = 5.25 \text{ L/min}\end{aligned}$$

The heart rate and hence pulse rate are influenced by various factors acting through neural, chemical and physically induced homeostatic mechanisms (see Figure 11.4 for factors that increase cardiac output).

- Neural changes in heart rate are caused by activation of the sympathetic nervous system which increases heart rate, while parasympathetic activation decreases heart rate (Patton and Thibodeau 2009).
- Chemical regulation of the heart is affected by hormones (adrenaline and thyroxine) and electrolytes (sodium, potassium and calcium) (Patton and Thibodeau 2009). High or low levels of electrolytes, particularly potassium, magnesium and calcium, can cause an alteration in the heart's rhythm and rate.
- Other factors that influence heart rate are age, sex, exercise and body temperature (Marieb and Hoehn 2010).

Table 11.1 Normal pulse rates per minute at various ages

Age	Approximate range
1 week–3 months	100–160
3 months–2 years	80–150
2–10 years	70–110
10 years–adult	55–90

Tachycardia

This is an abnormally fast heart rate, over 100 beats per minute in adults. It may result from an elevated body temperature, stress, certain drugs or heart disease (Marieb and Hoehn 2010). Persistent tachycardia is considered pathological because tachycardia occasionally promotes fibrillation (Marieb and Hoehn 2010).

Bradycardia

This is a heart rate slower than 60 beats per minute (Marieb and Hoehn 2010). It may be the result of a low body temperature, certain drugs or parasympathetic nervous system activation. It is also found in fit athletes when physical and cardiovascular conditioning occurs (Marieb and Hoehn 2010). This results in hypertrophy of the heart with an increase in its stroke volume, leading to a lower resting heart rate but with the same cardiac output (Marieb and Hoehn 2010). If persistent bradycardia occurs in an individual as a result of ill health, this may result in inadequate blood circulation to body tissues. Bradycardia is often a warning of brain oedema after head trauma (Marieb and Hoehn 2010) and is one of the indications of raised intracranial pressure.

Rhythm

The pulse rhythm is the sequence of beats. In health, these are regular. The co-ordinated action of the muscles of the heart in

producing a regular heart rhythm is due to the ability of cardiac muscle to contract inherently without nervous control (Marieb and Hoehn 2010). The co-ordinated action of the muscles in the heart results from two physiological factors.

- Gap junctions in the cardiac muscles which form interconnections between adjacent cardiac muscles and allow transmission of nervous impulses from cell to cell (Marieb and Hoehn 2010).
- Specialized nerve-like cardiac cells that form the nodal system. These initiate and distribute impulses throughout the heart, so that the heart beats as one unit (Marieb and Hoehn 2010). The nodal system is composed of the sinoatrial node, atrioventricular node, atrioventricular bundle and the Purkinje fibres.

The sinoatrial node is the pacemaker, initiating each wave of contraction. This sets the rhythm for the heart as a whole (Figure 11.5). Its characteristic rhythm is called *sinus rhythm*.

In patients younger than 40 years, irregularity may be linked to breathing, when the heart rate increases on inspiration and decreases on expiration. Although this is rarely noticeable in adults (Higgins 2008a), it is normal and is known as sinus arrhythmia (Woods et al. 2005). Defects in the conduction system of the heart can cause irregular heart rhythms, or arrhythmias, resulting in unco-ordinated contraction of the heart.

Fibrillation

Fibrillation is a condition of rapid and irregular contractions. A fibrillating heart is ineffective as a pump (Marieb and Hoehn 2010).

Atrial fibrillation is a disruption of rhythm in the atrial areas of the heart occurring at extremely rapid and unco-ordinated intervals. The rapid impulses result in the ventricles not being able to respond to every atrial beat and, therefore, the ventricles contract irregularly (Adam and Osborne 2005). The incidence of atrial fibrillation in the general population is approximately 1%, rising to 10% in people aged over 70 years (Goodacre and Irons 2002).

There are many causes of this condition, but the following are the most common:

- ischaemic heart disease
- acute illness
- electrolyte abnormality
- thyrotoxicosis.

Atrial fibrillation can complicate or cause many other medical conditions, including stroke and heart failure (Navas 2003). If poorly managed, patients are at increased risk of arterial thromboembolism and ischaemic stroke (Jevon 2007a). If the patient has a fast ventricular rate, some contractions may not be strong enough to transmit a pulse wave that is detectable at the radial artery. In this instance, checking the radial pulse is an unreliable method of assessing ventricular rate. Simultaneous monitoring of the apex beat and radial pulse is advisable in patients with atrial fibrillation, because it will determine the ventricular rate more reliably and identify whether there is an apex beat–radial pulse deficit (Jevon 2007a).

This procedure requires two nurses and is described in 'Assessing gross pulse irregularity'.

Ventricular fibrillation is an irregular heart rhythm characterized by chaotic contraction of the ventricles at very rapid rates (Adam

and Osborne 2005). Ventricular fibrillation results in cardiac arrest and death if not reversed with defibrillation and the injection of adrenaline. The cause of this condition is often myocardial infarction (MI), electric shock, acidosis, electrolyte disturbances and hypovolaemia (RCUK 2010).

Body fluids are good conductors of electricity so it is possible through electrocardiography to observe how the currents generated are transmitted through the heart. The electrocardiograph provides a graphic representation and record (electrocardiogram [ECG]) of electrical activity as the heart beats – see 'Twelve-lead electrocardiogram (ECG)'. The ECG makes it possible to identify abnormalities in electrical conduction within the heart. Changes in the pattern or timing of the deflection in the ECG may indicate problems with the heart's conduction system, such as those caused by MI (Marieb and Hoehn 2010). For examples of normal and abnormal ECGs, see 'Twelve-lead electrocardiogram (ECG)'.

Amplitude

Amplitude is a reflection of pulse strength and the elasticity of the arterial wall. This varies because of the alternating strong and weak ventricular contractions (Bickley and Szilagyi 2009). The flexibility of the artery of the young adult feels different from the hard artery of the patient suffering from arteriosclerosis. It takes some clinical experience to appreciate the differences in amplitude. However, it is important to be able to recognize major changes such as the faint flickering pulse of the severely hypovolaemic patient or the irregular pulse in cardiac arrhythmias.

Assessing gross pulse irregularity

Paradoxical pulse is a pulse that markedly decreases in amplitude during inspiration. On inspiration, more blood is pooled in the lungs and so decreases the return to the left side of the heart; this affects the consequent stroke volume. A paradoxical pulse is usually regarded as normal, although in conjunction with such features as hypotension and dyspnoea, it may indicate cardiac

tamponade (Bickley and Szilagyi 2009), hypovolaemia, and severe airway obstruction or tension pneumothorax (Wong 2007).

When there is a gross pulse irregularity, a stethoscope may be used to assess the apical heartbeat. This is done by placing the diaphragm of the stethoscope over the apex of the heart and counting the beats for 60 seconds. A second nurse should record the radial pulse at the same time. The deficit between the two should be noted using, for example, different colours on the patient's chart to indicate the apex and radial rates (Docherty 2002).

Evidence-based approaches

Rationale

The pulse is taken for the following reasons.

- To gather information on the heart rate, pattern of beats (rhythm) and amplitude (strength) of pulse.
- To determine the individual's pulse on admission as a base for comparing future measurements.
- To monitor changes in pulse (Marieb and Hoehn 2010).

Indications

Conditions in which a patient's pulse may need careful monitoring are described below.

- Post-operative and critically ill patients require monitoring of the pulse to assess for cardiovascular stability. The patient's pulse should be recorded pre-operatively in order to establish a baseline and to make comparisons. Hypovolaemic shock post surgery from the loss of plasma or whole blood results in a decrease in circulatory blood volume. The resulting acceleration in heart rate causes a tachycardia that can be felt in the pulse. The greater the loss in volume, the threadier the pulse is likely to feel.
- Blood transfusions require careful monitoring of the pulse as an incompatible blood transfusion may lead to a rise in pulse rate early in the transfusion (British Society for Haematology 2009) (see Chapter 7: Nutrition, fluid balance and blood transfusion) as an incompatible blood transfusion may lead to a rise in pulse rate.

- Patients with local or systemic infections or inflammatory reactions require monitoring of their pulse to detect sepsis/severe sepsis. This is characterized by a decrease in the mean arterial pressure (MAP) and a rise in pulse rate (Marieb and Hoehn 2010).
- Patients with cardiovascular conditions require regular assessment of the pulse to monitor their condition and the efficacy of medications.

Methods of pulse measurement

Manual

The pulse is measured by lightly compressing the artery against firm tissue and counting the number of beats in a minute and/or by auscultation the apex of the heart with a stethoscope.

Electronic

Automated electronic equipment such as a pulse oximeter, blood pressure recording devices, 12-lead ECG or continuous cardiac monitoring may be used to determine the pulse. However, even where the patient has continuous ECG monitoring, it is still essential to manually feel for a pulse to determine amplitude and volume and whether the pulse is irregular. In pulseless electrical activity (PEA), normal sinus rhythm is shown on the monitor but a pulse is not palpable (Levine et al. 2008).

Pre-procedural considerations

Equipment

Pulse can be measured by:

- *stethoscope* (apical pulse)
- *electronic pulse measurement* device (pulse oximeter): a small electronic device, consisting of a probe which is placed onto the end of a finger to record pulse rate.

Specific patient preparation

Ideally a patient should be at rest for 20 minutes before trying to obtain an accurate pulse. Strenuous activity will result in falsely elevated readings (Rawlings-Anderson and Hunter 2008).

Procedure guideline 11.1 Pulse measurement

Essential equipment

- A watch that has a second hand
- Alcohol handrub
- Observations chart
- Black pen
- A stethoscope (if counting the apical beat)
- Electronic pulse measurement device, for example pulse oximeter, blood pressure measuring device or cardiac monitor

Pre-procedure

Action

- 1 Wash hands and dry hands.
- 2 Explain and discuss the procedure with the patient.

Rationale

To prevent cross-infection (Fraiese and Bradley 2009, **E**).
To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

Procedure

- 3 Where possible, measure the pulse under the same conditions each time.
- 4 Ensure that the patient is comfortable and relaxed. Ideally the patient should refrain from physical activity for 20 minutes before pulse is measured.

To ensure continuity and consistency in recording (Alexis 2010, **E**).
To ensure that the patient is comfortable. **E**
Strenuous activity will result in falsely elevated readings (Rawlings-Anderson and Hunter 2008, **E**).

- | | |
|--|--|
| 5 Place the first and second or in addition the third finger along the appropriate artery and apply light pressure until the pulse is felt (Action figure 5). | The fingertips are sensitive to touch. Practitioners should be aware that the thumb and forefinger have pulses of their own and therefore these may be mistaken for the patient's pulse (Docherty and Coote 2006, E). |
| 6 Press gently against the peripheral artery being used to record the pulse. | The radial artery is usually used as it is often the most readily accessible (Bickley and Szilagyi 2009, E). |
| 7 If the apical heart rate requires recording, place a stethoscope on the left midclavical, 4th–5th intercostal space on left midclavicular line (typically under the breast area) and listen to the heart beat (Alexis 2010). | The apical heart rate is usually used if someone's heart rate is irregular to give a more accurate count of the pulse, in children, and prior to the initiation of some cardiac medications (Alexis 2010, E). |
| 8 The pulse should be counted for 60 seconds. | Sufficient time is required to detect irregularities in rhythm or volume. If the pulse is regular and of good volume subsequent readings may be taken for 30 seconds and then doubled to give beats per minute. If the rhythm or volume changes on subsequent readings then pulse must be taken for 60 seconds (Rawlings-Anderson and Hunter 2008, E). |
| 9 Record the pulse rate on appropriate documentation. Additional factors such as the rhythm, volume and skin condition (dry, sweaty or clammy) may be described in the patient's nursing notes. | To monitor differences and detect trends; any irregularities should be brought to the attention of the appropriate senior nursing and medical teams (NMC 2010, C). Additional qualitative characteristics of the pulse may aid diagnosis of the patient's condition (Rawlings-Anderson and Hunter 2008, E). |

Post-procedure

- | | |
|---|---|
| 10 Discuss result and any further action with the patient. | To involve the patient in their care and provide assurance of a normal result or explain the actions to be undertaken in the event of an abnormal result. E, P |
| 11 Wash and dry or decontaminate with alcohol handrub hands and/or stethoscope. | To prevent cross-infection (Fraiese and Bradley 2009, E). |

Action Figure 5 Taking a pulse.

Problem-solving table 11.1 Prevention and resolution (Procedure guideline 11.1)

Problem	Cause	Prevention	Action
No pulse palpable.	Incorrect positioning of fingers.	Refer to Figure 11.3 for palpation sites.	Place 2 or 3 fingers over the appropriate artery and lightly depress against the tissue or bone. Try alternative sites such as brachial or carotid artery.
Absent or faint pulse.	Poor perfusion.	Assess patient's existing co-morbidities for further information. Identify any causes of hypovolaemia.	Inform medical team if the patient is cardiovascularly compromised.

(continued)

Problem-solving table 11.1 Prevention and resolution (Procedure guideline 11.1) (continued)

Problem	Cause	Prevention	Action
	Obstruction, for example clot.	Perform a venous thromboembolism (VTE) risk assessment for your patient on admission (NICE 2007b) and ensure appropriate preventive measures in place, for example antiembolism stockings, mechanical devices applying intermittent pneumatic pressure, for example Flowtron, or injections of low molecular weight heparin preparations (Lees and McAuliffe 2010).	Perform a neurovascular assessment, assessing all pulse sites to determine compromised area. Also feel for warmth and sensation and capillary refill to provide further information on the degree of vascular sufficiency.
Pulse too fast and irregular to palpate manually.	Patient may be in an abnormal rhythm.	Haemodynamic assessment, monitoring and maintenance of electrolyte balance.	Use electronic recording device. New-onset tachycardia and irregular rhythms should prompt a full set of observations: BP, respiratory rate, oxygen saturation and temperature. It is essential to perform a 12-lead ECG and have this reviewed by a doctor.

Post-procedural considerations

Documentation

The pulse should be recorded in the patient’s notes on the institution’s approved observation chart. The recording should be dated and timed so that the pulse trend may be viewed easily as part of ongoing patient monitoring.

Twelve-lead electrocardiogram (ECG)

Definition

Electrical activity in the heart can be monitored and amplified with an instrument called an electrocardiogram (Marieb and Hoehn 2010). The ECG provides a graphical representation of the heart’s electrical conduction and myocardial excitation (Marieb and Hoehn 2010).

The 12-lead ECG is a routine clinical examination which can be performed by a range of healthcare professionals (Crawford and Doherty 2008). When used correctly and in the context of the patient’s clinical history, it is a valuable diagnostic tool used to ascertain information about the electrophysiology of the heart (Crawford and Doherty 2008, Marieb and Hoehn 2010). Electrical changes take place as the cardiac muscle contracts and relaxes; the 12-lead ECG records the electrical activity of the heart from 12 viewpoints or ‘leads’ through 10 cables attached to electrodes on the patient’s chest and limbs – note that in this setting ‘leads’ refers to viewpoints rather than the cables or wires that connect the patient to the machine (Jevon 2009). The 12 different views of cardiac electrical activity show the three-dimensional electrical activity occurring in the heart (Woodrow 2009b).

Anatomy and physiology

All myocardial cells are able to spontaneously generate impulses and initiate the cardiac electrical cycle without the need for external stimulation; this is known as automaticity (Docherty 2005). Cardiac conduction normally begins in the sinoatrial (SA) node, located in the wall of the right atrium. This is the heart’s natural pacemaker as it normally initiates impulses at a faster rate than other myocardial cells, generating impulses at a rate of 60–100 beats per minute (Woodrow 2009a). The impulse generated by the SA node spreads through the atrial muscle fibres (depolarization), causing atrial contraction, to the atrioventricular (AV) node.

The AV node acts as a gateway into the ventricular conduction system, delaying impulses for approximately 0.1–0.2 seconds and

creating a short period of electrical standstill before the depolarization spreads through the AV node into the ventricles, allowing the atria to finish contracting before ventricular contraction commences (Woodrow 2009a).

From the AV node, the impulse travels rapidly through specialized conduction tissue in the ventricles, firstly through the bundle of His, along the left and right bundle branches and then more slowly through the mass of ventricular muscle along the Purkinje fibres, resulting in the powerful ventricular contraction (Tortora and Derrickson 2011). The conduction pathway of the heart is shown in Figure 11.5.

The normal ECG waveform depicts five deflections or waves known as P, Q, R, S and T waves (Figure 11.6). The small P wave

Figure 11.6 Normal electrocardiograms or ECG (lead II). P wave = arterial depolarization; QRS complex = onset of ventricular depolarization; T wave = ventricular repolarization. Source: Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

Table 11.2 Precordial electrode anatomical positions

Electrode	Position
V1 (C1)	Fourth intercostal space at the right sternal edge
V2 (C2)	Fourth intercostal space at the left sternal edge
V3 (C3)	Midway between V2 and V4
V4 (C4)	Fifth intercostal space in the midclavicular line
V5 (C5)	Left anterior axillary line at same horizontal level as V4
V6 (C6)	Left midaxillary line at same horizontal level as V4 and V5

Source: Reproduced with permission from SCST (2014).

reflects atrial depolarization, the large QRS reflects the rapid spread of depolarization from the AV node to the Purkinje fibres through the ventricles, and the T wave reflects ventricular repolarization – the return of the ventricular muscle to its resting state. Atrial repolarization is not graphically represented on the ECG as it is hidden in the QRS complex (Sharman 2007).

Evidence-based approaches

The 12 leads

The 12-lead ECG shows 12 views of cardiac electrical activity, recording the impulses generated by the heart by recording the electrical energy from electrodes placed on specific areas of the body (Khan 2004). Six of these views are recorded from the four limb electrodes that use a combination of three electrodes placed on three limbs (right arm, left arm and left leg) along with one neutral electrode placed on the right leg to reduce interference or noise. These three electrodes together create a triangle around the heart, sometimes called Einthoven's triangle (Woodrow 2009b).

Table 11.3 Limb electrode positions

Electrode	Position
Right arm limb lead (RA, red)	Right forearm, proximal to wrist
Left arm limb lead (LA, yellow)	Left forearm, proximal to wrist
Left leg limb lead (LL, green)	Left lower leg, proximal to ankle
Right leg limb lead (RL, black)	Right lower leg, proximal to ankle

Source: Reproduced with permission from SCST (2014).

The other six views are recorded from the six chest electrodes that are placed in a horizontal plane along the chest wall – these are also known as precordial leads (Khan 2004).

- Limb leads (I, II, III, aVR, aVL, aVF)
- Chest (precordial) leads (V1–V6)

Electrode placement

Table 11.2 describes the anatomical location of each chest electrode and Figure 11.7 shows the standard position of the six chest electrodes (SCST 2014). The limb electrodes should be placed just proximally to the wrist and ankle bones unless there is a clinical reason, such as amputation, burns or surgical wounds, which prevents this; ECGs recorded using any other limb position must be clearly labelled as such to account for any changes that might affect interpretation (SCST 2014). It does not matter if the electrode is positioned on the inside or outside of the limb – position the patient comfortably and use the most accessible aspect for electrode placement (Crawford and Doherty 2010). Table 11.3 describes the anatomical location of each limb electrode.

Figure 11.7 Position of chest electrodes for 12-lead ECG. Source: SCST (2014). Reproduced with permission from The Society for Cardiological Science and Technology (www.scst.org.uk/)

The 12 different leads (or viewpoints) look at the heart from different directions. Each lead will record a positive or negative wave depending on which direction the impulse is travelling in relation to the observing lead; a positive wave will be recorded if the impulse is travelling towards the observing lead, a negative wave will be recorded if the impulse is travelling away from the observing lead (Docherty 2003). Correct electrode placement is essential to ensure an accurate ECG recording is obtained. Incorrect electrode placement can lead to morphology changes or alter the amplitude of waves, meaning that ECG changes may be due to artefact rather than physiological abnormalities which may lead to misdiagnosis of apparent abnormalities (Crawford and Doherty 2010).

An alternative positioning of the limb electrodes on the torso, known as the Mason–Likar 12-lead ECG system (Figure 11.8), can however be used in areas where continuous 12-lead ECG monitoring is required, as the waveforms are easily viewed without interference from limb movement (Pelter 2008). However, it should be noted that the QRS complexes are slightly different in amplitude and axis when repositioned on the torso (Drew et al. 2004) and so any deviation from the standard 12-lead electrode placement should be clearly documented on the ECG trace.

In acute clinical areas where continuous cardiac monitoring is required, the three limb electrodes can be placed according to Figure 11.9. The monitor should be set to display lead II as this runs from the right arm to the left foot and so is normally positive, showing the greatest deflection of all the limb leads in a normal heart (Docherty 2002, Khan 2004). The 12-lead ECG is, however, the gold standard for diagnostic purposes and is described in Procedure guideline 11.2: Electrocardiogram.

Rationale

Indications

A 12-lead ECG may be performed electively or to aid diagnosis following any acute deterioration or after any cardiac event such as:

- a baseline prior to surgery or course of medical treatment
- sudden onset of chest pain, shortness of breath
- haemodynamic disturbance
- cardiac rhythm or rate changes
- suspected acute coronary syndrome
- suspected or confirmed myocardial infarction
- cardiac surgery
- percutaneous coronary intervention
- after successful cardiopulmonary resuscitation (Jevon 2010, Woodrow 2009b).

Serial 12-lead ECGs may be required in patients known to have cardiac toxicity, developing myocardial ischaemia or infarction.

Ambulatory ECG monitoring, also known as a 24-hour tape, may be used to record and analyse the patient's heart rhythm during normal daily activities. This is a specialist test and is useful to capture abnormalities that might be missed with a standard 12-lead ECG. Typically the ECG is recorded continuously over a 24–48-hour period (ACC/AHA 2001).

Contraindications

There are no absolute contraindications to performing a 12-lead ECG, but this should not be undertaken in any patient in whom the delay to obtain the ECG would compromise or delay immediate care such as an arrhythmia requiring immediate shock or cardiac arrest (RCUK 2011).

Legal, professional and risk issues

Competencies

Any healthcare professional who has been trained and assessed as competent can perform a 12-lead ECG in line with local hospital policy. However, its analysis and diagnosis are usually undertaken by medical staff or specialist nurses (Sharman 2007).

Pre-procedural considerations

Equipment

- *12-lead ECG machine*: consisting of 10 cables which are connected to electrodes fixed to the body. The machine detects and amplifies the electrical impulses that occur at each heart beat and records the waveforms on to graphed paper, by a stylus, or

Figure 11.9 Three-lead ECG electrode placement.

Figure 11.8 Mason–Likar 12-lead ECG system.

Figure 11.10 ECG calibration verification signal. *Source:* Crawford and Doherty (2010). Reproduced with permission from Mark Allen Publishing Ltd.

on to a computer. All ECG machines should be tested to ensure accurate data are recorded. Calibration is usually undertaken by qualified engineers; however, this should be verified in the clinical setting to confirm that when a voltage of known magnitude (1 mV over 0.2 seconds) is put through the machine, the machine produces an expected deflection (10 mm) and the paper moves at the correct speed (25 mm per second). This calibration verification should be printed at the beginning or end of each line of the ECG as a box shape (Crawford and Doherty 2010, Woodrow 2009b); see Figure 11.10.

- **Electrodes:** the 10 electrodes are attached to the patient's body in the positions described above and in Procedure guideline 11.2: Electrocardiogram. The leads (cables from the ECG machine) clip onto these electrodes and record 12 views of the heart using different combinations of electrodes to measure various signals from the heart.
- **ECG paper:** ECG graph paper is divided into small squares of 1 mm each and five small squares make up a large square. The horizontal axis of the ECG paper represents time and the vertical axis represents amplitude. Standard ECG paper speed is 25 mm per second (mm/s) – each small square equals 0.04 seconds, one large square equals 0.2 seconds and therefore five large squares equal 1 second. ECG machines are calibrated so that the deflection amplitude of cardiac conduction is measured in mm/mV – 10 small squares or two large squares show a deflection of 1 mV (10 mm/mV); see Figure 11.10 (Crawford and Doherty 2010, Khan 2004, Levine et al. 2008).
- **Filter:** filters are electronic devices that remove artefacts from the ECG, improving the tracing obtained. ECG machines have internal pre-programmed filters set by the manufacturer or clinical engineers, which cannot be altered by clinical staff, and control panel filters which can be deployed by clinical staff. Theoretically, if all low-frequency and high-frequency signals were removed, a good-quality ECG would be obtained but the ECG would be of no diagnostic value because the filter distorts the ECG waveforms (Crawford and Doherty 2010). Control panel filters are therefore not recommended for routine use as they distort the waveforms, but they may be required if all other actions to reduce artefact have been unsuccessful (SCST 2014). If the filter is used this must be clearly documented on the ECG.
- **Ambulatory ECG recorder:** a continuous recording of an ECG over a 24–72-hour period, which enables a patient to continue with their daily activities.

All ECG machines should be used and maintained in accordance with the manufacturer's instructions. ECG machines form part of a department's emergency equipment and should always be available in good working order. After use, the ECG machine should be cleaned, returned to its storage location and plugged into a mains electrical supply to charge the internal battery ready for use in an emergency (Metcalf 2000). Any malfunctioning machine should be taken out of clinical use until repair or service can be undertaken by the relevant department, in accordance with local policy. All clinical incidents relating to ECG machines should be reported through the organization's incident reporting system.

Specific patient preparation

Female patients

The conventional placement of the lateral chest leads (V4, V5 and V6) is beneath the left breast, and whilst there is emerging evidence to support the positioning of these electrodes over the breast, it is currently insufficient to suggest a change of procedure (SCST 2014). It is also worth noting that the fifth intercostal space can only be found by lifting the breast and therefore it is logical to position the electrodes here (Crawford and Doherty 2010).

Dextrocardia

Dextrocardia is any situation where the heart is located within the right side of the chest rather than the left. It may be associated with the condition situs inversus where all of the patient's organs are in a mirror image position.

The SCST (2014) suggests the following approach to ECG recording for patients with suspected or known dextrocardia.

- Dextrocardia should be suspected if the ECG shows an inverted P wave in lead I (P-axis $>90^\circ$) together with poor R wave progression across the chest leads. In this case a second ECG should be recorded with the chest electrodes positioned on the right side of the chest using the same intercostal spacing and anatomical landmarks to provide a 'true' ECG representation. The limb lead complexes will continue to appear inverted, demonstrating the abnormal location of the heart, but the repositioned chest leads will now show the appropriate R wave progression. The revised electrode positions should be clearly documented on the ECG and both ECGs should be retained for inclusion in the patient's notes.
- Patients who are known to have dextrocardia should have the ECG recorded with the limb electrodes in the usual position and the chest electrodes placed across the right side of the chest as above. Note that swapping of the right and left limb electrodes will 'normalize' the appearance of the limb leads and when repositioning electrodes, it is imperative that the ECG is clearly annotated to describe the new positions of the electrodes (for example, V3R, V4R, etc.) to prevent the possibility of dextrocardia being overlooked.

Education

The patient must give their consent for the ECG to be performed (NMC 2013) and be adequately prepared for the procedure (Jevon 2010). The procedure should be explained and the patient's privacy and dignity ensured; the rationale for the ECG should be given, explaining that it will be useful to aid diagnosis. Reassurance should be provided, explaining that an ECG is not a painful procedure. The patient should be positioned comfortably either lying or sitting, preferably in a semi-recumbent position (at an angle of 45°) with their head supported (Jevon 2010, SCST 2014). It is important that the patient is relaxed and keeps still during the procedure to reduce interference and artefact and facilitate recording of a clear and stable ECG trace (Jevon 2010, SCST 2014).

Procedure guideline 11.2 Electrocardiogram

Essential equipment

- ECG machine with chest and limb leads labelled respectively, for example LA to left arm, V1 to first chest lead
- Disposable electrodes (check that these are in date and not dry prior to use)
- Alcohol handrub

Pre-procedure

Action	Rationale
1 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and dry.	To minimize the risk of infection (Fraiese and Bradley 2009, E).
2 Explain the procedure to the patient and gain their consent.	To ensure that the patient understands the procedure and is able to give their valid consent (NMC 2013, C ; Roberts 2002, E).
3 Ensure that the patient is comfortably positioned in semi-recumbent position. Any variations to standard recording techniques must be highlighted on the ECG recording (for example 'ECG recorded whilst patient in wheelchair').	To ensure optimal recording and comfort of the patient (Roberts 2002, E). The ECG may vary depending on the patient's position so it is important to note this on the ECG (SCST 2014, C).
4 Clean limb and chest electrode sites. If necessary, prepare skin by cleaning with soap and water or clipping hairs.	To ensure good grip and therefore good contact between skin and electrode – this results in less electrical artefact (Roberts 2002, E ; SCST 2014, C). Shaving should be avoided due to the risk of infection if the skin is grazed (Sharman 2007, E) or bleeding if the patient is on anticoagulation therapy (Pelter 2008, E).

Procedure

5 Apply the limb and chest electrodes as described in Tables 11.2 and 11.3 and Figure 11.7. For advice on placement in females and known cardiac abnormalities see 'Specific patient preparation'.	To obtain a three-dimensional view of the electrical activity of the heart (Woodrow 2009b, E). Following a standard arrangement ensures consistency between recordings and prevents invalid recordings and misdiagnosis (SCST 2014, C).
6 Attach the cables from the ECG machine to the electrodes, checking that the cables are connected correctly and to the relevant electrode.	To obtain the ECG recording (Roberts 2002, E). To ensure the correct polarity in the ECG recording (Roberts 2002, E).
7 Ensure that the cables are not pulling on the electrodes or lying over each other. Offer the patient a gown or sheet to place over their exposed chest.	To reduce electrical artefact and to obtain a clear ECG recording (Roberts 2002, E). To ensure patient dignity and reduce shivering (SCST 2014, C).
8 Ask patient to relax and refrain from movement.	To obtain the optimal recording by the reduction of artefact from muscular movement (Jevon 2010, E ; SCST 2014, C).
9 Encourage the patient to breathe normally and not to speak while the recording is being taken.	Speaking can alter the recording (Roberts 2002, E).
10 Switch the machine on and enter the patient's details into the machine.	To ensure that it is clear which patient the ECG was taken from (NMC 2010, C).
11 Check that the machine is functioning correctly and that calibration is 10 mm/mV.	To ensure standard recording to aid interpretation (Crawford and Doherty 2010, E ; SCST 2014, C).
12 Commence the recording.	To obtain ECG, E
13 In the case of artefact or poor recording, check electrodes and connections.	To ensure optimal recording (Jevon 2010, E).
14 During the procedure give reassurance to the patient.	To ensure the patient is informed and reassured (Roberts 2002, E).
15 Detach the ECG print-out and ensure the recording is labelled with the patient's name, hospital number, date and time. Also include any diagnostic information (i.e. if the patient has chest pain during the recording) and deviations to the standard electrode placement.	To ensure that the ECG forms part of the correct patient's medical record (NMC 2010, C). To help with diagnosis and interpretation (Jevon 2010, E ; SCST 2014, C).
16 If the ECG is irregular or abnormal, record a 10-second rhythm strip, usually from lead II.	To assist with interpretation if there have been any acute rhythm disturbances (SCST 2014, C).

Post-procedure

17	Inform patient that the procedure is completed and help to remove the electrodes.	To ensure that the patient can relax and that the electrodes are removed to prevent them drying out and causing any skin irritation. E
18	Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and dry.	To minimize the risk of infection (Fraiese and Bradley 2009, E).
19	Inform relevant nursing and medical staff that the ECG has been completed – show the recording to the person who will analyse the recording.	To enable relevant nursing and medical staff to use the ECG data in their care planning and treatment (NMC 2010, C).
20	File the ECG recording in the appropriate documentation.	To ensure appropriate record keeping and aid continuity of care (NMC 2010, C).
21	Clean the ECG machine in accordance with manufacturer's recommendations. Return it to its storage place and plug it in to mains electricity to keep the battery fully charged.	The ECG machine forms part of a department's emergency equipment and should always be available and in good working order with a charged battery for use in an emergency (Metcalf 2000, E).

Problem-solving table 11.2 Prevention and resolution (Procedure guideline 11.2)

Problem	Cause	Prevention	Action
Unable to turn on the ECG machine.	Low battery.	Ensure the ECG is left on continuous charge when not in use.	Connect to mains electricity – the ECG will function once it is connected to a power supply.
ECG machine is working but the rhythm display is blank.	Loose connection.	Carefully store the cables after use to prevent damage.	Check that each lead is connected to the electrode clip and that the base of the cable is connected to the ECG machine.
	Electrode stickers peel off from the patient's skin.	The patient may have used body lotion or the skin may be clammy, making adhesion difficult.	Cleanse the electrode sites with soap and water to remove the lotion or reduce skin moisture and allow to dry. Reapply new electrode stickers.
		The patient may have a lot of chest hair which makes adhesion difficult.	If the patient has a lot of chest hair, try to push the hair out of the way when applying stickers to make a better contact; reinforcement with tape may be required. If this is unsuccessful, ask the patient for permission to clip the hair at the electrode sites, cleanse to remove loose hair, allow to dry and apply new electrode stickers.
	The electrode stickers may be intact but there is still no rhythm – the patient's skin may be excessively dry and flaky.	Identify underlying causes and severity of dry skin and address them with the multidisciplinary team as appropriate.	With the patient's consent, perform vigorous but gentle rubbing with soap and water to remove the superficial dead skin cells. The skin should be allowed to dry and new electrode stickers applied.
ECG is printing but some of the views are missing.	A loose connection.	Good skin preparation and maintenance of the ECG machine.	Check that the electrode sticker is intact and follow above suggestions for skin preparation. Check that the cables are all securely connected.
ECG is printing but there is interference, making it difficult to interpret safely.	Patient movement.	Ask the patient to remain still and not to speak, but to breathe normally.	Ensure the patient is not moving or talking and repeat the ECG once the displayed rhythm has stabilized.
		The patient may be cold and therefore involuntarily shivering.	Once the electrodes are connected, place a gown, sheet or blanket over the patient to warm them.
	Peripheral interference.	As above – ask the patient to remain still and ensure they are warm.	Place the limb electrodes more centrally as shown in the Mason–Likar placement (see Figure 11.8) to reduce interference from limb movement.

(continued)

Problem-solving table 11.2 Prevention and resolution (Procedure guideline 11.2) (continued)

Problem	Cause	Prevention	Action
	General interference/ wandering baseline.	Poor skin contact with the electrodes, poor electrode placement or thoracic movement (Metcalfe 2000).	Ensure good skin preparation. Ask the patient to lie still and breathe normally. Check that the electrodes are properly placed. If necessary, record an additional ECG with the 'filter' function on to limit interference. Write on the ECG that the 'filter' function was used.
		Electrical interference from nearby devices (such as infusion pumps, other monitoring devices or haemodialysis machines).	It may be necessary to temporarily remove or suspend electrical devices if safe and appropriate to do so – repeat the ECG once the displayed rhythm has stabilized. If necessary, record an additional ECG with the 'filter' function on to limit interference. Write on the ECG that the 'filter' function was used.
ECG is working and displays a rhythm but the print-out is blank.	Different manufacturer's ECG paper has been loaded.	Only use the manufacturer's recommended paper for the ECG machine.	Reload using the correct paper and repeat the recording.
	Internal fault.	Ensure manufacturer's recommendations on maintenance and servicing are followed.	Contact in-house engineer, medical device technician or manufacturer for advice in accordance with local policy.

Post-procedural considerations

Immediate care

Any changes on the ECG that might require urgent medical attention should be identified and advice sought from a senior member of nursing or medical staff. If the patient had any cardiac symptoms at the time of recording, such as chest pain or palpitations, this should be noted on the tracing and brought to the immediate attention of a senior member of nursing or medical staff (SCST 2014). Examples of a normal 12-lead ECG and some important abnormal ECG tracings are shown in Figure 11.11 and Figure 11.12.

Documentation

It is good practice for the reviewer, who may be a doctor or senior nurse, to document their interpretation of the ECG directly on to the ECG and to sign and date it. Once reviewed, the ECG should

be filed in the patient's medical notes. Nurses should document in the nursing notes when the ECG was recorded, who was asked to review it and the actual time the ECG was reviewed and indicate whether it was normal or, if abnormal, what further action was taken.

Blood pressure

Definition

Blood pressure may be defined as the force of blood inside the blood vessels against the vessel walls (Marieb and Hoehn 2010). Systolic pressure is the peak pressure of the left ventricle contracting and blood entering the aorta, causing it to stretch and therefore in part reflects the function of the left ventricle (Marieb and Hoehn 2010). Diastolic pressure is when the aortic valve

Figure 11.11 Normal 12-lead ECG. Source: Davey (2008). Reproduced with permission from John Wiley & Sons.

Figure 11.12 Abnormal ECG tracings. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

closes, blood flows from the aorta into the smaller vessels and the aorta recoils back. This is when the aortic pressure is at its lowest and tends to reflect the resistance of the blood vessels (Marieb and Hoehn 2010).

Related theory

Blood pressure is determined by cardiac output and vascular resistance and can be described as (Woodrow 2004):

$$\text{BP (Blood pressure)} = \frac{\text{CO (Cardiac output)}}{\text{SVR (Systemic vascular resistance)}}$$

Cardiac output is the volume of blood which flows out of the heart over a specified length of time (Marieb and Hoehn 2010). It is governed by the stroke volume of the heart (the amount of blood pumped out of the ventricles per beat) and the heart rate. The relationship is (Patton and Thibodeau 2009):

$$\text{CO (Cardiac output)} = \text{SV (Stroke volume)} \times \text{HR (Heart rate)}$$

Therefore, if the two equations are combined, blood pressure could be seen as being (Woodrow 2004):

$$\text{BP} = \text{SV} \times \text{HR} \times \text{SVR}$$

In theory, anything which alters one of the above components (stroke volume, heart rate or resistance) will therefore produce a change in blood pressure. However, this is not always the case as a drop in one may be compensated for by an increase in the other (Patton and Thibodeau 2009).

Normal blood pressure

Normal blood pressure ranges between 110–140 mmHg systolic and 70–80 mmHg diastolic at rest (Marieb and Hoehn 2010).

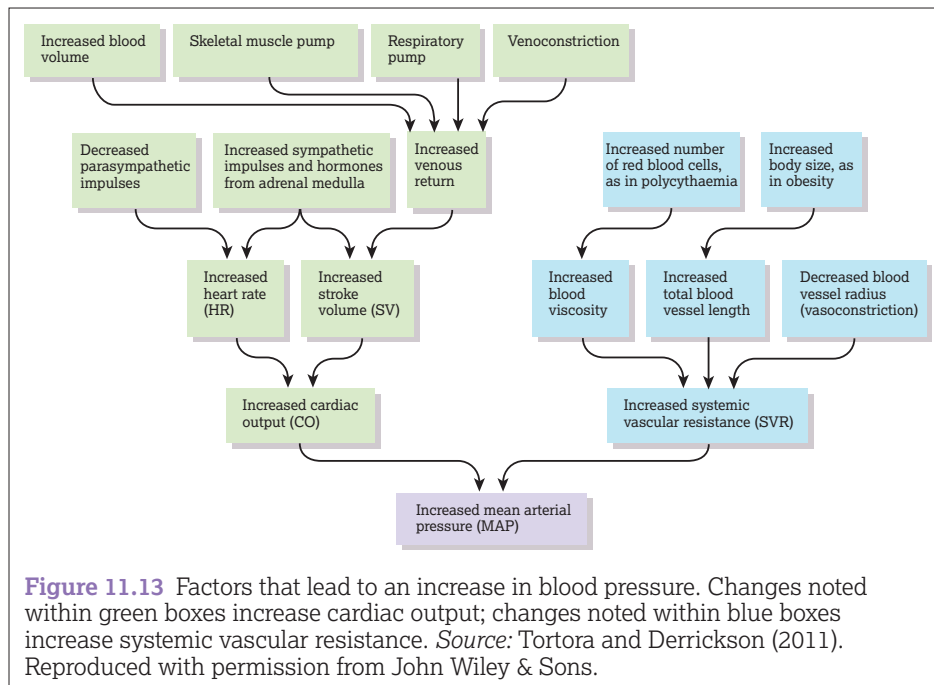

However, it varies depending on age (increasing with age), activity and sleep, emotion and positioning, physical condition and fitness (Levick 2010, Tortora and Derrickson 2011). It also varies depending on the time of day, being at its lowest while we sleep (Levick 2010). Blood pressure therefore reflects individual variations but an abnormal blood pressure should not be assumed to be the individual's norm; rather, it will need to be assessed in relation to their previous results, general condition and other observations.

Hypotension

Hypotension is generally defined in adults as a systolic blood pressure below 100 mmHg (Marieb and Hoehn 2010). A low blood pressure may indicate orthostatic hypotension, that is, sudden drop in blood pressure when the patient rises from a supine or sitting position. This is usually compensated for by the baroreceptor reflex and the sympathetic nervous system but, especially in older people, this may not work as efficiently (Marieb and Hoehn 2010). Hypotension can also be a symptom of many other conditions including shock, haemorrhage and malnutrition (Marieb and Hoehn 2010). Hypotension results in reduced tissue perfusion leading to hypoxia and an accumulation of waste products (Foxall 2009).

Hypertension

Hypertension is defined as blood pressure of 140/90 mmHg or greater. It can also be defined as a subsequent ambulatory blood pressure monitoring (ABPM) daytime average or home blood pressure monitoring (HBPM) average blood pressure of 135/85 mmHg or higher (NICE 2011b, Patton and Thibodeau 2009). It can be either *primary* hypertension, with no single known cause, or *secondary* hypertension related to another factor such as kidney disease (Patton and Thibodeau 2009). Factors leading to hypertension include gender, genetic factors and age, alongside risk factors such as obesity, lack of exercise, smoking and high caffeine and alcohol intake (Patton and Thibodeau 2009). If hypertension is sustained, the heart will have an increased workload

to maintain circulation; greater stress will be placed on the blood vessel walls and cardiac ischaemia can occur (Foxall 2009, NICE 2011a). There are many illnesses and factors which can lead to changes in blood pressure (Figure 11.13) and hypertension is one of the most important preventable causes of premature morbidity and mortality in the UK (NICE 2011a).

Mean arterial pressure

The MAP indicates the average pressure of blood throughout the pulse cycle and thus is a reliable indication of perfusion (Woodrow 2004). Mathematically, the MAP is derived from the diastolic pressure and the pulse pressure (which is the difference between systolic and diastolic blood pressure). The equation is (Marieb and Hoehn 2010):

$$\text{MAP} = \text{diastolic pressure} + (\text{pulse pressure}/3)$$

Therefore, a patient with a blood pressure of 123/90 mmHg has a MAP of 101 mmHg. An adequate MAP is usually deemed to be between 65 mmHg (Hinds and Watson 2009) and 70 mmHg (Woodrow 2004).

Resistance

Resistance is effectively opposition to blood flow (Marieb and Hoehn 2010) and is created by friction between the walls of blood vessels and the blood itself (Patton and Thibodeau 2009). It is termed peripheral or systemic resistance because most of the resistance occurs in the vessels away from the heart (Marieb and Hoehn 2010). Peripheral resistance varies depending on the degree of vasoconstriction or vasodilation and the viscosity of blood and the length of the vessels, although the latter two factors generally remain relatively static (Marieb and Hoehn 2010). Arterioles can dilate or contract; when contracted, peripheral resistance increases and blood flow to the tissues decreases, increasing the arterial blood pressure (Patton and Thibodeau 2009). This can occur systemically, when there is total peripheral resistance, or locally (Patton and Thibodeau 2009). Blood pressure in the vessels of the cardiovascular system can be seen in Figure 11.14.

Blood pressure control

There are many inter-related physiological mechanisms which control blood pressure.

Hormonal control

Many hormones help to regulate blood pressure, including adrenaline and noradrenaline which are released from the adrenal medullae in response to a drop in blood pressure; these hormones increase cardiac contractility and thus cardiac output (Foxall 2009). Atrial natriuretic peptide (ANP) is a hormone which is produced from the atria of the heart in response to hypertension. It works by inhibiting the renin-angiotensin system, raising the glomerular filtration rate by causing specific vasodilation, inhibiting sodium reabsorption and causing fluid transfer into the interstitial space (Levick 2010).

Figure 11.14 Blood pressure in various parts of the cardiovascular system. The dashed line is the mean (average) blood pressure in the aorta, arteries and arterioles. *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Neural control

When blood pressure increases, the baroreceptors, or stretch receptors, are stimulated and in turn stimulate the cardiac inhibitory centre, reducing sympathetic nerve impulses and increasing parasympathetic nerve impulses (Foxall 2009). This causes a vasodilation and a decrease in cardiac output, thereby reducing the blood pressure (Foxall 2009). When blood pressure is low the opposite occurs. This response is termed a reflex arc, continually maintaining homeostasis (Marieb and Hoehn 2010). Baroreceptors are located in the aortic arch, carotid sinuses and in the walls of most of the large arteries in the thorax and neck (Marieb and Hoehn 2010). Close to these are chemoreceptors which are stimulated when the pH of the blood drops or when the carbon dioxide rises, and when oxygen levels drop significantly, these cause an increase in cardiac output and vasoconstriction, leading to an increase in blood pressure (Marieb and Hoehn 2010).

Renal control

When there is a decrease in blood pressure, adrenaline, increased sympathetic activity and a reduction in the stimulation of stretch receptors stimulate the juxtaglomerular cells within the kidneys to release renin (Levick 2010). This causes angiotensin I to be produced, leading to the production of angiotensin-converting enzyme which converts angiotensin I to angiotensin II (Patton and Thibodeau 2009). Angiotensin II has a potent effect on blood pressure, causing cardiac output and vasoconstriction to increase, stimulating the production of aldosterone and antidiuretic hormone which leads to the reabsorption of water and sodium and stimulates the thirst receptors (Foxall 2009). This increases the circulatory volume of fluid and thereby blood pressure (Foxall 2009). Similarly, the reverse happens when fluid volume in the circulatory system is high.

Other mechanisms which influence blood pressure

Skeletal muscle contractions and respiration promote venous return of blood to the heart and therefore increase cardiac output. The skeletal muscles contract on movement, compressing the veins and pushing the blood towards the heart, and respiration causes a change in thoracic and abdominal pressure which acts to pump venous blood (Patton and Thibodeau 2009). A factor which affects stroke volume is Starling's Law of the heart which states that the force of the contraction of the heart is related to how much blood volume is in the heart (Patton and Thibodeau 2009). The more stretched the muscle fibres are prior to contraction, the stronger the contraction and the greater volume it will pump (Foxall 2009).

Patient positioning can also influence a patient's blood pressure measurement (Cicolini et al. 2010, Eser et al. 2007, Mourad et al. 2003, Netea et al. 2003). It is recommended to measure the blood pressure where possible in the supine or seated position with uncrossed legs, with the back and arms supported, in order to ensure that the middle of the cuff on the upper arm is at the level of the right atrium (the midpoint of the sternum) (Adiyaman et al. 2006).

It is also suggested that a patient's knowledge of their own 'goal blood pressure' is independently associated with improved blood pressure control and any interventions to improve knowledge of specific blood pressure targets may have an important role in optimizing blood pressure management (Wright-Nunes et al. 2012).

Evidence-based approaches

Rationale

Indications

Blood pressure measurements should be taken as follows.

- On admission to a ward, in A&E departments when a decision to admit has been made (NICE 2007a).
- When a patient is transferred to a ward setting from intensive or high-dependency care (NICE 2007a).

- At least once every 12 hours while in hospital (NICE 2007a).
- For patients at risk of, or with known, infections (Chalmers et al. 2008).
- To assess response to interventions to correct the patient's blood pressure (Curran 2009, NICE 2011a).
- On patients pre-operatively, to establish a baseline, and post-operatively to assess cardiovascular stability.
- Critically or acutely ill patients, or those who are at risk of rapid deterioration, will require close and potentially continuous monitoring.
- Patients who are being transfused blood or blood products, to establish a baseline, during and after the transfusion (McClelland 2007).
- Any patient showing any signs of shock should have frequent monitoring.
- Any patient who is receiving medications which could alter their blood pressure, such as epidurals or anaesthetics.

Contraindications

There are times when certain methods of blood pressure measurement should be used with caution.

- Oscillometric blood pressure devices may not be accurate in those with weak or thready pulse or patients with pre-eclampsia (MHRA 2005).
- The brachial artery should not be used to measure blood pressure in those with arteriovenous fistulas (Turner et al. 2008).
- Patients with atrial fibrillation should have auscultatory blood pressure measurements taken, rather than oscillometric, and may require multiple readings (Williams et al. 2004).
- Korotkoff sounds are not dependably audible in children under the age of 1 year, and many children under 5 years (Curran 2009). Therefore, ultrasound, Doppler or oscillometric devices are recommended (O'Brien et al. 2003).
- Patients who have had trauma to the upper arm, previous mastectomy or a forearm amputation should not have blood pressure measured on the affected side at the brachial artery (Turner et al. 2008).
- Oscillometric devices should be used with caution in those with atherosclerosis and/or high or low blood pressures, as they may not measure accurately (Bern et al. 2007).
- The manufacturer's guidance should be sought for contraindications specific to the device used.
- Blood pressure should not be measured on an arm that has had brachial artery surgery or is at risk of lymphoedema (Bickley and Szilagyi 2009).

Methods of measuring blood pressure

There are two main methods of measuring blood pressure – direct and indirect.

Direct

The direct method enables continuous monitoring of the blood pressure and so is commonly used for critically ill patients, for example in intensive care units and theatres (Woodrow 2004). To do this, a cannula is inserted into an artery, most commonly the radial artery, as it is easy to access and monitor (Foxall 2009). The cannula has a transducer attached to it and is attached at the external end to a cardiac monitor where the blood pressure is shown as a waveform; it is also attached to a pressurized flush of solution to prevent blood backflow (Foxall 2009). This method has potential risks of severe haemorrhage, thrombosis and air embolism (Foxall 2009); therefore, it must only be used where patients can be continuously observed (Woodrow 2004).

Indirect

For indirect blood pressure measurement, either manual auscultatory sphygmomanometers or automated oscillometric devices are used (Bern et al. 2007). Oscillometric devices electronically measure blood pressure by measuring the oscillation of air pressure

Box 11.1 Korotkoff sounds

The sounds heard are called the Korotkoff sounds and have five phases.

- 1 The first phase is the clear tapping, repetitive sounds which increase in intensity and indicate the systolic pressure.
 - 2 The second phase is murmuring or swishing sounds heard between systolic and diastolic pressures.
- Some people may have an auscultatory gap – a disappearance of sounds between the second and third phases.
- 3 The third phase is sharper and crisper sounds.
 - 4 The fourth phase is the distinct muffling of sounds which may sound soft and blowing.
 - 5 The fifth phase is silence as the cuff pressure drops below the diastolic blood pressure. This disappearance is considered to be the diastolic blood pressure.

Source: NICE (2011a), O'Brien et al. (2003).

614

in the cuff, so when the artery begins to pulse it causes a corresponding oscillation of cuff pressure (Levick 2010). Manual auscultatory blood pressure involves occluding the artery by use of a pressurized cuff and then gradually releasing the pressure; when the systolic blood pressure exceeds cuff pressure, blood re-enters the arteries briefly, during systole, enabling a pulse to be palpated and producing vibrations in the artery (Levick 2010). As the cuff pressure descends, the sounds cease as the artery remains open throughout the pulse wave (Kacmarek et al. 2005).

Systolic blood pressure is usually defined as being at stage 1 of the Korotkoff sounds and diastolic at stage 5 (Curran 2009, Marieb and Hoehn 2010, NICE 2011b, Patton and Thibodeau 2009). See Box 11.1 for the Korotkoff sounds and the five phases. However, in some patients the Korotkoff sounds may continue until the cuff is completely deflated; in such cases stage 4 will represent the diastolic blood pressure (Williams et al. 2004). The auscultatory gap represents silence between the Korotkoff sounds and may sometimes be present; it is often associated with arterial stiffness, and it is vital not to mistake this for the actual blood pressure (Bickley and Szilagyi 2009). See Figure 11.15 for the Korotkoff sounds.

Figure 11.15 Korotkoff sounds.

Alternative sites/methods**Blood pressure measurement at the thigh**

In some patients brachial artery blood pressure measurement is inappropriate; therefore, alternative sites have to be considered. To measure the blood pressure in the thigh, the patient should be prone with the BP bladder centred over the posterior popliteal artery and the stethoscope placed over the artery below the cuff (Bickley and Szilagyi 2009). When the appropriate sized cuffs are used, they should give an equal pressure to that in the arm (Bickley and Szilagyi 2009).

Measurement of orthostatic blood pressure

Orthostatic blood pressure measurement may be indicated if the patient has a history of dizziness or syncope on changing position (Lahrman et al. 2006). The patient needs to rest on a bed in the supine position for 10 minutes prior to the initial blood pressure measurement being taken, and then they should stand upright and have their blood pressure taken again within 3 minutes (Bickley and Szilagyi 2009). While in the standing position, the practitioner should support the patient's arm at the elbow, to maintain it at the correct level and ensure accuracy (O'Brien et al. 2003). Orthostatic (postural) hypotension is defined by a drop in arterial BP of at least 20 mmHg for systolic BP and 10 mmHg for diastolic BP after standing (Tyberghein et al. 2013).

Pre-procedural considerations**Equipment****Sphygmomanometers**

The device used to measure blood pressure is called a sphygmomanometer. It consists of a rubber cuff connected to a rubber bulb that is used to inflate the cuff and a meter that registers the pressure in the cuff (Tortora and Derrickson 2011). Sphygmomanometers which are uncalibrated or not working accurately are a cause of potential blood pressure measurement error (Curran 2009). If using a manual sphygmomanometer, check that the dial is set at zero or the mercury level is at zero prior to commencing (O'Brien et al. 2003). In addition, follow the manufacturer's recommendations and local policies regarding servicing and care of the device.

Manual mercury sphygmomanometers have gradually been phased out of mainstream clinical practice and replaced with a dial or electronic manometer (MHRA 2012). This is primarily due to potential mercury leaks which are hazardous to both the environment and humans and secondly because from April 2009 they were no longer available to either members of the public or healthcare professionals (MHRA 2012).

Manual aneroid sphygmomanometers

Aneroid sphygmomanometers measure blood pressure through a lever and bellows system which is more complex than the mercury sphygmomanometer. However, if it is damaged it may become inaccurate (O'Brien et al. 2003). If aneroid sphygmomanometers have a dial gauge then there is a risk of damage with significant errors occurring with the calibration and setting of zero (MHRA 2005). As a result, O'Brien et al. (2003) recommend that these devices are serviced every 6 months to ensure accuracy.

Automated oscillometric sphygmomanometers

These devices show blood pressure on an electronic display (MHRA 2005). Some studies have found that the results differ between automated and manual blood pressure devices (Bern et al. 2007). Indeed, there are concerns that there is a greater need for validation of the devices so it is recommended that only devices that have passed recognized validation criteria should be used (BHS 2006, MHRA 2005, Stergiou et al. 2010, Williams et al.

2004). If levels of accuracy and reliability can be achieved then they do have certain advantages:

- many devices combine blood pressure with other observations (O'Brien et al. 2003)
- a print-out can be obtained, reducing the risk of bias (O'Brien et al. 2003)
- the preference of terminal digits (0 or 5) should be eradicated (O'Brien et al. 2003)
- data can be stored on the device (O'Brien et al. 2003)
- they enable the setting of alarms (MHRA 2005).

Practitioners must refer to the manufacturer's instructions and be aware of the limitations of the device. If there is any doubt about a measurement then it should be verified by an accurate manual blood pressure reading. Patients who have arrhythmias, hypotension or hypertension or are acutely unwell should have a manual blood pressure taken rather than an automated one (NICE 2011b).

The cuff

The cuff is made of an inelastic material, which encloses an inflatable bladder and encircles the arm. It is important that the correct cuff size is selected for the individual patient (Veiga et al. 2009). Cuffs that are too small yield a reading that is falsely high and large cuffs give a falsely low reading (Williams et al. 2004). With the correct size cuff the bladder should encircle 80% of the patient's arm (Williams et al. 2004). Please see Table 11.4 for guidance on blood pressure cuff sizes.

Alternative adult cuffs (width × length, 12 × 35 cm) have been recommended for all adult patients, but can result in problems with over- and undercuffing. The British Hypertension Society recommends that cuff size be selected based on arm circumference (Williams et al. 2004).

The inflatable bladder, valve, pump and tubing

In a manual sphygmomanometer, the system used to inflate and deflate the bladder consists of a bulb attached to the bladder with rubber tubing. When the bulb is compressed, air is forced into the bladder; to deflate the bladder there is a release valve (O'Brien et al. 2003). The rubber tubes have conventionally been placed so they are inferior to the cuff; however, it is now recommended that they are placed superiorly to prevent them impeding auscultation (O'Brien et al. 2003).

The stethoscope

It is recommended that the stethoscope be of high quality with well-fitting earpieces (O'Brien et al. 2003). It should be placed over the brachial artery at the antecubital fossa (O'Brien et al. 2003). The bell part of the stethoscope may capture the low pitch of the Korotkoff sounds better than the diaphragm but the diaphragm has a larger surface area and is easier to manipulate with one hand (O'Brien et al. 2003).

Table 11.4 Blood pressure cuff sizes for mercury sphygmomanometer, semi-automatic and ambulatory monitors

Indication	Bladder width × length (cm)	Arm circumference (cm)
Small adult/child	12 × 18	<23
Standard adult	12 × 26	<33
Large adult	12 × 40	<50
Adult thigh cuff	20 × 42	<53

Figure 11.16 Correct blood pressure reading techniques.

Specific patient preparation

It is important to maintain a standardized environment in which to take the patient's blood pressure (NICE 2011a). The patient should be seated (unless thigh or orthostatic blood pressure measurements are required) in a relaxed, quiet, temperate setting (NICE 2011a). Their arm should be outstretched and supported, as in unsupported arms diastolic blood pressure may be increased by 10% (O'Brien et al. 2003). The brachial artery at the antecubital fossa should be positioned equal to heart level, approximately equal to where the fourth intercostal space meets the sternum (Bickley and Szilagyi 2009).

The patient's back should be supported (Turner et al. 2008) and their feet should be on the floor as systolic blood pressure can increase by an average of 6.6 mmHg in people with their legs crossed (van Groningen et al. 2008). Blood pressure should be taken after a short period of rest, as slight hypertension on standing and moving is initiated by the baroreceptor reflex (Turner et al. 2008). Correct patient positioning can be seen in Figure 11.16.

Blood pressure should initially be measured in both arms as often people have a significant difference in blood pressure measurement between their arms (NICE 2011a). Those patients who have a large and persistent disparity may have underlying conditions such as occlusive artery disease (Eguchi et al. 2007, O'Brien et al. 2003). Differences up to 10 mmHg can be due to random variation (Eguchi et al. 2007). The arm with the highest reading should be the one used for subsequent measurements (NICE 2011a).

Procedure guideline 11.3 Blood pressure measurement (manual)**Essential equipment**

- A range of cuffs
- Documentation
- Sphygmomanometer, working and calibrated
- Alcohol handrub
- Stethoscope
- Detergent wipes

Optional equipment

- Pillow if required to provide extra arm support
- If necessary a bed or examination bench, so the patient can have their blood pressure measured lying down

Pre-procedure

Action	Rationale
1 Explain to the patient that you need to measure their blood pressure, discuss the procedure, and obtain valid consent.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and dry.	To minimize the risk of infection (Fraise and Bradley 2009, E).
3 Ask/observe the patient if they have any of the following. <ul style="list-style-type: none"> • Lymphoedema or are at risk • An arteriovenous fistula • Trauma or surgery to their arm/axilla • Brachial artery surgery • Intravenous (IV) infusion in progress If there is a contraindication, use other arm or, if bilateral, the lower extremity.	To ensure there are no contraindications to using a particular arm (Bickley and Szilagyi 2009, E ; Curran 2009, E ; Turner et al. 2008, E). Taking blood pressure is not recommended on a limb with an IV infusion in progress because the pressure could damage the vein, placing the patient at risk of extravasation or infiltration. If there is no other choice, a blood pressure can be taken on a limb with IV catheter <i>in situ</i> although the infusion must be temporarily stopped in consultation with registered nursing staff (RCN 2011, C).
4 Provide a standardized environment, which should be relaxed and temperate. The patient needs to be seated comfortably, in a chair with back support, for at least 5 min prior to measuring blood pressure.	To enable comparisons to be drawn with prior blood pressure results (NICE 2011a, C). Variations in temperature and emotions can alter blood pressure readings (O'Brien et al. 2003, E). Resting for 5 minutes will ensure an optimum reading (Bickley and Szilagyi 2009, E ; O'Brien et al. 2003, E ; Turner et al. 2008, E).
5 Ensure the cuff is the correct size for the arm. The cuff bladder length should be 80% of the arm circumference and its width 40% (BHS 2006).	To prevent falsely high readings that may occur if small cuffs are used or falsely low readings if large cuffs used (Williams et al. 2004, E).
6 Check the patient's arm is free from clothing, supported, e.g. with a pillow (whether sitting or standing) and placed at heart level (midsternal level) (Bickley and Szilagyi 2009, NICE 2011a, O'Brien et al. 2003). The patient's bladder should have been recently emptied, their legs uncrossed with their feet flat on the floor if positioned in a chair and ankles uncrossed if in a bed (Turner et al. 2008). See Figure 11.16.	If the arm is lower than heart level it can lead to falsely high readings, and vice versa (O'Brien et al. 2003, E). Diastolic pressure can increase by up to 10% if the arm is unsupported (O'Brien et al. 2003, E) and alter the systolic pressure by 10 mmHg (Reeves 1995, E). Obtaining a measurement before bladder emptying can also increase the systolic blood pressure by up to 10 mmHg (Reeves 1995, E). Blood pressure results can be falsely high if the patient has their legs crossed (Handler 2009, E ; van Groningen et al. 2008, R3b). Taking measurements over clothing or with tight clothing pushed up on the arm can cause a tourniquet effect, and also produce significant artefacts (Reeves 1995, E).

Procedure

7 Wrap the cuff of the sphygmomanometer around the bare arm, with the bladder centred over the brachial artery and superior to the elbow (Marieb and Hoehn 2010, Patton and Thibodeau 2009). The lower edge of the cuff should be 2–3 cm above the brachial artery pulsation (O'Brien et al. 2003).	To obtain an accurate reading (BHS 2006, C), and so that the artery can easily be palpated (NICE 2011a, C).
8 Ask the patient to stop talking, and eating, during the procedure.	Activity can cause a falsely high blood pressure (BHS 2006, C).
9 Palpate the brachial artery while pumping air into the cuff using the bulb. Once the pulse can no longer be felt, rapidly inflate the cuff a further 20–30 mmHg (Bickley and Szilagyi 2009, NICE 2011a).	Palpation of the artery prior to obtaining a blood pressure is recommended as it locates the correct position for stethoscope placement (Valler-Jones and Wedgbury 2005, E). Although the radial artery is also available for palpating, the brachial artery is selected due to its proximity to the most common cuff positioning (superior to the elbow). Inflating the cuff to only 20–30 mmHg above the predicted systolic level prevents undue discomfort (Bickley and Szilagyi 2009, E). Therefore the brachial pulse is advocated rather than the radial pulse (NICE 2011a, C).

10 Slowly deflate the cuff and note the point at which the pulse becomes detectable again. This approximates the systolic blood pressure.	This provides an indication of systolic pressure and can ensure accurate results in those who have an auscultatory gap (BHS 2006, C ; Curran 2009, E ; NICE 2011a, C ; O'Brien et al. 2003, E ; Tortora and Derrickson 2011, E).
11 Deflate the cuff completely and wait 15–30 seconds (Bickley and Szilagyi 2009).	To allow venous congestion to resolve (O'Brien et al. 2003, E).
12 The diaphragm of the stethoscope should be firmly, but without too much pressure, placed on bare skin over the brachial artery where the pulse was palpable.	The bell of the stethoscope may hear the tone of the Korotkoff sounds better (Bickley and Szilagyi 2009, E). However, the diaphragm has a larger surface area and is easier to hold in place (O'Brien et al. 2003, E). If the stethoscope is in contact with material it may distort the Korotkoff sounds (O'Brien et al. 2003, E). Applying pressure with the stethoscope may partially occlude the artery (O'Brien et al. 2003, E).
13 Inflate the cuff again to 20–30 mmHg above the predicted systolic blood pressure (Bickley and Szilagyi 2009).	To ensure an accurate measurement (NICE 2011a, C).
14 Release the air in the cuff slowly (at an approximate rate of 2–3 mmHg per pulsation) until the first tapping sounds are heard (first Korotkoff sound). This is the systolic blood pressure (Patton and Thibodeau 2009).	The cuff should not be deflated too quickly as this may result in inaccurate readings being taken (O'Brien et al. 2003, E).
15 Continue to deflate the cuff slowly, listening to the Korotkoff sounds; the point at which the sound completely disappears is the best representation of the diastolic blood pressure (fifth Korotkoff sound).	To ensure an accurate diastolic blood pressure and that you note any irregularities such as if the sounds never disappear, or disappear significantly below the fourth Korotkoff sound (Bickley and Szilagyi 2009, E).
16 Once sounds can no longer be heard, rapidly deflate the cuff.	To prevent venous congestion to the arm (O'Brien et al. 2003, E).
17 If you need to recheck the blood pressure, wait 1–2 min before proceeding (BHS 2006).	Venous congestion may make the Korotkoff sounds less audible (Bickley and Szilagyi 2009, E).
Post-procedure	
18 Inform patient that the procedure is now finished.	To reassure the patient (Major and Holmes 2008, R4).
19 Wash hands using bactericidal soap and water or bactericidal alcohol handrub, and dry. Clean bell and diaphragm of stethoscope and cuff with detergent wipe (no alcohol).	To minimize the risk of infection (Fraiese and Bradley 2009, E).
20 Document as soon as the measurement has been taken and compare with previous results (O'Brien et al. 2003). Take action as appropriate and document.	Any interruption in the process may result in the measurement being incorrectly remembered (O'Brien et al. 2003, E). Records should identify any risks or problems that have arisen and show the action taken to deal with them (NMC 2010, C).

Problem-solving table 11.3 Prevention and resolution (Procedure guideline 11.3)

Problem	Cause	Prevention	Action
The result is unexpectedly low or high.	This may be due to poor technique or faulty equipment. It may also be due to the patient being incorrectly positioned or post exercise.	Check the sphygmomanometer prior to use to see when it was last serviced. Check all the components for signs of damage. Ensure the patient is correctly positioned, and has rested prior to the procedure.	Wait 1–2 min before repeating the blood pressure measurement (BHS 2006). If the measurement is still unexpected, consider changing devices or asking a colleague to repeat the procedure. If it remains abnormal, notify the medical team of the result.
On auscultation the Korotkoff sounds disappear after the initial sound, then reappear and then disappear again (Curran 2009).	This is called the auscultatory gap – it may mislead the practitioner into obtaining an incorrect result (Curran 2009).	Palpate the pulse as the cuff is being deflated to gain an approximation of the systolic blood pressure (O'Brien et al. 2003).	Document that the patient has an auscultatory gap and ensure other practitioners are aware to prevent future errors (O'Brien et al. 2003). Recheck using the correct procedure.

(continued)

Problem-solving table 11.3 Prevention and resolution (Procedure guideline 11.3) (*continued*)

Problem	Cause	Prevention	Action
On auscultation the Korotkoff sounds are inaudible or very weak.	May be due to poor placement of the stethoscope, a noisy environment, venous congestion or the patient may be in shock (Bickley and Szilagyi 2009, Verrij et al. 2009).	Find a quiet environment in which to measure the patient's blood pressure, listen with the bell of the stethoscope rather than the diaphragm, wait for venous congestion to resolve (Bickley and Szilagyi 2009).	If still inaudible, ask the patient to elevate their arm overhead for 30 seconds, then bring it back to the correct height to inflate the cuff and measure their blood pressure; this increases the loudness of the sounds (Bickley and Szilagyi 2009, Verrij et al. 2009).

Post-procedural considerations

618

Immediate care

Notify medical staff of an abnormal blood pressure result. As the treatment will depend on what is causing the abnormality, and its severity, it is important that practitioners try to ascertain the possible cause for the physiological change in blood pressure (Kisiel and Perkins 2006). Hypovolaemia will require fluid replacement and, if persistent, then inotropes and other cardiovascular drugs may be necessary (Hinds and Watson 2009). If the hypertension is transient, for example related to anxiety or pain, then it is important to address that issue and monitor the blood pressure until it resolves. However, if the patient is diagnosed as having hypertension, they will require drug therapy to control their condition (NICE 2011a). To determine the cause of the altered blood pressure more information will be required, including:

- gaining a comprehensive medical history from the patient (Steele and Hardin 2007)
- gaining a full set of observations
- an ECG (Steele and Hardin 2007)
- urinalysis including protein, leucocytes, blood and the osmolality of the urine (Steele and Hardin 2007)
- blood tests for full blood count, urea, creatinine and electrolytes (Steele and Hardin 2007) and fasting blood tests for glucose and lipids (Camm and Bunce 2009)
- a chest X-ray or further radiological investigations may be required (Camm and Bunce 2009)
- a septic screen including blood cultures, sputum specimen, swabs of any wounds or potential sites of infection (Hinds and Watson 2009)
- their current fluid balance (Kisiel and Perkins 2006).

Ongoing care

If the patient is hypertensive and in primary care, they will require at least monthly blood pressure measurement and more frequently if it is accelerated hypertension or there are any further concerns (NICE 2011a). Additionally, it will be necessary to give lifestyle advice on, for example, eating healthily and smoking cessation (NICE 2011a). If the hypotension is orthostatic then advise the patient to change position slowly so the baroreceptors and sympathetic nervous system have time to adapt the blood pressure to each stage (Marieb and Hoehn 2010).

Documentation

As well as the accurate recording of the blood pressure measurement, it is also important to record:

- the position the patient was in
- the arm used, and if both arms were used initially, the pressure of each
- arm circumference and the cuff size used
- if there is an auscultatory gap or any difficulties in obtaining a reading, such as the absence of stage 5

- the state of the patient, for example were they in pain, frightened, and so on
- any medication they are on and when they last took it (O'Brien et al. 2003).

When documenting the medication the patient is on, it is important to include not only cardiovascular medication but also other medication which might affect their blood pressure, including tricyclic antidepressants, neuroleptic agents (O'Brien et al. 2003), contraceptives, decongestants, non-steroidal anti-inflammatory drugs (NSAIDs) and cocaine (Steele and Hardin 2007).

Respiration and pulse oximetry

Definition

The major function of the respiratory system is to supply the cells of the human body with oxygen and to remove carbon dioxide, in order that they can continue to function effectively (Tortora and Derrickson 2011). Respiration is composed of four processes:

- *pulmonary ventilation*: the movement of air into and out of the lungs to continually refresh the gases there, commonly called 'breathing'
- *external respiration*: movement of oxygen from the lungs into the blood, and carbon dioxide from the lungs into the blood, commonly called 'gaseous exchange'
- *transport of respiratory gases*: transport of oxygen from the lungs to the cells, and of carbon dioxide from the cells to the lungs, accomplished by the cardiovascular system
- *internal respiration*: movement of oxygen from blood to the cells, and of carbon dioxide from the cells to the blood (Marieb and Hoehn 2010) (see Chapter 9: Respiratory care).

Anatomy and physiology

The organs and structures of the respiratory system can be split into two zones: the conducting zone and the respiratory zone (Marieb and Hoehn 2010). The conducting zone consists of a series of interconnecting passageways, both outside and within the lungs, through which air passes to get to the area of gaseous exchange, such as the nasal cavity, trachea and bronchi. The function of this area is to provide conduits through which air can pass and can also filter, cleanse, warm and humidify the air whilst conducting it to the lungs (Tortora and Derrickson 2011). The respiratory zone consists of the bronchioles, alveolar ducts and alveoli, the main sites where gaseous exchange occurs between air and blood (Marieb and Hoehn 2010).

A variety of efficient inter-relationships exist between the different body systems in order for effective respiration to occur; these include the cardiovascular system, nervous system and musculoskeletal system (Patton and Thibodeau 2010). The respiratory muscles (the diaphragm and intercostal muscles) promote ventilation by causing volume and pressure changes within the respiratory system (Marieb and Hoehn 2010).

The mechanism of breathing

The key mechanism of pulmonary ventilation is that changes of volume within the respiratory system lead to changes in pressure and that these in turn lead to a flow of gases to equalize the pressure (Marieb and Hoehn 2010). The relationship between the pressure and volume of a gas is called Boyle's Law, whereby at a constant temperature the pressure of a gas varies inversely with its volume; in a larger container the pressure of a gas is less than in a smaller one (Marieb and Hoehn 2010). As air will flow from an area of high pressure to an area of lower pressure, air moves into the lungs when the air pressure inside the lungs is lower than the air pressure in the atmosphere, and out of the lungs when the air pressure outside the lungs is greater than the air pressure in the atmosphere (Tortora and Derrickson 2011).

Inspiration

For inspiration to occur, the pressure in the alveoli must be lower than the air pressure in the atmosphere; this is achieved by increasing the size (volume) of the lungs through the contraction of the muscles of inhalation – the diaphragm and the intercostal muscles. The diaphragm flattens and descends and the intercostal muscles lift the ribcage and sternum, causing the ribs to broaden outwards and increasing the diameter of the thoracic cavity, both from side to side and front to back (Patton and Thibodeau 2009). During normal inspirations, the pressure between the two pleural layers in the pleural cavity (intrapleural pressure) is always just lower than atmospheric pressure (756 mmHg at an atmospheric pressure of 760 mmHg). As the volume of the lungs and pleural cavity increases, the intrapleural pressure drops to 754 mmHg. At the same time, the pressure within the lungs (alveolar or intrapulmonary pressure) drops from 760 mmHg to

758 mmHg, and so a pressure difference between the atmosphere and the alveoli is established and air flows into the lungs (Tortora and Derrickson 2011). The relationship of these pressures can be seen in Figure 11.17.

Expiration

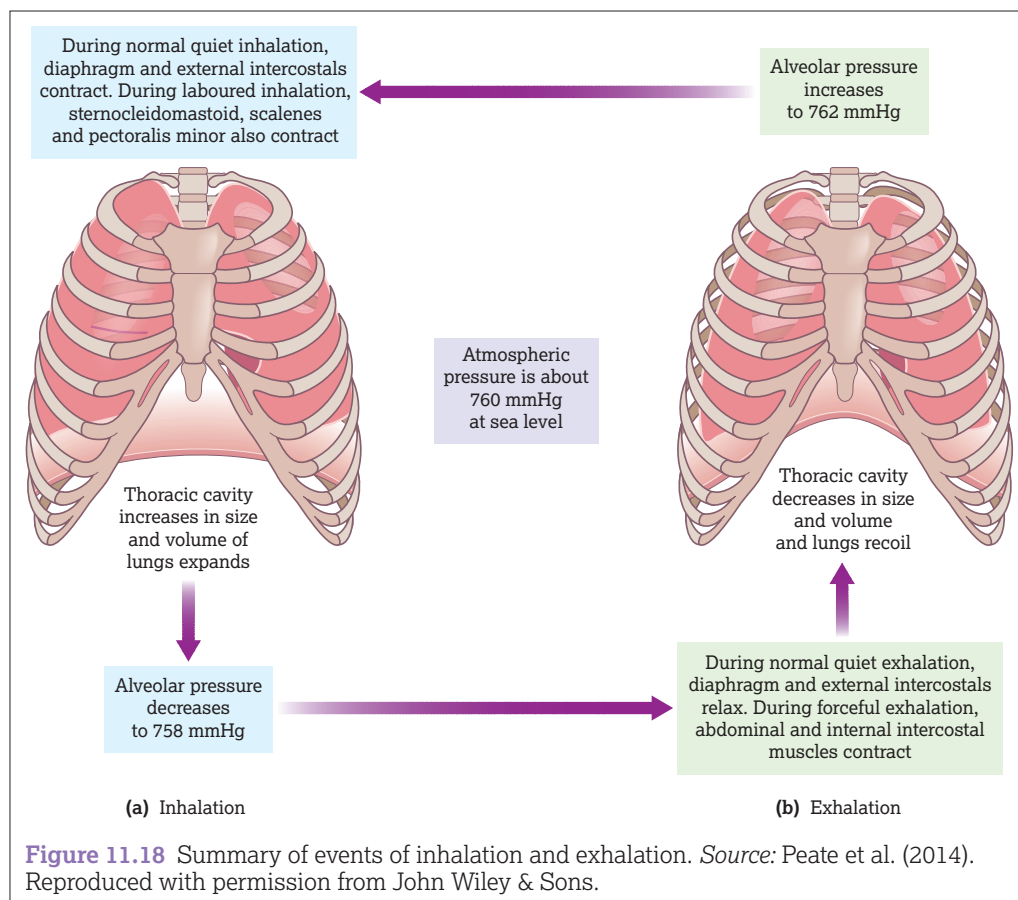

Expiration also occurs due to a pressure gradient but in the opposite direction, whereby the pressure within the lungs is greater than the pressure of the atmosphere. In normal gentle breathing, the process of expiration is largely passive, not involving any muscular contractions but resulting from elastic recoil of the chest wall and lungs (Tortora and Derrickson 2011).

Expiration begins when the inspiratory muscles relax, causing the diaphragm to move superiorly and the ribs to depress, decreasing the diameter of the thoracic cavity and returning it to its normal size. This results in a decrease in lung volume and compression of the alveoli, causing an increase in alveolar (intrapulmonary) pressure to 762 mmHg. This forces gases to flow out from the area of higher pressure in the lungs to the area of lower pressure in the atmosphere (Tortora and Derrickson 2011). A summary of events during inspiration and expiration can be seen in Figure 11.18.

The accessory muscles

The accessory muscles of inspiration further increase the volume of the thoracic cavity and therefore increase the volume of breathing; these include the sternocleidomastoid muscles which elevate the sternum and the scalene muscles and the pectoralis minor muscles which elevate the first to the fifth ribs (Tortora and Derrickson 2011). These muscles may be used during exercise or if the individual is in respiratory distress (Marieb and Hoehn 2010).

The accessory muscles of expiration are used only during forceful breathing, such as when playing a wind instrument or during exercise. Contraction of the abdominal wall muscles, primarily the oblique and transversus muscles, increases intra-abdominal pressure, forcing the abdominal organs upwards against the diaphragm, and also depresses the ribcage. The internal intercostal muscles also depress the ribcage and decrease thoracic volume, forcing air out of the lungs (Marieb and Hoehn 2010).

Control of respiration

Oxygen consumption increases exponentially during periods of strenuous exercise; several mechanisms help to match respiratory effort to the metabolic demand of the cells (Tortora and Derrickson 2011). Higher brain centres, chemoreceptors and other reflexes modify the basic respiratory rhythms generated in the brainstem. Control of respiration primarily involves neurones in the medulla and pons (Marieb and Hoehn 2010).

The respiratory centres

Within the medulla are two clusters of neurones which are critically important in the co-ordination of the respiratory system: the *dorsal respiratory group* and the *ventral respiratory group* (Marieb and Hoehn 2010).

The ventral respiratory group contains neurones that fire during inspiration, stimulating the diaphragm and the external intercostal muscles to contract, via the phrenic and intercostal nerves, and other neurones which fire during expiration causing the stimulation to stop and the muscles relax. These neurones deliver our normal respiratory rate of 12–15 breaths per minute (Marieb and Hoehn 2010).

The dorsal respiratory group co-ordinates input from the peripheral baroreceptors (or stretch receptors) and chemoreceptors and

relays this to the ventral respiratory group to alter respiratory rate as required (Marieb and Hoehn 2010). Baroreceptors monitor the stretch of the bronchi and bronchioles during overinflation of the lungs (Tortora and Derrickson 2011). Chemoreceptors monitor the arterial blood for changes in the partial pressure of carbon dioxide (PCO_2) and pH, but also, to a lesser extent, the partial pressure of oxygen (PO_2) (Patton and Thibodeau 2009). For more information on the chemical factors which affect respiration, see Chapter 9: Respiratory care.

Pontine respiratory centres also relay impulses to the ventral respiratory group to modify breathing rhythms so that there is a smooth transition from inspiration to expiration and so that breathing can be modified to allow for speech, exercise and sleep (Marieb and Hoehn 2010).

Carbon dioxide

Although oxygen is essential for every cell in the body, the body's need to rid itself of carbon dioxide is the most vital stimulus to respiration in a healthy person (Marieb and Hoehn 2010). Arterial PCO_2 is very closely monitored and acceptable levels maintained by a sensitive homeostatic mechanism mediated mainly by the effect that increased CO_2 levels have on the central chemoreceptors of the brainstem. Carbon dioxide passes easily from the blood into the cerebrospinal fluid where it forms carbonic acid, releasing hydrogen ions (H^+). This increase of H^+ causes the pH to drop, stimulating the central chemoreceptors in the brainstem to increase the rate and depth of breathing and so increase the amount of carbon dioxide exhaled (Marieb and Hoehn 2010). Similarly, metabolic causes for low pH levels, such as a build-up of lactic acid, will also provoke alterations in respiration (Marieb and Hoehn 2010). See Figure 11.19 for negative feedback mechanisms by which changes in PCO_2 and blood pH regulate

ventilation. Abnormally low PCO_2 levels cause inhibition of respiration, with breathing becoming slow and shallow, and periods of apnoea may occur, until arterial PCO_2 rises again and stimulates respiration (Marieb and Hoehn 2010).

Oxygen

The peripheral chemoreceptors, found in the aortic arch and carotid arteries, are responsible for sensing the arterial PO_2

(Marieb and Hoehn 2010). Normally, decreasing levels of oxygen only affect respiratory rate by causing the peripheral chemoreceptors to have an increased sensitivity to carbon dioxide (Marieb and Hoehn 2010). Arterial PO_2 must drop substantially, from the normal level of 100 mmHg to at least 60 mmHg, before it stimulates respiratory function; at this point the central receptors become suppressed and at the same time the peripheral receptors stimulate the respiratory centres to increase ventilation even if PCO_2 is normal (Marieb and Hoehn 2010).

Other ways in which respiration is controlled

There are a number of receptors in the lungs which respond to a variety of irritants. Accumulated mucus or inhaled debris stimulates receptors in the bronchioles that cause reflex constriction of those air passages. When stimulated in the bronchi or trachea, a cough is initiated, and a sneeze is triggered when in the nasal cavity (Marieb and Hoehn 2010). These irritant receptors have a protective mechanism to prevent obstruction or aspiration of food or liquids (Patton and Thibodeau 2009). There are also stretch receptors present in the conducting passages and the visceral pleura which are stimulated when the lungs inflate; these then signal the respiratory centres to end inspiration. These receptors are thought to act more as a protective response to prevent excessive stretching of the lungs rather than a normal regulatory mechanism (Marieb and Hoehn 2010).

Respiration can also be altered in the higher cortical centres in response to factors such as strong emotions, pain and alteration of temperature (Patton and Thibodeau 2009, Tortora and Derrickson 2011). The cerebral motor cortex yields a degree of voluntary control over breathing; however, this can be over-ridden by the other mechanisms (Patton and Thibodeau 2009).

Some of the mechanisms through which breathing is controlled are summarized in Figure 11.20.

Related theory

Respiratory volumes

The quantity of air that is breathed in and out of the lungs varies depending on the conditions of inspiration and expiration (Marieb and Hoehn 2010). As such, several respiratory volumes can be described, combinations of which (termed respiratory capacities) are measured to gain information about a person's respiratory status (Marieb and Hoehn 2010). A summary of these volumes can be seen in Figure 11.21. See Table 11.5 for a summary of respiratory volumes and capacities for males and females.

Gaseous exchange

Gaseous exchange occurs during *external respiration* where oxygen diffuses from the air in the alveoli of the lungs into blood in the pulmonary capillaries, and carbon dioxide diffuses from the blood into the alveolar air. This occurs as there is a flow of gases from areas of higher pressure to areas of lower pressure; oxygen diffuses from alveolar air where its partial pressure is higher than in the capillary blood, and carbon dioxide diffuses from the blood where its partial pressure is higher than in the alveolar air (Tortora and Derrickson 2011). *Internal respiration*, or systemic gas exchange, takes place where the same gases move into or out of the cells of the body by diffusion, so oxygen moves into the tissues and carbon dioxide moves out of them. See Figure 11.22 for the changes in partial pressures of oxygen and carbon dioxide during internal and external respiration (Tortora and Derrickson 2011). Please see Chapter 9: Respiratory care for further information.

Transport through the blood

Oxygen does not dissolve easily in water and therefore only 1.5% of the oxygen is transported in the blood by being dissolved in the plasma; the other 98.5% is bound to haemoglobin in the red blood cells, forming oxyhaemoglobin (Hb-O₂) (Tortora and Derrickson 2011). The majority of carbon dioxide is transported in the blood as bicarbonate ions (HCO₃⁻) within the plasma

(70%), approximately 20–23% is bound to haemoglobin forming carbaminohaemoglobin (Hb-CO₂), and the remaining 7–10% is dissolved in the plasma (Marieb and Hoehn 2010). This process is summarized in Figure 11.23; see Chapter 9: Respiratory care.

Hypoxia and hypercapnia

Hypoxia is defined as inadequate oxygen delivery to the tissues. Hypoxia can have various causes, and based on this, can be classified into four types (Marieb and Hoehn 2010, Tortora and Derrickson 2011).

- *Hypoxaemic hypoxia*: caused by a low PO₂ in arterial blood as a result of breathing air with inadequate oxygen (such as at high altitude) or abnormal ventilation/perfusion matching in the lungs (due to airway obstruction or fluid in the lungs). Carbon monoxide poisoning can also cause this.
- *Anaemic hypoxia*: caused by too little functioning haemoglobin being present in the blood which reduces the transport of oxygen to the cells (such as haemorrhage or anaemia).
- *Ischaemic hypoxia*: caused when blood flow to a specific area is inadequate to supply enough oxygen, even though PO₂ and Hb-O₂ levels are normal (due to embolism or thrombosis).
- *Histotoxic hypoxia*: caused by the cells being unable to use the oxygen that has been delivered; this can occur as a result of poisons such as cyanide.

Signs of hypoxia include tachypnoea, dyspnoea, tachycardia, restlessness and confusion, headache, mild hypertension and pallor; in its severe stages the symptoms will worsen, leading to slow, irregular breathing, cyanosis, hypotension, altered level of consciousness, blurred vision and eventual respiratory arrest (Beachey 2012).

Hypercapnia is an elevated level of carbon dioxide level in the blood. Signs include tachypnoea (eventually becoming bradypnoea as it worsens), dyspnoea, tachycardia, hypertension, headaches, vasodilation, drowsiness, sweating and a red colouration (Beachey 2012). Patients with hypercapnia will require urgent

Figure 11.21 Spirogram of lung volumes and capacities. The average values for a healthy average male and female are indicated, with the values for a female in parenthesis. Note that the spirogram is read from right (start of record) to left (end of record). *Source:* Peate et al. (2014). Reproduced with permission from John Wiley & Sons.

Table 11.5 Respiratory volumes and capacities

Respiratory volumes and capacities	Adult male average value	Adult female average value	Description
Tidal volume (V_T)	500mL	500mL	The volume of air inhaled or exhaled in one breath
Minute volume (MV)			The total volume of air inhaled or exhaled each minute = 12 breaths per minute \times 500mL/breath = 6 litres/minute
Inspiratory reserve volume (IRV)	3100mL	1900mL	The volume of air that can be forcibly inhaled after a normal tidal volume inhalation
Expiratory reserve volume (ERV)	1200mL	700mL	The volume of air that can be forcibly exhaled after a normal tidal volume exhalation
Residual volume (RV)	1200mL	1100mL	The volume of air left in the lungs after a forced exhalation
Inspiratory capacity (IC)	3600mL	2400mL	The sum of the tidal volume and inspiratory reserve volume = 500+3100 = 3600mL (male) = 500+2400 = 2900mL (female)
Functional residual capacity (FRC)	2400mL	1800mL	The sum of the residual volume and expiratory reserve volume = 1200+1200 = 2400mL (male) = 1100+700 = 1800mL (female)
Vital capacity (VC)	4800mL	3100mL	The sum of inspiratory reserve volume, tidal volume and expiratory reserve volume = 3100+500+1200 = 4800mL (male) = 1900+500+700 = 3100mL (female)
Total lung capacity (TLC)	6000mL	4200mL	The sum of vital capacity and residual volume = 4800+1200 = 6000mL (male) = 3100+1100 = 4200mL (female)

623

medical attention and close monitoring as hypercapnia will cause respiratory acidosis (Beachey 2012). Patients with chronic hypercapnia, such as those who have chronic obstructive pulmonary disease (COPD), will have at least partially adapted to the chronically high levels of carbon dioxide; oxygen therapy needs to be administered with caution in these patients as they are at risk of hypercapnic respiratory failure (O'Driscoll et al. 2008).

Evidence-based approaches

Rationale

The purpose of respiratory assessment is to determine the respiratory status of the patient (Hunter and Rawlings-Anderson 2008). A thorough respiratory assessment is vital to:

- identify patients who are at risk of deterioration
- commence treatment that may stabilize and improve the patient's condition and outcomes
- help prevent unnecessary admission to critical care units (Higginson and Jones 2009).

Alteration in respiratory observations may indicate a severe derangement in a range of body systems, not simply the respiratory system, so it is a vital indicator of morbidity (Cretikos et al. 2008). Respiratory dysfunction is also a known precursor to adverse events with an associated increase in mortality (NICE 2007a). Breathing, and more specifically respiratory rate, is one of the most sensitive indicators of critical illness and is usually the first vital sign to alter in the deteriorating patient; therefore timely, accurate observations, with early, effective and appropriate interventions may vastly improve patient outcomes

(Hunter and Rawlings-Anderson 2008, Moore 2007). Despite this, research shows that respiratory rate is often not recorded or it is just guessed (Jonsson et al. 2011, Leuvan and Mitchell 2008).

Indications

As mentioned previously in this chapter, all patients who are in hospital should have observations taken and recorded regularly (NICE 2007a). In addition, respiratory observations should also be taken and recorded:

- following surgery, investigative procedures, trauma, infections or emergency situations in order to compare and identify any changes to baseline observations (Booker 2009, Hunter and Rawlings-Anderson 2008)
- to monitor before and during blood or blood product transfusions or intravenous fluids (Hunter and Rawlings-Anderson 2008)
- to monitor response to medications, including opiates and bronchodilators (Hunter and Rawling-Anderson 2008).

If the patient is acutely ill or at risk of respiratory deterioration, they will require continuous pulse oximetry and frequent respiratory assessment (Booker 2009, Levine 2007). Similarly, if the patient is receiving oxygen therapy then they will need to be closely monitored to ensure its efficacy (Higginson and Jones 2009). Any patient who has, or is at risk of, chronic hypercapnia should have close monitoring of their respiratory function, with observations performed at least hourly (O'Driscoll et al. 2008).

Any healthcare professional who has been trained and assessed as competent can perform a respiratory assessment and pulse oximetry in accordance with local hospital policy.

Methods of assessing respiration

Airway assessment

It is important to assess whether there is any obstruction to the patient's airway. Such obstruction may be from vomit, foreign bodies or the patient's tongue (Higginson and Jones 2009). In the conscious patient, a quick way to check airway patency is to ask them a question; a normal verbal response confirms that the patient's airway is clear, they are breathing and perfusing their brain (Higginson and Jones 2009) (see Chapter 9: Respiratory care).

Breathing assessment

This is required to assess the patient's ability to adequately ventilate. The initial stage of the breathing assessment is to observe the patient and watch how they breathe, termed inspection. It is important that the following aspects are observed:

- colour of the patient's skin and mucous membranes
- use of accessory muscles or other respiratory signs

- rhythm, rate and depth of respiration
- shape and expansion of the chest (Higginson and Jones 2009).

Skin colour

Cyanosis is a blue tone to the skin and mucous membranes which may occur when high levels of unsaturated haemoglobin are present in the blood; it may be detectable when oxygen saturation of arterial blood drops below 85% (Moore 2007). Cyanosis is, however, often considered a late sign of respiratory deterioration and may be difficult to appreciate, particularly in artificial lighting. There are two types of cyanosis: central, affecting the lips and oral mucosa, usually indicating cardiorespiratory insufficiency, and peripheral, observed in the skin and nail beds, usually indicating poor peripheral circulation if seen in isolation (Moore 2007). Patients who are anaemic may not be cyanotic as there is insufficient haemoglobin to generate the blue tone (Moore 2007); similarly, a pale skin tone may indicate that the patient is anaemic or in shock (Bickley and Szilagyi 2009).

Use of accessory muscles

The use of accessory muscles to increase inspiration such as the sternocleidomastoid, scalene, trapezius and abdominals may suggest that the patient has difficulty breathing and is in respiratory distress (Higginson and Jones 2009, Moore 2007). Observe the patient's neck during inspiration to see if there is any contraction of the sternomastoid or other accessory muscles (Bickley and Szilagyi 2009). In addition, some patients may breathe through pursed lips on expiration as they try to force air out of overdistended alveoli, or have nasal flaring as they attempt to force more air into the lungs (Moore 2007).

Rhythm, rate and depth of respiration

The normal respiratory rate in adults is 12–18 breaths per minute with expiration lasting approximately twice as long as inspiration (Higginson and Jones 2009). The rate should be counted for one full minute to fully assess both the rate and the rhythm (Morton and Rempher 2009). An increase from the patient's normal respiratory rate by as little as 3–5 breaths per minute is an early and important sign of respiratory distress (Field 2006). Patients with a respiratory rate greater than 24 breaths per minute should have frequent observations and be closely monitored; if they also

have other physiological alterations, they should receive prompt medical attention, as should all patients with a respiratory rate greater than 27 breaths per minute (Cretikos et al. 2008). Respiratory rates of eight or less also require urgent medical care (Docherty 2002). Respiratory rate can be classified into one of the following.

- *Eupnoea*: unconscious, gentle respiration, the normal respiratory rate and rhythm, usually between 12–17 breaths per minute (Patton and Thibodeau 2009).
- *Bradypnoea*: a respiratory rate which is slower than the normal range – less than 10 breaths per minute; this may signify depression of the respiratory centre, opioid overdose, increased intracranial pressure or a diabetic coma; regardless of the cause, this indicates a severe deterioration in the patient's condition (Bickley and Szilagyi 2009, Moore 2007).
- *Tachypnoea*: a respiratory rate which is faster than the normal range and shallow – greater than 18–24 breaths per minute; this may indicate a number of conditions including anxiety, pain, restrictive lung disease, cardiac or circulatory problems, or pyrexia and is the first indication of respiratory distress (Bickley and Szilagyi 2009, Moore 2007, Simpson 2006).

- *Dyspnoea*: breathing where the individual is conscious of the effort to breathe and finds it more difficult; when dyspnoea occurs when the patient lies flat, it is termed orthopnoea (Patton and Thibodeau 2009).
- *Apnoea*: is a temporary cessation of breathing (Patton and Thibodeau 2009).
- *Biot's breathing*: irregular respiratory rate and depth – alternating periods of deep gasping with periods of apnoea, seen in patients with increased intracranial pressure, head trauma, brain abscess, spinal meningitis and encephalitis (Patton and Thibodeau 2009, Simpson 2006).
- *Cheyne–Stokes breathing*: regular pattern of alternating periods of deep breathing with periods of apnoea; this may have many causes including heart failure, renal failure, brain damage, drug overdose or increased intracranial pressure, and may also be present at the end-stage of life (Bickley and Szilagyi 2009, Simpson 2006).
- *Kussmaul breathing*: rapid deep breathing resulting from stimulation of the respiratory centre caused by metabolic acidosis and occurs in diabetic ketoacidosis (Moore 2007).
- *Hyperventilation*: increase in respiratory rate and depth and can be caused by anxiety, exercise, metabolic acidosis, diabetic ketoacidosis or alteration in blood gas concentrations (Bickley and Szilagyi 2009, Simpson 2006).
- *Hypoventilation*: is shallow and irregular breathing and can be caused by an overdose of certain anaesthetic agents or opiate drugs; it may also occur with prolonged bedrest or conscious splinting of the chest to avoid respiratory pain (Simpson 2006).

Shape and expansion of the chest

The respiratory assessment should also consider the shape and expansion of the chest. The anteroposterior (AP) diameter of the chest wall may give an indication of underlying respiratory conditions or other problems (Higginson and Jones 2009); it may change with ageing or increase in chronic pulmonary disease (Bickley and Szilagyi 2009). It is also important to view the way the chest expands with each breath; when normal, it should be equal and bilateral (Higginson and Jones 2009). Any paradoxical movements such as only one side of the chest moving, greater movement on one side or one side moving up and the other moving down should be noted as they can indicate a particular problem with one side of the chest (Higginson and Jones 2009). Asymmetrical chest expansion is abnormal and may indicate pleural disease, pulmonary fibrosis, collapse of upper lobes or bronchial obstruction; spinal deformities such as kyphosis also influence lung expansion (Moore 2007).

General condition or distress of the patient

Respiratory assessment also involves assessing the entire patient for other signs or symptoms of respiratory insufficiency; high temperature may be suggestive of pneumonia, increased pulse may indicate cardiovascular disease and low blood pressure may indicate sepsis. The patient's level of consciousness should also be assessed, along with how alert and orientated they are and if they appear distressed (Moore 2007). If the patient can only speak in very short sentences or only a few words without needing to stop to breathe then they are in respiratory distress (Higginson and Jones 2009).

Pulse oximetry

Pulse oximetry provides continuous and non-invasive monitoring of the oxygen saturation from haemoglobin in arterial blood (Moore 2007). Pulse oximetry is an effective method of monitoring for hypoxaemia and will immediately alert the practitioner to a fall in arterial oxygen saturation, often even before any obvious symptoms are displayed (Higginson and Jones 2009, Moore 2007). It also provides useful information about heart rate (Jevon and Ewens 2000).

Normal oxygen saturation ranges between 95% and 100%; however, patients with chronic respiratory conditions may have

adjusted to lower oxygen saturation levels (Higginson and Jones 2009) and therefore the aim should be to keep oxygen saturations as near to the patient's normal range as possible (Levine 2007, O'Driscoll et al. 2008). In general terms, a level below 90% is of concern, but the trend of oxygen saturations may be of more importance than individual readings as this gives an indication of whether the patient is responding to therapy or deteriorating (Higginson and Jones 2009, Jevon and Ewens 2007). The British Thoracic Society states that oxygen saturation should be kept at 94–98% for acutely ill adults and 88–92% for those at risk of hypercapnic respiratory failure (O'Driscoll et al. 2008). It also states that in patients who are not hypoxic, a sudden drop of greater than 3% in oxygen saturation within the target saturation range should prompt the nurse to check that the device is working correctly and to undertake further assessment of the patient's condition (O'Driscoll et al. 2008).

Arterial blood gas analysis has been the gold standard for monitoring arterial oxygen saturation, but it is invasive, time consuming, costly and involves repeated arterial blood sampling and only provides intermittent information (Jevon and Ewens 2007). The use of pulse oximetry may therefore reduce the need for arterial samples to be taken (Simpson 2006).

Although pulse oximetry is a useful tool in the assessment of respiratory status, its limitations should be recognized. One of the main limitations is its inability to reliably detect hypoventilation (particularly in patients receiving supplemental oxygen) and carbon dioxide retention (Higginson and Jones 2009, Jevon and Ewens 2007); this is usually confirmed by measurement of PaCO₂ by arterial blood gas analysis. Likewise, pulse oximetry does not give an indication of haemoglobin so if the patient is profoundly anaemic then their oxygen saturation may be normal but they may still be hypoxic (Levine 2007). Other factors which may impact on the pulse oximetry readings include the following.

- *Nail polish*: particularly dark colours such as black, blue and green will affect the accuracy of readings (Moore 2007).
- *Intravenous dyes*: pulse oximetry may be inaccurate in patients who have received dye treatment such as methylene blue, indocyanine green and indiocarmine (Levine 2007).
- *Poor peripheral perfusion*: to work effectively, an adequate peripheral blood flow is required. This may be impaired by factors such as hypovolaemia, hypotension, hypothermia, vasoconstriction or heart failure (Elliott and Coventry 2012) and may result in falsely low readings.
- *Cardiac arrhythmias*: such as atrial fibrillation can cause inadequate or irregular perfusion resulting in falsely low readings (Jevon and Ewens 2007).
- *Recording blood pressure*: inflation of the blood pressure cuff will cause the readings to be inaccurate; the probe should be positioned on a finger of the opposite arm to where blood pressure is being taken (Moore 2007).
- *Carbon monoxide poisoning*: pulse oximetry should not be used on patients with suspected or confirmed carbon monoxide poisoning as the sensor cannot differentiate between oxyhaemoglobin and carboxyhaemoglobin and will therefore provide falsely elevated oxygen saturation readings; arterial blood gas analysis should be undertaken instead (Levine 2007, Moore 2007).
- *Methaemoglobinemia*: changes in the structure of haemoglobin, caused by lignocaine, nitrates, metoclopramide and local anaesthetics, can inhibit oxygen release from the haemoglobin, resulting in tissue hypoxia and unreliable oxygen saturation measurements (Jevon and Ewens 2007).
- *Bright external light*: fluorescent lighting or light interference from surgical lamps, infra-red warming lamps or direct sunlight can give falsely high readings (Adam and Osborne 2005, Jevon and Ewens 2007).
- *Movement*: sudden movement, due to shivering or seizures, or restlessness may dislodge the sensor or cause motion artefact affecting the ability of light to travel from the light-emitting diode to the detector in the probe (Moore 2007).

Pre-procedural considerations

Equipment

Pulse oximeter

A pulse oximeter is a device that measures the amount of haemoglobin saturation in the tissue capillaries. The probe consists of two light-emitting diodes (one red and one infra-red) on one side of the probe and a photodetector on the other side. The device projects light through the tissue to the detector measuring absorption in pulsatile blood by saturated haemoglobin (visible red) and desaturated haemoglobin (infra-red wavelength). This is translated by the receiver into a percentage of oxygen saturation of the blood, symbolized as SpO₂ (McMorrow and Mythen 2006, Moore 2007).

In order to achieve a successful reading, the sensor of the pulse oximeter should be placed on an appropriate site with an adequate pulsating vascular bed (the probe must be designed for use on the chosen site). Therefore the sensor may be attached to the patient's fingers, ears, toes or nose (Goodell 2012, Higginson and Jones 2009, Jevon and Ewens 2007, Johnson et al. 2012, Yönt et al. 2011).

Pulse oximeters should be serviced and calibration checked according to the manufacturer's recommendations to ensure accurate and reliable data are recorded (Booker 2008). They should be used and maintained in accordance with the manufacturer's instructions. Any malfunctioning probes or machines should be taken out of clinical use until repair or service can be undertaken by the relevant department, in accordance with local policy.

Pulse oximeters are essential in all areas where emergency oxygen is given (O'Driscoll et al. 2008). Pulse oximeters form part of a department's emergency equipment and so should always be available in good working order. After use, the probe and machine should be cleaned, returned to its storage location and plugged into a mains electrical supply to charge the internal battery ready for use in an emergency.

Specific patient preparation

Appropriate positioning of the patient can help to ease any respiratory distress and facilitate the assessment and observation of their breathing (Moore 2009b). The patient should have rested and not have engaged in any strenuous physical activity prior to the assessment (Hunter and Rawlings-Anderson 2008). If this is not contraindicated, the patient should be positioned upright or lying in bed with the head section elevated to an angle of 45–60° to allow good lung expansion; pillows can help to support the patient in this position (Hunter and Rawlings-Anderson 2008). With the patient's consent, it may be useful to remove clothing from their thorax to aid with observation of breathing (Moore 2007, 2009b). Positioning can also help to relax the patient and therefore potentially reduce the distress resulting from breathlessness (Gosselink et al. 2008). The patient should give their consent to the assessment and be asked to keep still while pulse oximetry is being performed so that an accurate result can be obtained (Hunter and Rawlings-Anderson 2008). Similarly, blood pressure measurement should not be performed whilst pulse oximetry recording is under way and nail polish should be removed from the probe site (Moore 2007).

Procedure guideline 11.4 Respiratory assessment and pulse oximetry

Essential equipment

- Pulse oximeter
- Power source
- Cleaning materials (according to manufacturer's recommendations and local policy)
- Sensor (probe) applicable to the chosen site
- A watch with a second hand
- Appropriate method of documentation and a pen

Optional equipment

- Variety of sensors (probes) available for different sites

Preprocedure

Action	Rationale
1 Wash hands thoroughly with soap and water and dry.	To reduce the risk of cross-contamination (Fraise and Bradley 2009, E ; Hunter and Rawlings-Anderson 2008, E).
2 Explain the procedure to the patient, answering any questions they may have, and gain their consent.	Consent must be gained prior to commencing any procedure (NMC 2013, C).
3 Ask the patient to remain as still as possible during the procedure and ensure that a constant temperature is maintained in the patient's environment.	Artefacts from movement such as shivering may adversely affect the accuracy of measurement (Barnett et al. 2012, E).
4 While talking to the patient, assess their respiratory status, including their ability to talk in full sentences, the colour of their skin, whether they appear to be in distress or not, and whether they are alert and orientated.	This initial assessment can give important information about the patient's respiratory function and any potential problems (Higginson and Jones 2009, E ; Kallet 2012, E).
5 Determine the site to be used to perform pulse oximetry. The site should have a good blood supply, determined by checking it is warm, with a proximal pulse and brisk capillary refill.	To ensure the sensor will get strong enough signals to produce a result by being located in a well-perfused area (Adam and Osborne 2005, E ; Jevon and Ewens 2000, E ; Levine 2007, E).
6 Ensure that the area to be used is clean and free from dirt, and that the sensor is also clean (Moore 2009a). If using the patient's fingers, ensure that all nail polish and any artificial nails have been removed.	Dirt or nail polish may interfere with the transmission of the light signals, causing inaccurate results (Booker 2008, E ; Moore 2009a, E).

(continued)

Procedure guideline 11.4 Respiratory assessment and pulse oximetry (continued)

Action	Rationale
7 Select the correct pulse oximeter sensor for the site which is most appropriate for your patient, dependent on circulation and the manufacturer's instructions.	The correct sensor should be used for each site to ensure good contact, that excessive pressure is not applied (Levine 2007, E) and that an accurate reading from the chosen site is obtained (Johnson et al. 2012, E).
Procedure	
8 Position the sensor securely but do not secure it with tape, unless specifically recommended by the manufacturer (MHRA 2010) (Action figure 8). If the pulse oximetry is to be continuous then the site should be changed at least every 4 hours.	If the probe is too tight it may impede the blood flow, leading to inaccurate results and the potential for pressure ulcer formation to the site, particularly in patients whose conditions can compromise skin integrity (Goodell 2012, E ; Moore 2009a, E).
9 Turn the pulse oximeter on and, if using continuously, set the alarms on the device dependent on the patient's condition and within locally agreed limits.	To ensure that it is ready to use (Adam and Osborne 2005, E).
10 Ask the patient not to talk while you palpate their pulse. Check that the pulse reading on the device corresponds with the patient's actual pulse.	Any large deviations in pulse may show that the device is not measuring accurately or is being affected by movement (Levine 2007, E ; Moore 2007, E).
11 Assess respiration by keeping your fingers on the patient's wrist once the pulse rate has been obtained. Count their respiratory rate for a full minute – one breath is equal to one inspiration and expiration and is done by watching the abdomen or chest wall move in and out (Hunter and Rawlings-Anderson 2008). Assess the regularity and depth of breathing, the shape and expansion of the chest, and look for any use of accessory muscles.	The patient should ideally not be aware that their respiratory rate is being counted as this may produce inaccurate results (Kallet 2012, E ; Moore 2007, E).
Post-procedure	
12 Document results clearly, including the time and date of the reading.	Records must be kept of all assessments made and care provided (NMC 2010, C).
13 Clean the pulse oximeter according to manufacturer's recommendations and local policy.	It may become colonized and be a source of infection to another patient (Goodall and Allan 2009, E).
14 Wash hands thoroughly with soap and water and dry.	To reduce the risk of cross-contamination (Fraise and Bradley 2009, E).

Action Figure 8 Position of an oxygen saturation probe.

Problem-solving table 11.4 Prevention and resolution (Procedure guideline 11.4)

Problem	Cause	Prevention	Action
Unable to turn on the pulse oximeter.	Low battery.	Ensure the pulse oximeter is left on continuous charge when not in use.	Connect to mains electricity – the pulse oximeter will function once it is connected to a power supply.
Pulse oximeter is working but the heart rate and saturations display is blank.	Loose connection.	Carefully store the cables after use to prevent damage.	Check that the probe is securely connected to the machine.
Poor trace or inconsistent reading.	Movement from shivering, seizures or tremors can affect the accuracy of the reading (Levine 2007, Moore 2007).	Encourage the patient to keep as still as possible. If still unable to obtain an accurate reading, try to use a site which is less affected by movement, for example an ear lobe (Levine 2007, Moore 2007).	If the finger has been used, compare the pulse rate as given by the oximeter with the palpated radial pulse – if there is a difference then the oxygen saturation reading will not be accurate and arterial blood gases may be required to monitor the patient's oxygen saturation, if accurate pulse oximetry cannot be obtained from an alternative site (Levine 2007).
Unexpectedly low result which does not correlate with the patient's clinical condition.	The site chosen may not have an adequate blood supply (Adam and Osborne 2005).	Check for perfusion by palpating for a pulse and checking the area is warm with good capillary refill.	Reposition sensor to new site. If it remains low, arterial blood gases may need to be considered (Adam and Osborne 2005).
Pulse oximetry heart rate does not correlate with palpated pulse.	Not all pulsations are being detected.	Check for perfusion by palpating for a pulse and checking the area is warm with good capillary refill.	Obtain a replacement probe and/or monitor (Moore 2007).

Post-procedural considerations

Immediate care

Any abnormalities of respiration discovered during the respiratory assessment should prompt rapid action (Higginson and Jones 2009) as early intervention is essential to improve patient outcomes (Moore 2007). If there is risk of a compromised airway or respiratory insufficiency/failure then senior nursing and medical assistance, including an anaesthetist, should be requested urgently (RCUK 2011). Further information will be needed, including obtaining:

- a full set of observations including temperature, blood pressure and heart rate (Higginson and Jones 2009)
- a history of the patient's current condition and any past medical history, including a list of the medications they are taking (Bickley and Szilagyi 2009).

Other tests may also be required depending on the condition of the patient. These may include the following.

- Arterial blood gases to check for level of carbon dioxide, oxygen level, pH, acid/base balance (Higginson and Jones 2009).
- Sputum collection to assess for infection and/or specific diseases such as tuberculosis (Moore 2007, Simpson 2006).
- Chest X-ray or CT scan (Simpson 2006).
- Blood tests including a full blood count, urea and electrolytes, clotting screen and cross-match (Docherty 2002).
- Fluid balance to monitor for signs of fluid overload or dehydration (Docherty 2002).

Airway management and administration of oxygen

If a patient's condition necessitates the administration of oxygen, this should be provided as quickly and efficiently as possible. Although oxygen should be prescribed, in an emergency situation the absence of a prescription should not delay its administration (Higginson and Jones 2009). For further information see Chapter 9: Respiratory care.

Ongoing care

As well as involving senior nurses, the medical team and potentially anaesthetists in the care of the patient, it may also be useful to refer the patient to the physiotherapy team for further support and appropriate interventions (Docherty 2002).

Documentation

It is vital that all documentation on oxygen saturations should state whether the patient was breathing air or oxygen, and the flow of oxygen and method of administration (O'Driscoll et al. 2008). If the oxygen is being given in an emergency situation without a prescription then subsequent documentation must state the rationale for the administration of oxygen and the flow rate (O'Driscoll et al. 2008).

Education of patient and relevant others

One of the key focuses of education of patients with respiratory conditions should be to ascertain if they smoke and, if they do, to encourage them to stop as smoking cessation may help to improve their prognosis (Tonnesen et al. 2007). For more information on this topic see Chapter 9: Respiratory care.

Complications

It is recommended that to prevent any tissue damage, the pulse oximeter sensor is not taped in place (unless recommended by the manufacturer) and that the sensor should be resited routinely every 4 hours or more frequently if necessary, depending on the patient's condition and the manufacturer's recommendation. Assess tissues integrity before siting the probe and avoid placement on damaged tissue (Goodell 2012).

Peak flow

Definition

Peak expiratory flow (PEF) is the highest flow achieved on forced expiration from a position of maximum lung inflation expressed in litres per minute (L/min) (Miller et al. 2005). PEF is a simple test of lung function, commonly used to help detect and monitor moderate and severe respiratory disease, and is particularly useful in the diagnosis and monitoring of patients with asthma to assess the degree of airway obstruction, the severity of an asthma attack and response to treatment (Booker 2007, British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012, NICE 2013).

Anatomy and physiology

In healthy individuals without any pathological conditions of the airways, factors which determine PEF include:

- the quality of the large airways
- the volume of the lungs (a function of thoracic dimensions and the individual's stature)
- the elastic properties of the lungs (the degree of stretch the lungs have been subjected to previously and the recoil ability of the lungs)
- the power and co-ordination of the expiratory muscles, primarily abdominal muscles (related to lung inflation and the speed with which maximum alveolar pressure is reached)
- the resistance of the instrument used to measure peak expiratory flow (Quanjer et al. 1997).

Any condition which alters any of the above factors could affect PEF. However, a reduction in one of these factors may be compensated for by an increase in one of the others, meaning that PEF may not alter, resulting in staff potentially underestimating the severity of the condition (Quanjer et al. 1997).

Related theory

Peak expiratory flow reflects a range of physiological characteristics of the lungs, airways and neuromusculature; the most common disorders which affect PEF are those which increase the resistance to air flow in the large conducting intrathoracic airways, such as asthma (Booker 2009, Quanjer et al. 1997). However, PEF may also be impaired by:

- disorders which limit chest movement and respiratory musculoskeletal problems
- obstruction of the extrathoracic airways
- impairment of nerves supplying the respiratory system (Quanjer et al. 1997).

Peak expiratory flow readings are subject to individual variation depending on the patient's age, gender, ethnic origin and stature (Quanjer et al. 1997). Therefore, the patient's results should be compared against normal reference values for people of the same age, gender and height (Figure 11.24) and more importantly against previous results for that individual (Higgins 2005, Jevon 2007b).

Figure 11.24 Normal peak expiratory flow rate measurements. Source: Reproduced with permission from Clement Clarke International, Ltd (www.peakflow.com).

Peak expiratory flow is similar to forced expired volume in 1 second (FEV₁) measurements but the two are not interchangeable and both measure different aspects of lung function (Ruffin 2004). FEV₁ measures the volume of air exhaled during the first second of forced vital capacity (FVC), which occurs when an individual exhales forcefully to their maximum capacity following a deep inspiration (Marieb and Hoehn 2010). FEV₁ is usually 80% of FVC in healthy participants (Marieb and Hoehn 2010). FEV₁ is felt to be more sensitive in detecting mild airway obstruction as peak expiratory flow is effort dependent and so can have a greater degree of intrasubject variability (Hansen et al. 2001). However, both FEV₁ and PEF were found to have similar predictive ability in relation to mortality in patients with COPD, although FEV₁ was found to be a better predictor in patients with asthma (Booker 2009, Hansen et al. 2001).

Evidence-based approaches

Rationale

Peak expiratory flow is a simple, objective procedure which can be used to measure the degree of air flow limitation and, although it may not give a full representation of lung function, it can monitor efficacy of treatment and progression of the condition (Frew and Doffman 2012).

Indications

Peak expiratory flow can be used to:

- confirm a diagnosis of asthma and identify asthma control (Booker 2009, Ruffin 2004)
- determine the severity of an asthma exacerbation (Booker 2009)
- monitor the severity of the condition in patients with chronic severe asthma (Reddel 2006)
- identify exacerbating factors (Reddel 2006)

- monitor progression of respiratory disease (Frew and Doffman 2012)
- evaluate effectiveness of treatment (Frew and Doffman 2012).

Contraindications

There are no absolute contraindications for peak expiratory flow measurement but PEF should be used and interpreted with caution in the following situations.

- Patients who are acutely breathless, as the procedure requires physical effort (Higgins 2005)
- Patients with severe air flow obstruction, as included in the measurement may be air coming from the collapsing airway, yielding an erroneously high result (Quanjer et al. 1997).
- Patients unable to take a full inspiration, for example if they have a persistent cough, as the results will be inaccurate (Quanjer et al. 1997).
- Consecutive results producing a reduction in scoring – the procedure itself may cause an exacerbation of the air flow limitation (Quanjer et al. 1997).
- Young children may not understand or be able to comply with the procedure correctly (Gorelick et al. 2004).

Methods for measuring peak flow

Treatment is often based on PEF measurements and so it is vital that these are as accurate as possible. Patients should be advised to perform PEF measurements in accordance with their monitoring regimen even if symptom free (Buist et al. 2006) as trends can be more important than isolated results (unless the isolated results reflect an exacerbation) (Booker 2009). The patient should repeat the procedure three times with the best result of the three being documented (Miller et al. 2005). Unless the procedure induces an exacerbation, there should be consistency between the three results. If the top two results have a greater disparity than 40 L/min then, as long as the patient is not fatigued, a further two attempts can be made to reach a greater level of consistency (Miller et al. 2005).

Timing of peak flow readings

Whilst an isolated PEF measurement can indicate a restriction in air flow, in general sequential measurements are of more value, displaying trends essential to understanding the severity and progression of the disease (Booker 2009, Quanjer et al. 1997). However, there may be significant diurnal variations, with higher values obtained in the evenings and the lowest measurements occurring during the night and first thing in the morning (Jevon 2007b, Quanjer et al. 1997). Therefore, it is recommended that measurements should be taken and documented on waking, in the afternoon and prior to going to bed (Frew and Doffman 2012). If it is suspected that the patient may have restricted air flow due to occupational causes, the patient should take measurements for a minimum of 2 weeks while at work and 2 weeks while not at work to enable a comparison (Frew and Doffman 2012).

Legal and professional issues

Competencies

All healthcare professionals who measure PEF must have received appropriate approved training and undertaken supervised practice; this role should be undertaken in accordance with local hospital policy (Higgins 2005, Jevon 2007b).

Pre-procedural considerations

Equipment

Wright and mini-Wright peak flow meter

Peak flow is measured by the patient exhaling as quickly and forcefully as possible following maximal inspiration; the

maximum expiratory flow is measured by the PEF meter and usually occurs early in expiration (Bongers and O'Driscoll 2006). The Wright peak flow meter was developed in 1959 as a portable, simple device for monitoring PEF in the home. It has since been redesigned as the mini-Wright peak flow meter which is commonly used today (Ruffin 2004). In September 2004 the scales of measurement used on peak flow meters were changed from the non-linear Wright scale, which was found to overestimate PEF by up to 30%, to a new EU scale (Bongers and O'Driscoll 2006). The EU scale specifies one measurement range from 60 L/min to 800 L/min and increases the accuracy of the assessment, enhancing the ability to compare measurements with conventional spirometry (Higgins 2005). All new prescriptions and sales of peak flow meters in the European Union after this time have been for this new model which is labelled as 'EN 13826' or 'EU scale'.

Patients with their own meter should be encouraged to bring it with them to appointments. If the patient does not have their own meter then most hospitals and clinics have multiple patient use PEF meters which are valved and have disposable single patient use mouthpieces to prevent infection (Booker 2009). Most hand-held PEF meters do not need day-to-day calibration (Miller et al. 2005) but all PEF meters should be replaced annually as with regular use the spring becomes slack and so the meter becomes inaccurate (Booker 2007).

All PEF meters should be used and maintained in accordance with the manufacturer's instructions. In settings where meters are used between patients, a log should be kept of cleaning and disinfection procedures and disposable one-way mouthpieces that prevent patients inhaling through the meter should be used (Booker 2007).

Spirometers

Spirometers can produce a reading for PEF alongside other lung function measurements such as FVC. However, these results may not be comparable to those obtained using a mini-Wright meter due to both the equipment and technique used. Therefore, the patient should use the same equipment and technique each time to enable comparisons with previous results (Bongers and O'Driscoll 2006).

Assessment and recording tools

Recording peak flow measurements on individualized action plans/booklets gives patients a greater degree of control and awareness about when they need to access medical care. The use of these recording tools is strongly advocated (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012, Gibson et al. 2003).

Specific patient preparation

The procedure should be performed when the patient is at rest (unless otherwise specified) and may be performed with them sitting upright or standing as long as their neck is not flexed (Quanjer et al. 1997). To increase reliability and enable comparisons to be drawn, it is advisable that the patient uses the same posture each time (Booker 2009).

Education

The practitioner must ensure that the patient is fully informed about how to perform the procedure and performs it accurately, as even small alterations in technique may produce inaccurate results. If the patient has not performed the procedure previously then they will need a full explanation of what PEF is, what it measures and how they should interpret and act on the results (Higgins 2005). Patients should have the opportunity to have the procedure demonstrated for them and have their own practice attempts (Quanjer et al. 1997).

Procedure guideline 11.5 Peak flow reading using a manual peak flow meter*Essential equipment*

- Peak flow meter
- Disposable mouthpiece
- Peak flow chart to document results and a pen
- Other respiratory function tests including pulse oximetry
- Oxygen mask and oxygen source
- Equipment to give a nebulizer
- Emergency resuscitation equipment

*Pre-procedure***Action****Rationale**

- | | |
|--|---|
| 1 Explain the procedure to the patient and obtain their consent. | To ensure the patient understands the procedure and gives valid consent (NMC 2013, C). |
| 2 Ask the patient what their best peak flow measurements have been and what their current peak flow readings are. | This will enable a comparison to be drawn between their current and previous results (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012, C). |
| 3 Wash and dry hands or use alcohol handrub. | To minimize the spread of cross-infection (Fraise and Bradley 2009, E). |
| 4 Assemble equipment; ask the patient to use their own meter, if it is in good working order and less than 1 year old.
If using a multiple patient use device, ensure that it is valved and has a disposable single patient use mouthpiece. | As different equipment might have slight variations in results (Bongers and O'Driscoll 2006, E). Regular use causes the spring to become slack and so the meter may become inaccurate (Booker 2007, E).
To prevent cross-infection (Booker 2009, E). |
| 5 Ask the patient to adopt the position in which they normally undertake the procedure; this can be either standing or sitting. They should be advised not to flex their neck. | In order that their maximal lung volume can be reached and so that there is no positional obstruction which could affect the results, and to enable comparisons between results (Booker 2009, E ; Quanjer et al. 1997, E). |
| 6 Push needle on the gauge down to zero. | To ensure the results are accurate (Booker 2009, E). |

Procedure

- | | |
|--|---|
| 7 Ask the patient to hold the peak flow meter horizontally, ensuring their fingers do not impede the gauge. | So that the movement of the needle is not obstructed and can move easily (Booker 2009, E ; Frew and Doffman 2012, E). |
| 8 Ask the patient to take a deep breath in through their mouth to full inspiration. | To ensure they achieve the greatest measurement (Frew and Doffman 2012, E ; Quanjer et al. 1997, E). |
| 9 Ask the patient to immediately place their lips tightly around the mouthpiece. The inspiration should be held for no longer than 2 seconds at total lung capacity. | To ensure a good seal around the mouthpiece and to prevent their tongue and teeth from obstructing it (Booker 2009, E ; Quanjer et al. 1997, E). |
| 10 Ask the patient to blow out through the meter in a short sharp 'huff' as forcefully as they can. See Action figure 10 . | This can be very quick and need only take about 1 second, to enable accuracy of results (Booker 2009, E ; Quanjer et al. 1997, E). |
| 11 Take a note of the reading and return the needle on the gauge to zero. Ask the patient to take a moment to rest and then repeat the procedure twice, noting the reading each time. Ideally there should be less than 20 L/min difference between the three readings. If there is more than 40 L/min difference in the recordings, two additional blows can be performed. Document the highest of the three acceptable readings, stating the specific time or previous medication. | To ensure that the best possible result is achieved (Frew and Doffman 2012, E ; Miller et al. 2005, E ; Quanjer et al. 1997, E). |

Post-procedure

- | | |
|---|---|
| 12 Document the readings on the patient's record chart, comparing measured values against predicted values or patient trends and report any abnormality to medical or senior nursing staff. | Records must be kept of all assessments made, treatment or care provided and the outcome of this (NMC 2010, C). |
| 13 Dispose of the mouthpiece and clean the meter in line with local policies and the manufacturer's recommendation. | To prevent the risk of cross-infection (Fraise and Bradley 2009, E). |
| 14 Wash and dry hands or use alcohol handrub. | To minimize the spread of cross-infection (Fraise and Bradley 2009, E). |

Action Figure 10 Manual peak flow meter technique.

Problem-solving table 11.5 Prevention and resolution (Procedure guideline 11.5)

Problem	Cause	Prevention	Action
A higher than expected result is obtained.	May be caused by the needle not being pushed back to zero prior to commencement, or by poor technique leading to 'explosive decompression' whereby there is sudden opening of the glottis, or release of the tongue occluding the mouthpiece, or caused by coughing or spitting into the mouthpiece (Quanjer et al. 1997).	Allow practice runs prior to the procedure and ensure that the patient is educated on technique.	Reset the needle back to zero, educate the patient on the correct technique, and if they appear fatigued, allow them to rest prior to repeating the procedure.
A lower than expected result is obtained.	Failing to take a maximal inhalation. Holding breath at maximal inhalation and delaying blowing into the meter. Failure to make maximum effort. Mouthpiece leaks due to blowing out cheeks, loose-fitting dentures or facial palsy (Booker 2007).	Allow practice runs prior to the procedure and ensure that the patient is educated on the correct technique.	Reset the needle back to zero, educate the patient on the correct technique, and if they appear fatigued, allow them to rest prior to repeating the procedure.

Post-procedural considerations

Immediate care

A reduction in peak flow may indicate a life-threatening situation and so should receive urgent medical attention. For example, a PEF <50% of the reference value indicates acute severe asthma and <33% indicates acute life-threatening asthma (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012). The treatment provided will be aimed at increasing air flow and oxygenation. Oxygen therapy is usually applied with the aim of keeping oxygen saturations at 94–98% (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012). In patients who are known, or suspected, to have hypercapnia, oxygen should be initially administered at 28% via a Venturi mask out of hospital, and in hospital at 24% via a Venturi mask, unless their condition is of such severity to require a greater flow (O'Driscoll et al. 2008). However, if the patient's oxygen saturation exceeds 92% then the flow of oxygen should be reduced (O'Driscoll et al. 2008).

All these patients will require arterial blood gas samples to be taken at the earliest opportunity to enable their condition to be more thoroughly assessed (O'Driscoll et al. 2008). Medication will be used to try and reverse the air flow reduction and will usually include a combination of inhaled bronchodilators and steroids (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012).

Ongoing care

It should be noted if the patient has experienced or been in contact with any of the following prior to the exacerbation.

- Cold air.
- Heightened levels of emotion.
- Exposure to allergens.
- Viral infection.
- Inhaled irritants such as pollution or dust.
- Medication or drugs, including anti-inflammatories and beta-adrenoreceptor blocking agents.
- Occupational sensitizers (Frew and Doffman 2012).

The patient will probably require other medical tests to assess their condition; these may include chest X-ray, blood and sputum tests (Frew and Doffman 2012).

Education of patient and relevant others

Patient education is vital so that patients can manage their own condition (Buist et al. 2006). This will include information on exacerbating factors, smoking cessation and when to access medical help. Written personalized action plans as part of self-management education have been shown to improve health outcomes for people with asthma, with particularly good evidence for those with moderate-to-severe disease. It is also useful for those who have had recent exacerbations where successful interventions have reduced hospitalizations and emergency department attendances in people with severe asthma; patients also report improvement in outcomes such as self-efficacy, knowledge and confidence (British Thoracic Society/Scottish Intercollegiate Guidelines Network 2012).

634

Temperature

Definition

Body temperature represents the balance between heat production and heat loss (Marieb and Hoehn 2010). If the rate of heat generated equates to the rate of heat lost, the core body temperature will be stable (Tortora and Derrickson 2011). All body tissues produce heat depending on how metabolically active they are. When the body is resting, most heat is generated by the heart, liver, brain and endocrine organs (Marieb and Hoehn 2010).

Anatomy and physiology

Core body temperature measurements are taken to assess for deviation from the normal range of 36–37.5°C, to maintain cell metabolic activity. The core body temperature is set and closely regulated by the thermoregulatory centre of the hypothalamus in the brain (Tortora and Derrickson 2011).

Body temperature is a regulated function of the hypothalamus, and is the balance between heat gain (metabolism) and heat loss (respiration). All tissues produce heat as a result of cell metabolism, and this is increased by exercise and activity (Marieb and Hoehn 2010). Humans have the ability through homeostasis to maintain a constant core temperature in spite of environmental changes. The body core generally has the highest temperature while the skin is the coolest (Figure 11.25). Core temperature reflects the heat of arterial blood and represents the balance between the heat generated by body tissues in metabolic activity and that lost through various mechanisms (Marieb and Hoehn 2010).

The hypothalamus comprises a group of neurones in the anterior and posterior portions, referred to as the preoptic area (Tortora and Derrickson 2011), which works as a thermostat (Figure 11.26). A relatively constant temperature is maintained by homeostasis, which is a constant process of heat gain and heat loss. The body requires stability of its temperature to produce an optimum environment for biochemical and enzymic reactions to maintain cellular function. Body temperature above or below this normal range affects total body function (Marieb and Hoehn 2010). A temperature above 41°C can cause convulsions and a temperature of 43°C renders life unsustainable.

Heat is a by-product of the metabolic reactions of all cells in the body, especially of the muscles and liver (Jenkins and Tortora 2013). Heat loss is achieved through the skin by the processes of radiation, convection, conduction and evaporation (Marieb and Hoehn 2010). Various factors cause fluctuations of temperature.

- The body's circadian rhythms cause daily fluctuations. The body temperature is higher in the evening than in the morning (Marieb and Hoehn 2010). Minor and Waterhouse (1981)

Figure 11.25 Body core and skin temperature.

recorded a difference of 0.5–1.5°C between morning and evening measurements.

- Ovulation can elevate the body's temperature as it influences the basal metabolic rate (Tortora and Derrickson 2011).
- Exercise and eating cause an elevation in temperature (Marieb and Hoehn 2010).
- Extremes of age affect a person's response to environmental change. While young people will shiver at a temperature of 36°, most people over the age of 80 will not shiver until the body temperature falls to 35.1° (Kenney and Munce 2003). Thermoregulation is inadequate in the newborn and especially in low-birthweight babies. In older people, there is an increased sensitivity to cold and the body temperature is generally lower (Nakamura et al. 1997).

Related theory

Hypothermia

Hypothermia (lowered body temperature) is defined as a core temperature of 35°C (Frink et al. 2012) that causes the metabolic rate to decrease (Trim 2005). Hypothermia may be classified as mild (32–35°C), moderate (28–32°C) and severe (less than 28°C) (Cuddy 2004). Hypothermia occurs when the body loses more heat and is subsequently unable to maintain homeostasis (Neno 2005). In contrast to a raised temperature, during hypothermia cellular metabolism slows, and the need for oxygen is reduced as more oxygen remains bound to haemoglobin (Jenkins and Tortora 2013). This can lead to a reduction in respiratory rate.

If the temperature does fall below 35°C, the patient will start to shiver severely (Edwards 1997). However, hypothermia frequently escapes detection due to symptoms being non-specific and an oral thermometer's failure to record in the appropriate range (Marini and Wheeler 2012). It can occur in all ages, although the

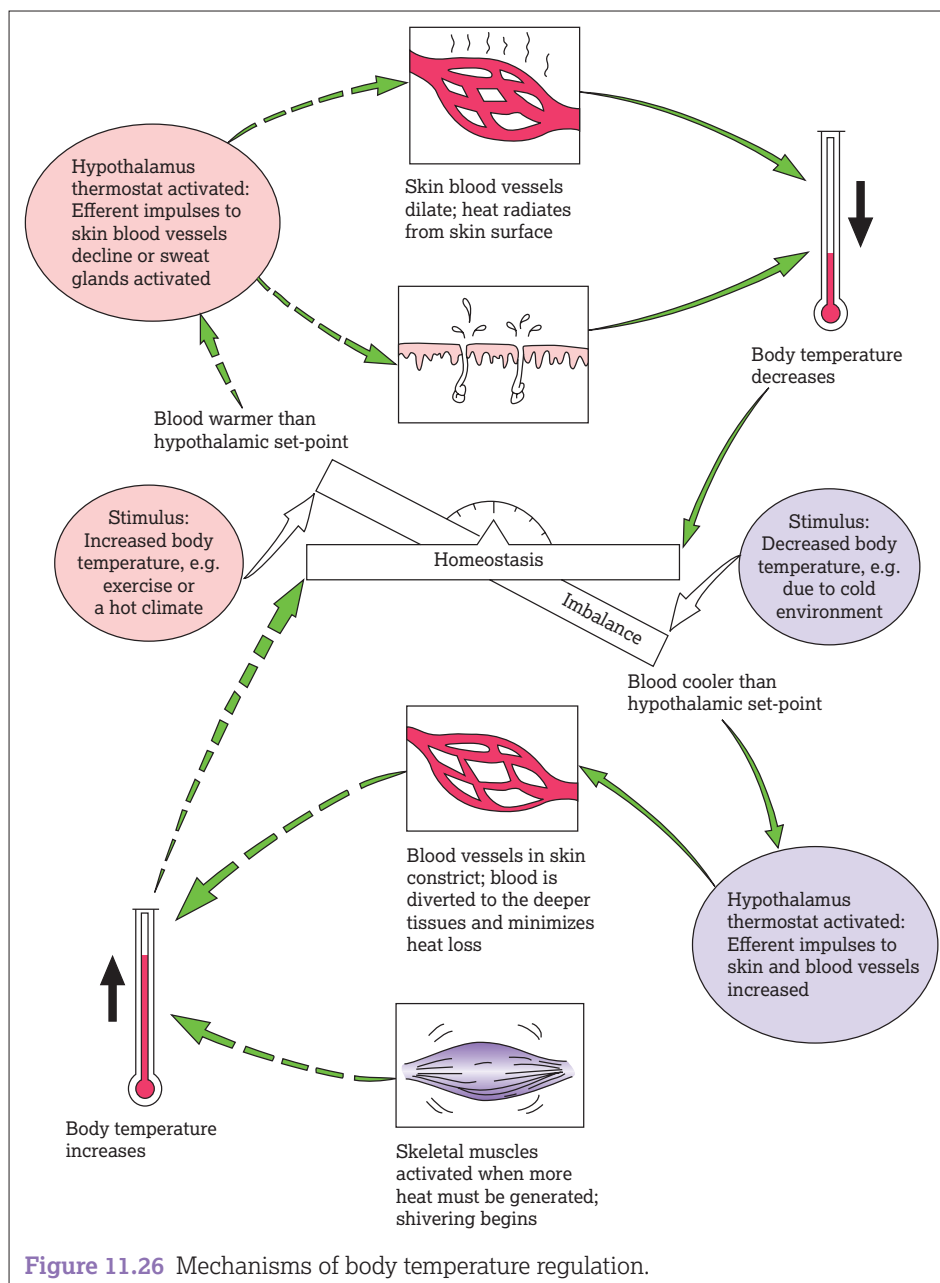

Figure 11.26 Mechanisms of body temperature regulation.

elderly are at particular risk, and is often multifactorial in origin with other risk factors including a Body Mass Index lower than 30 or an ambient temperature lower than 20°C (68°F) (Winslow et al. 2012).

Hypothermia can arise as a result of:

- environmental exposure
- medications that can alter the perception of cold, increase heat loss through vasodilation or inhibit heat generation, for example alcohol or paracetamol
- metabolic conditions, for example hypoglycaemia and adrenal insufficiency
- the exposure of the body and internal organs during surgery and the use of drugs which dampen the vasoconstrictor response (Marini and Wheeler 2012).

There are three known entities of hypothermia: induced, endogenous and accidental (Frink et al. 2012). Induced hypother-

mia is commonly used in elective cardiac surgery and in the management of patients with brain injuries (Yokobori et al. 2011). This is due to the theorized protective effects on apoptosis and the post-traumatic immune response (Frink et al. 2012).

Endogenous hypothermia results from a metabolic dysfunction with decreased heat production (e.g. hypothyroidism, hypoglycaemia, hypoadrenalism) or disturbed thermoregulation (e.g. intracranial tumour or degenerative neurological disorders). Finally, accidental hypothermia is characterized by an unintentional decrease of the core temperature, due to exposure to a cold environment without a thermoregulative dysfunction (Frink et al. 2012).

Surgical patients having procedures longer than 1 hour have increased disruption to normal homeostatic mechanisms, resulting in a drop in temperature. Complications can include cardiovascular ischaemia, delayed wound healing and increased risk of wound infections and increase in postoperative recovery time (Wagner 2006). To prevent unplanned perioperative hypothermia, aggressive use of convective and conductive warming measures

Table 11.6 Non-infectious causes of hyperthermia

Agonist drugs	Malignancy
Alcohol withdrawal	Malignant hyperthermia
Anticholinergic drugs	Neuroleptic malignant syndrome
Allergic drug or transfusion reaction	Phaeochromocytoma
Autonomic insufficiency	Salicylate intoxication
Crystalline arthritis (gout)	Status epilepticus
Drug allergy	Stroke or central nervous system damage
Heat stroke	Vasculitis hyperthyroidism

636 and an increased ambient temperature is recommended, especially for the following patients:

- those undergoing major surgery
- those with compromised thermoregulatory systems (such as older adults)
- those undergoing surgery considered to be exceptionally painful (such as total knee arthroscopy) (Benson et al. 2012, Winslow et al. 2012).

Hyperthermia

Sudden temperature elevations usually indicate infection, making it prudent to perform a directed physical examination and, if indicated, obtain appropriate cultures and institute antibiotics. However, although infection is the most common explanation, several life-threatening non-infectious causes of fever are frequently overlooked (Marini and Wheeler 2012) (Table 11.6).

Fever caused by pyrexia (elevated body temperature) is the result of the internal thermostat resetting to higher levels. This is the result of the action of pyrogens, which are chemical substances now known to be cytokines. Cytokines are chemical mediators, which are involved in cellular immunity (Marieb and Hoehn 2010). They enhance the immune response and are released from white blood cells, injured tissues and macrophages. This causes the hypothalamus to release prostaglandins, which in turn reset the hypothalamic thermostat (Scrase and Tranter 2011). The body then promotes heat-producing mechanisms such as vasoconstriction. As a result of vasoconstriction, heat loss from the body surface declines, the skin cools and shivering begins to generate heat. These 'chills' are a sign that body temperature is rising (Marieb and Hoehn 2010) and are often referred to as 'rigors'. Shivering marks a rigor and the patient complains of feeling cold. The temperature quickly rises as a result of the normal physiological response to cold; see the grades of pyrexia in Table 11.7. This results in the following physiological changes.

- Thermoreceptors in the skin are stimulated, resulting in vasoconstriction. This decreases heat loss through conduction and convection.
- Sweat gland activity is reduced to minimize evaporation.

- Shivering occurs; muscles contract and relax out of sequence with each other, thus generating heat.
- The body increases catecholamine and thyroxine levels, elevating the metabolic rate in an attempt to increase temperature (Marieb and Hoehn 2010).

All these changes contribute to a rise in metabolism and a faster rate of diffusion, with an increase in carbon dioxide excretion and the need for oxygen (Jenkins and Tortora 2013). This leads to an increased respiratory rate. When the body temperature reaches its new 'setpoint', the patient no longer complains of feeling cold, shivering ceases and sweating commences.

There are several grades of pyrexia, and these are described in Table 11.7. However, the intensity of a pyrexia is not an indicator of the severity of infection (NICE 2007a), which varies from person to person.

Evidence-based approaches

Rationale

Core body temperature measurements are taken to assess for deviation from the normal range that may indicate disease, deterioration in condition, infection or reaction to treatment.

Body temperature measurement is part of routine care in clinical practice and can influence important decisions regarding tests, diagnosis and treatment (Lefrant et al. 2003). Temperature needs to be measured accurately and monitored effectively to enable changes to be detected quickly and any necessary intervention commenced (NICE 2007a, van Vliet et al. 2010). Temperature assessment accuracy depends on several factors: measurement technique, device type, body site and a healthcare professional's training (McCallum and Higgins 2012). Temperature recording is a core assessment (and reassessment) in nursing practice, but can create clinical issues if not performed appropriately (Docherty 2000).

Indications

Conditions in which a patient's temperature requires careful monitoring include the following.

- Patients with conditions that affect basal metabolic rate, such as disorders of the thyroid gland, require monitoring of body temperature. Hypothyroidism is a condition where inadequate secretion of hormones from the thyroid gland results in slowing of physical and metabolic activity; thus the individual has a decrease in body temperature. Hyperthyroidism is excessive activity of the thyroid gland; a hypermetabolic condition results, with an increase in all metabolic processes. The patient complains of a low heat tolerance. Thyrotoxic crisis is a sudden increase in thyroid hormones and can cause a hyperpyrexia (Walsh and Crumby 2007).
- Post-operative and critically ill patients require monitoring of temperature. The patient's temperature should be observed pre-operatively in order to make any significant comparisons. In the post-operative period the nurse should observe the patient for hyperthermia or hypothermia as a reaction to the surgical procedures (Wagner 2006).
- Patients with a susceptibility to infection, for example those with a low white blood cell count (less than 1000 cells/mm³) or

Table 11.7 Grades of pyrexia

Level of pyrexia	Temperature	Remarks
Low-grade pyrexia	Normal to 38°C	Indicative of an inflammatory response due to a mild infection, allergy, disturbance of body tissue by trauma, surgery, malignancy or thrombosis
Moderate to high-grade pyrexia	38–40°C	May be caused by wound, respiratory or urinary tract infections
Hyperpyrexia	40°C and above	May arise because of bacteraemia, damage to the hypothalamus or high environmental temperatures

those undergoing radiotherapy, chemotherapy or steroid treatment will require more frequent observation of temperature. The fluctuation in temperature is influenced by the body's response to pyrogens. Immunocompromised patients are less able to respond to infection. Bacteraemia means a bacterial invasion of the bloodstream. Septic shock is a circulatory collapse as a result of severe infection. Pyrexia may be absent in those who are immunosuppressed or in the elderly (Neno 2005).

- Patients with a systemic or local infection require monitoring of temperature to assess development or regression of infection.
- Pyrexia can occur when patients are receiving a blood transfusion but severe transfusion reactions usually occur within the first 15 minutes of starting (British Society for Haematology 2009).

Methods of recording temperature

All metabolizing body cells manufacture heat in varying amounts. Therefore, temperature is not evenly distributed across the body (Childs 2011). The measurement of core body temperature may seem simple, but several issues affect the accuracy of the reading (McCallum and Higgins 2012); these include the measurement site, the reliability of the instrument and user technique (Pusnik and Miklavc 2009).

True core temperature readings can only be measured by invasive means, such as placing a temperature probe into the oesophagus, pulmonary artery or urinary bladder (Childs 2011), and are therefore used most in the critical care setting. This must be undertaken by specialists or nurses who have received additional training that incorporates anatomical imaging technology (Makic et al. 2012).

Traditionally, the mouth, axilla, rectum and external auditory canal have been the preferred sites for obtaining temperature readings, due to their accessibility. As temperature between these sites can vary greatly, ideally the same site should be used continuously throughout patient assessments to allow for comparison, and the location of the site must be recorded on the observation chart (Davie and Amoores 2010). Unfortunately, an accurate, non-invasive method to measure core temperature has yet to be established, as current instruments produce a wide range of temperatures (Hooper and Andrews 2006).

Oral

To most accurately measure the temperature orally, the thermometer is placed in the posterior sublingual pocket of tissue at the base of the tongue (Torrance and Semple 1998). It is important that the thermometer is placed in this region and not in the area under the front of the tongue, as there may be a temperature difference of up to 1.7°C between these areas. This temperature difference is due to the sublingual pockets being protected from the air currents, which cool the frontal areas (Neff et al. 1989). This area is in close proximity to the thermoreceptors which respond rapidly to changes in the core temperature, hence changes in core temperatures are reflected quickly here (Carroll 2000, Stevenson 2004).

Oral temperatures are thought to be affected by ingested foods and fluids, smoking, the muscular activity of chewing, exercise and the environment such as draughts (Mazerolle et al. 2011). A respiratory rate that exceeds 18 breaths per minute, together with a patient who smokes, will also reduce the core temperature values (Knies 2003).

Rectal

The rectal temperature is often higher than the oral temperature because this site is more sheltered from the external environment. Rectal thermometry has been demonstrated in clinical trials to be more accurate than oral or axillary thermometry; however, it is not advocated due to its invasive nature (Trim 2005).

Aspects relating to privacy, dignity and patient choice should be considered when assessing temperature via this route. While other more precise methods can still detect fever, the rectal method offers greater precision in terms of obtaining the core temperature. However, the presence of soft stool may separate the thermometer

from the bowel wall and give a false reading, especially if the central temperature is changing rapidly. In infants and the immunosuppressed, this method is not recommended as it carries a risk of rectal ulceration or perforation (Price and Gwin 2008).

A rectal thermometer should be inserted at least 4 cm into the rectum in an adult to obtain the most accurate reading.

Axillary

The axilla is considered less desirable than the other sites because of the difficulty in achieving accurate and reliable readings (Evans and Kenkre 2006) as it is not close to major vessels, and skin surface temperatures vary more with changes in temperature of the environment (Woollons 1996). It is usually only used for patients who are unsuitable for, or who cannot tolerate, oral thermometers, for example after general anaesthetic or patients with mouth injuries (Edwards 1997).

To take an axillary temperature reading, the thermometer should be placed in the centre of the armpit, with the patient's arm firmly against the side of the chest. It is important that the same arm is used for each measurement, as there is often a variation in temperature between left and right (Heindenreich and Giuffe 1990).

Whichever route is used for temperature measurement, it is important that this is then used consistently, as switching between sites can produce a record that is misleading or difficult to interpret.

Consideration is required when interpreting variations in 4–6 hourly observations, and when taking once-only daily temperatures as the average person experiences circadian rhythms, with the highest body temperature occurring in the late afternoon or early evening, that is between 4 pm and 8 pm. The most sensitive time for detecting pyrexias appears to be between 7 pm and 8 pm (Angerami 1980). Samples et al. (1985) found the highest temperature between 5 pm and 7 pm. These studies suggest that the most useful time to measure and detect an abnormal temperature would be approximately 6 pm.

Tympanic

The tympanic membrane is an increasingly popular method, as it is less invasive and provides rapid results (<1 minute) (McCallum and Higgins 2012). It has been suggested by some that tympanic membrane thermometers give an accurate representation of actual body temperature. This is because the tympanic membrane lies close to the temperature regulation centre in the hypothalamus, shares the same artery and is therefore considered to directly reflect core temperature in adults (Chue et al. 2012).

In 2003, the MHRA published a medical device alert following reports of tympanic thermometers providing low temperature readings and these were attributed to a dirty probe and probe covers and user error (MHRA 2003). A soiled probe or probe cover would record a low temperature because the infra-red emissions from the tympanic membrane will be affected.

Anticipated patient outcomes

To determine the patient's temperature on admission as a baseline for comparison with future measurements and to monitor fluctuations in temperature.

Pre-procedural considerations

Temperature can be measured at a number of different sites, using different tools for measurement. When assessing the body temperature it is important to consider the methods and tools used for measurement (Docherty and Foudy 2006).

The critical issue to consider when using any thermometer is whether you are controlling the factors that affect the accuracy and precision of the measurement. These factors must be addressed when educating staff on the use of different temperature measurement methods. It is therefore important to recall that therapeutic decisions should not be made on the basis of a single vital sign (Bridges and Thomas 2009).

Equipment

There are a number of devices on the market, including electronic contact thermometers, chemical thermometers and infra-red-sensing thermometers, each obtaining temperatures in differing time frames and working in different ways. If the device can be used on multiple sites the programming will need to be altered to reflect the chosen site per manufacturer’s guidelines. Clinical thermometry is governed by the International Standard BS EN ISO 80601-2-56 (British Standards Institution 2012) which stipulates the need for regular calibration and maintenance.

In terms of health and safety, the MHRA advised that equipment with mercury should be replaced, primarily due to the potential for mercury leaks (MHRA 2012). Coupled with the fact that mercury thermometers respond slowly to temperature changes, this has meant that use of an electronic device is preferable when recording temperature extremes and rapid fluctuations (Marini and Wheeler 2012). In clinical practice other types of thermometer should be used instead.

- Single-use plastic-coated strips with heat-sensitive recorders (dots) which change colour to indicate the temperature (record from 35.5 to 40.4°C).
- Digital analogue probe thermometers with plastic disposable sheets (record from 32 to 42°C).
- Invasive thermometers attached to a pulmonary artery catheter (record from 0 to 50°C) (Braun et al. 1998, O’Toole 1997).

Tympanic membrane thermometer

Tympanic thermometers are small hand-held devices that have a disposable probe cover that is inserted into the patient’s ear canal. The sensor at the end of the probe records the infra-red radiation (IRR) that is emitted by the tympanic membrane, as a result of its warmth, and converts this into a temperature reading presented on a digital screen (Davie and Amoore 2010). The probe is protected by a disposable cover, which is changed between patients to prevent cross-infection (Gallimore 2004). Advantages of tympanic membrane thermometry are speed (temperature reading available within seconds), safety and ease of use (Gasim et al. 2013).

A common problem with using tympanic thermometers is poor technique leading to inaccurate temperature measurements (Farnel et al. 2005, Gilbert et al. 2002). The placement of the probe to fit snugly within the ear canal (Figure 11.27) is crucial

Figure 11.27 Tympanic membrane thermometer.

as differences between the opening of the ear canal and the tympanic membrane can be as much as 2.8°C (Munro 2009). Jevon and Jevon (2001) highlight other causes of false readings, which include dirty or cracked probe lens, incorrect installation of the probe cover and short time intervals between measurements (less than 2–3 minutes). Ear infections and wax are reported to influence the true temperature of the tympanum (Callejo et al. 2004, Farnel et al. 2005), therefore the ear should be inspected prior to obtaining a reading and if wax or evidence of an infection is present, an alternative route for obtaining the temperature should be sought. For infection prevention and control purposes, the appropriate disposable probe cover should be used and the nurse should inspect the cover to ensure that it has been fitted correctly and that there are no wrinkles over the tip end. This will ensure an accurate reading is achieved (Davie and Amoore 2010).

Specific patient preparation

Ask the patient when they last ate, smoked and had a drink as these may influence their temperature.

Procedure guideline 11.6 Temperature measurement	
Essential equipment <ul style="list-style-type: none">• Tympanic membrane thermometer• Disposable probe covers• Alcohol handrub	
Pre-procedure	
Action	Rationale
1 Explain and discuss procedure with the patient. If patient is wearing a hearing aid, remove the device from the ear and wait 10 minutes before taking a reading.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Wash and dry hands.	To minimize the risks of cross-infection and contamination (Fraise and Bradley 2009, E).
Procedure	
3 Inspect the ear canal for the presence of ear drainage, blood, cerebrospinal fluid, vernix, cerumen (compacted ear wax) or foreign bodies.	The presence of these substances can affect the accuracy of the reading (Covidien 2011, C). Ear wax does not affect accuracy but cerumen plugs or impactions containing debris can lower the temperature measurement by several tenths of a degree (Covidien 2011, C).

4 Remove thermometer from the base unit and ensure the lens is clean, not cracked and that the probe lens is free of smudge/debris. Use a dry lint-free swab to wipe clean if required and calibrate according to the manufacturer's guidelines.	Alcohol-based wipes should not be used as this can lead to a false low temperature measurement (Jevon and Jevon 2001, E).
5 Verify the mode setting on LCD display to show the route by which the temperature is due to be measured, e.g. ear, oral, core, rectal or axillary.	To ensure accuracy when interpreting the result (Covidien 2011, C).
6 Place disposable probe cover on the probe tip, ensuring the manufacturer's instructions are followed, e.g. ensuring the cover is flush with the thermometer end and not touching the plastic film on the distal tip of the probe cover.	The probe cover protects the tip of the probe and is necessary for the functioning of the instrument (Jevon and Jevon 2001, E).
7 Obtain a reading from both ears and take the greater of the readings. A new probe cover must be used for each reading to ensure the highest degree of accuracy and to prevent cross-contamination between ears.	Recent evidence suggests there are no anatomical differences between the two ears with the newer generation of infra-red tympanic thermometers (Haugan et al. 2013, R3d). However, previous evidence has suggested a difference of up to 1°C (Heusch and McCarthy 2005, R1b ; Jevon and Jevon 2001, E).
8 Ensure the patient has not been lying on either ear in the 20-minute interval immediately preceding temperature measurement (Bridges and Thomas 2009). If a patient is lying on their side, always take the temperature in the exposed ear.	There are significant differences in tympanic temperature caused when the patient has been lying on their ear (Arslan et al. 2011, R3b).
9 Align the probe tip with the ear canal and gently advance into the ear canal until the probe lightly seals the opening, ensuring a snug fit. See Figure 11.27.	To prevent air at the opening of the ear from entering it, causing a false low temperature measurement (Covidien 2011, C ; Jevon and Jevon 2001, E).
10 Press and release SCAN button.	To commence the scanning (Covidien 2011, C).
11 Remove probe tip from the ear as soon as the thermometer display reads DONE or displays the temperature reading, usually indicated by beeps.	To ensure procedure is carried out for allocated time. Measurement is usually complete within seconds (Gasim et al. 2013, E).
12 Read the temperature display and document in the patient's records and compare with previous results along with the ear used. Take action as appropriate.	Any interruption in the process may result in the measurement being incorrectly remembered (O'Brien et al. 2003, E). Deviations from normal temperature ranges may result in urgent medical/clinical attention (Jevon and Jevon 2001, E ; NMC 2010, C).
Post-procedure	
13 Press RELEASE/EJECT button to discard probe cover into a waste bin per local infection control guidelines.	Probe covers are for single use only (Covidien 2011, C ; Jevon and Jevon 2001, E).
14 Wipe thermometer clean as per manufacturer's guidelines and return to the base unit for storage.	To reduce the risk of cross-infection (Fraise and Bradley 2009, E).

Problem-solving table 11.6 Prevention and resolution (Procedure guideline 11.6)

Problem	Cause	Prevention	Action
Thermometer is not working properly, for example 'error' is showing.	The battery may be low.	At the first level, the low battery sign is lit and approximately 100 more temperatures may be taken.	Replace the battery.
If the 'wait' indicator is on.	'Wait' indicator will appear if you attempt to take successive temperatures in too short a period of time.	Wait briefly until the 'wait' indicator disappears before taking another temperature.	Retry and if still instructing to 'wait', send for repair.
'Use new cover' showing even though probe cover has been installed.	Probe cover replaced too quickly.	Check that probe cover has been fitted correctly.	Press RELEASE/EJECT button and reinstall probe cover.

Post-procedural considerations

Immediate care

Hyperthermia

A rise in temperature can be regarded as a cure, in that it is part of the autonomic response to remove infection and create a favourable environment for antibiotics (Gardner 2012). A post-operative fever is often a normal inflammatory response to surgery; however, it can also be a manifestation of a serious underlying infectious or non-infectious aetiology (Burke 2010). If a temperature rises above 40°C (hyperthermia), it is dangerous and may indicate that the patient's regulatory systems have failed.

It remains common practice to try to reduce fever with medication such as antipyretics and physical cooling methods. Antipyretics, including paracetamol or ibuprofen, can mask the function of the hypothalamus by reducing the temperature while hiding the underlying signs of disease (Cuddy 2004). It is thought that these drugs inhibit the inflammatory action of prostaglandins, affecting the hypothalamus by temporarily resetting the thermostat to normal levels. Currently the evidence on how to reduce fever in practice is weak and does not support the routine administration of antipyretic therapies (Carey 2010, Outzen 2009). Therefore nurses should assess patients individually, using antipyretic therapies selectively and with caution. Physical cooling methods alone should never be used (Carey 2010).

Consideration of a patient's comfort is also important (although caution and individualized assessment are also needed when considering physical cooling methods). Fanning is of benefit for moderate-to-high pyrexia but fanning and tepid sponging are not recommended while the patient's temperature is still rising as this will only make the patient feel colder, and could cause distress (Sharber 1997). Fanning during this time can actually increase a person's body temperature as it can stimulate a compensatory response by the hypothalamus, initiating heat-gaining activities such as shivering and peripheral vasoconstriction that could compromise unstable patients by depleting their metabolic reserve (Brooker and Nicol 2003, Carey 2010).

Nurses should be aware of the side-effects associated with cooling techniques, such as:

- arrhythmias, bradycardia
- coagulation pathway impairment
- electrolyte disorders from intracellular shifts and renal excretion (calcium, magnesium, phosphate and potassium levels can be affected)
- insulin resistance with hyperglycaemia
- patient discomfort from shivering and skin breakdown (Polderman et al. 2009).

Comfort measures in addition to reassurance may include:

- providing dry clothing and bedlinen
- offering oral hygiene to keep the mouth moist
- limit patient exertion to minimize heat production, particularly during the flush stage
- offering sufficient nutrition and fluids (2.5–3 L daily) to meet the patient's higher metabolic demands to avoid dehydration
- providing extra blankets when the patient feels cold, but remove surplus blankets when the patient complains of too much warmth (Kozier et al. 2008).

Hypothermia

The immediate management of a low temperature needs to address potential emergency conditions, such as cardiac arrhythmias and hypotension, as well as fluid and electrolyte shifts (Davis 2012). Nursing management should therefore focus on preventing further heat loss and rewarming the body core temperature because there is an increased risk of mortality and morbidity below 34°C (Frink et al. 2012).

Davis (2012) suggests there are three basic types of hypothermia treatment: passive external, active external and active internal rewarming. Passive treatments include removing wet clothing and providing a greater insulation. Passive external rewarming is used for patients with mild hypothermia (34–35°C), who are neither neurologically nor cardiovascularly compromised and are still able to generate heat. Active external methods are advised for moderate (30–33.9°C) accidental hypothermia and poor cardiac performance and include forced-air/warm blankets and water circulating suits (Davis 2012). Active internal methods are reserved for patients who have severe hypothermia (<30°C) and are haemodynamically unstable. Active internal methods include the use of warmed intravenous fluids such as saline or blood, because a 2 litre crystalloid bag administered at a temperature of 18°C will decrease a patient's core temperature about 0.6°C (Hohlrieder et al. 2007). Other active internal techniques include warmed oxygen administration, and bladder, peritoneal or thoracic lavage (Davis 2012).

During any rewarming process attention must be paid to the speed because patients who are warmed slowly have a higher mortality rate (Vassal et al. 2001) and rewarming that results in hyperthermia has been reported to cause ischaemia and hypoxia (Kjaergaard and Bach 2006). For both active external and internal treatment types, specific training and knowledge of the associated devices and products are necessary.

Documentation

Recordings of body temperature are an index of biological function and a valuable indicator of a patient's health.

Urinalysis

Definition

Urinalysis is the analysis of the volume and physical, chemical and microscopic properties of urine (Tortora and Derrickson 2011) and can provide valuable information about a patient's condition, allowing detection of systemic disease and infection (Bishop 2008).

Anatomy and physiology

Urine is formed in the kidneys, which process approximately 180 litres of blood-derived fluid a day. Approximately 1% of this total actually leaves the body as urine, the rest returns to the circulation (Marieb and Hoehn 2010). Urine formation, and the simultaneous adjustment of blood composition, involves three processes (Figure 11.28):

- glomerular filtration
- tubular reabsorption
- tubular secretion (Marieb and Hoehn 2010).

Glomerular filtration

This occurs in the glomeruli of the kidney, which act as non-selective filters. Filtration occurs as a result of increased glomerular blood pressure caused by the difference in diameter between afferent and efferent arterioles. The effect is a simple mechanical filter that permits substances smaller than plasma proteins to pass from the glomeruli to the glomerular capsule (Marieb and Hoehn 2010).

Tubular reabsorption

Tubular reabsorption then occurs, removing necessary substances from the filtrate and returning them to the peritubular capillaries. Tubular reabsorption is an active process that requires protein carriers and energy. Substances reabsorbed include nutrients and most ions. It is also a passive process, however, driven by electrochemical gradients. Substances reabsorbed in this way include sodium ions and water. Creatinine and the

Figure 11.28 Summary of filtration, reabsorption and secretion in the nephron and collecting duct. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

metabolites of drugs are not reabsorbed because of their size, insolubility or a lack of carriers. Most of the nutrients, 65% of the water and sodium ions, and the majority of actively transported ions are reabsorbed in the proximal convoluted tubules (Marieb and Hoehn 2010).

Reabsorption of additional sodium ions and water occurs in the distal tubules and collecting ducts and is hormonally controlled. Aldosterone increases the reabsorption of sodium, and antidiuretic hormone (ADH) enhances water reabsorption by the collecting ducts (Marieb and Hoehn 2010).

Tubular secretion

Tubular secretion is an active process that is important in eliminating drugs, certain wastes and excess ions and in maintaining the acid/base balance of blood (Marieb and Hoehn 2010).

Regulation of urine concentration and volume occurs in the loop of Henle, where the osmolarity of the filtrate is controlled. As the filtrate flows through the tubules, the permeability of the walls controls how dilute or concentrated the resulting urine will be. In the absence of ADH, dilute urine is formed because the filtrate is not reabsorbed as it passes through the kidneys. As levels of ADH increase, the collecting tubules become more permeable to water, and water moves out of the filtrate back into the blood. Consequently, more concentrated urine is produced, and in smaller amounts (Marieb and Hoehn 2010).

Urine is a clear, straw-coloured fluid. The normal composition of urine includes water, urea, creatinine, sodium, potassium, organic acids, protein, small traces of glucose and cellular components.

The colour of urine is due to a pigment called urochrome which is derived from the body's destruction of haemoglobin. The more concentrated urine is, the deeper yellow it becomes. An abnormal colour such as pink or brown may result from eating certain foods (beetroot or rhubarb), or may be due to the presence of bile products or blood (Marieb and Hoehn 2010). Often fresh urine appears turbid (cloudy), indicating that there may be an infection of the urinary tract. The urinary tract is the most common site of bacterial infection. Risk factors for urinary tract infections (UTI) include presence of a urinary catheter, female gender, diabetes and advanced age (Marini and Wheeler 2012). See Figure 11.29 for other UTI predisposing factors.

Bacteriuria is defined as the presence of bacteria in the urine (Rigby and Gray 2005). Urine specimens are rarely sterile, as a result of contamination with periurethral flora during collection. Infection is distinguished by counting the number of bacteria. Significant bacteriuria is defined as the presence of more than 10⁵ organisms per mL of urine in the presence of clinical symptoms (Marini and Wheeler 2012). See Figure 11.30 for illustration of significant bacteriuria.

Fresh urine is slightly aromatic. This can change as a result of disease processes such as diabetes mellitus, when acetone is present in the urine, giving it a fruity smell (Marieb and Hoehn 2010). The composition of urine can change dramatically as a result of disease, and abnormal substances may be present. Urinalysis can identify many of these substances, and should be part of every physical assessment (Cook 1996, Torrance and Elley 1998).

- To assess for pregnancy.
- To detect the presence of drug metabolites or alcohol.
- To contribute to the assessment of hydration.

A sensible approach to urine collection is advised dependent on the clinical situation (Schmiemann et al. 2010). The collection of urine for sampling may be obtained via natural voiding, a pad, a catheter specimen of urine (CSU) or a suprapubic aspirate (SPA) collected via the rubber specimen side port (Struthers et al. 2012). An initial urine investigation with a dipstick, from a fresh spontaneous urine sample, will be sufficient in most clinical situations. In other circumstances, a clean-catch midstream urinalysis (MSU) will be required as contamination is frequent in 'spontaneous' urine collected without any special hygiene precautions (Roche Diagnostics 2010). This is especially the case in women, where urine contains leucocytes in the presence of discharge and erythrocytes in the presence of menstruation. For this reason, no urine testing should be attempted in women for 2–3 days after menstruation finishes (Roche Diagnostics 2010).

When collecting an MSU it is necessary to clean the genitals to ensure the culture specimen is processed with as little contamination as possible. This is to minimize the presence of contaminating elements, such as bacteria, analytes and formed particles (Lifshitz and Kramer 2000, Manoni et al. 2011).

Consideration should be given to whether a urine sample should be obtained at the first or second morning void (before noon). This will be guided by referring to local guidelines and liaising with the requesting party. First morning voids have proven worthwhile for most test purposes (Roche Diagnostics 2010), although clinical circumstances where the first morning void may be necessary include testing for microalbuminuria (Genova Diagnostic 2012, Witte et al. 2009) or spot urine testing for evaluating daily salt intake (Kawamura et al. 2012). This is because the urine has been in the bladder for a reasonably long period, and its composition is independent of daily variations in food and fluid intake and physical activity (Roche Diagnostics 2010).

Indications

The composition of urine can change dramatically as a result of disease processes. Urine may contain red blood cells, glucose,

Evidence-based approaches

Rationale

Urinalysis (urine testing) is commonly undertaken in general practice as a non-invasive means of:

- measuring response to certain treatments
- assessing particular symptoms
- assisting in the diagnosis of medical conditions

and as a part of routine health assessments. Interpretation of urinalysis is generally based on reviewing all the test components and correlating them with the physical examination and the patient's clinical signs and symptoms.

Urinalyses are performed for several reasons.

- To detect renal and metabolic diseases.
- To diagnose diseases or disorders of the kidneys or urinary tract.
- To monitor patients with diabetes mellitus.

proteins, white blood cells or bile (Marieb and Hoehn 2010). It can reveal diseases that have gone unnoticed because they do not produce striking symptoms, and may also be used in ongoing management of conditions (Higgins 2008b).

- *Screening and prevention:* for systemic disease, for example, diabetes mellitus, renal conditions such as kidney or urogenital diseases, liver disease and haemolytic disorders.
- *Diagnosis:* to confirm or exclude suspected conditions, for example urinary tract infection.
- *Management and planning:* to ascertain as a baseline, monitor progress of an existing condition and/or plan programme of care and medication (Roche Diagnostics 2010).

Methods of urinalysis

There are three main methods by which urinalysis is performed.

- Using urine reagent test strips (dipstick).
- Light microscopy.
- Timed collection.

Reagent test strips

Before using a reagent strip to analyse a sample of urine, the following observations should be made to support the overall assessment.

- Colour
- Clarity/debris
- Odour

These properties should be considered with reference to the clinical condition, urine output and fluid balance records over the past 24 hours.

The main advantages of urine dipstick are that it is convenient, quick and non-invasive with results usually determined in a few minutes. The main disadvantages are in terms of accuracy, both with colour changes being affected by the factors listed below and a certain degree of subjectivity during interpretation.

The following are a few examples of factors that can affect the analysis of results and could lead to false positives or negatives.

- Bilirubin and urobilinogen are relatively unstable when subjected to light and at room temperature, so it is important to use fresh urine to obtain the most accurate result (Roche Diagnostics 2010).
- Exposure of unpreserved urine at room temperature for a considerable period of time (>4 hours) may result in an increase in micro-organisms in the urine and change in pH (Veljkovic et al. 2012).
- Bacterial growth of contaminated organisms in urine may produce a positive blood reaction (Roche Diagnostics 2010).
- Urine that is highly alkaline may show false-positive results for the presence of protein (Roche Diagnostics 2010).
- Glucose in urine may reduce its pH as a result of metabolism of glucose by organisms present in the urine (Roche Diagnostics 2010).
- The presence of urea-splitting organisms that convert urea to ammonia may cause urine to become more alkaline (Roche Diagnostics 2010).
- *Drug and chemical interferences:* such as false-positive influence with the leucocyte reading from cefoxitin, levodopa or tetracycline, or false negatives with nitrates from high concentrations of trimethoprim or mesna (Roche Diagnostics 2010).

Light microscopy

Having undertaken a urine dipstick and discovered adverse results, further testing may be necessary under laboratory conditions. This may include culture and sensitivity testing to identify organisms responsible for infection and to determine the most effective treatment (Wilson 2005) (Table 11.8).

Optical or light microscopy involves passing visible light transmitted through or reflected from the sample through single or multiple lenses to allow for a magnified view of the sample. The image generated can then be read and interpreted by the eye, imaged on a photographic plate, or captured digitally. The light microscopy will examine the number and types of cells and/or

Table 11.8 Routine observations of urine: possible indications and plan of action

Observation	Possible indications	Plan of action
Colour		
Green	<i>Pseudomonas</i> infection, presence of bilirubin	Culture and microscopy
	Excretion of cytotoxic agents, for example mitomycin, or substances, for example methylene blue	Discard with care
Pink/red	Blood	Culture and microscopy. If currently receiving chemotherapy, for example ifosfamide, further mesna may need to be given
	Excretion of cytotoxic agents, for example doxorubicin	Discard with care
Orange	Excess urobilinogen, rifampicin	Discard
Yellow	Bilirubin	Discard
Brown	Bilirubin	Discard
Odour		
Fishy	Infection	Culture and microscopy
Sweet smelling	Ketones	Culture and microscopy
Debris		
Cloudy	Infection, stale urine	Culture and microscopy
Sediment	Infection, contamination	Culture and microscopy

material in the urine and can yield a great detail of information and suggest a more specific diagnosis. For light microscopy, an MSU should be used as opposed to a fresh spontaneous sample so that any contaminating bacteria in the urethra are flushed out first, and the sample represents the bladder contents. This reduces the chance of contamination of the specimen with epithelial cells, especially vaginal flora (Struthers et al. 2012).

In the microbiology laboratory, urine samples constitute about 40% of the total workload; of these, 70–80% of samples are not infected (Manickam 2013). This means that much time, energy and finances are wasted on unnecessary sample processing and investigation (Manickam 2013), which is why it is so vital to only send samples where urine dipstick has indicated cause for concern.

Timed urinalysis

Timed urine collection is typically undertaken over an 8-, 12- or 24-hour period. It simply requires a person to collect their urine in a special container over the set period, although it is important to follow local guidelines in terms of the time of day to commence collection, storage and processing requirements. During collection, the sample is usually stored in a cool/refrigerated environment or on ice. This test typically focuses on renal creatinine clearance, sodium and protein. Renal clearance refers to the volume of plasma that is cleared of a particular substance in a given time, usually 1 minute. Renal clearance tests are done to determine the glomerular filtration rate (GFR), which allows us to detect glomerular damage and follow the progress of renal disease (Marieb and Hoehn 2010). Timed urinalysis may also examine hormone levels, urea nitrogen or copper as well as measuring substances such as steroids, white cells and electrolytes or determining urine osmolality (Tortora and Derrickson 2011).

Pre-procedural considerations

Equipment

Dipstick (reagent) tests

Dipstick reagents have been primarily used as screening tools for components in the urine such as protein, glucose or ketones. More sophisticated reagents are now available which test for nitrites and leucocyte esterase as indicators of bacterial infection. Leucocyte esterase is an enzyme from neutrophils not normally found in urine and can be a marker of infection (Reynard et al. 2013). Nitrites are produced by the bacterial breakdown of dietary nitrate, which is a waste product of protein metabolism (Rigby and Gray 2005). Other reagent dipsticks also test for presence of blood, urobilinogen and bilirubin, test the specific gravity and determine the urine pH.

The urine dipstick is usually a narrow plastic strip, which has several squares on it impregnated with chemicals and represented by different colours. Each small square represents one of the components described above. When dipped in urine, the chemicals react with abnormal substances and change colour. Once the

Table 11.9 How drugs may influence the results of reagent sticks

Drug	Reagent test	Effect on the results
Ascorbic acid	Glucose, blood, nitrite	High concentrations may diminish colour
L-dopa	Glucose	High concentrations may give a false-negative reaction
	Ketones	Atypical colour
Nalidixic acid	Urobilinogen	Atypical colour – probenacid
Phenazopyridine (pyridium)	Protein	May give atypical colour
	Ketones	Coloured metabolites may mask a small reaction
	Urobilinogen, bilirubin	May mimic a positive reaction
Rifampicin	Nitrite	Causes false-positive result
	Bilirubin	Coloured metabolites may mask a small reaction
	Glucose	High doses may give a false-negative reaction

strip is quickly dipped into the urine sample and the necessary time has lapsed for the colour changes to take place, the strip is then compared either visually (manually) or electronically (automated) to a standardized colour chart, which will display results in terms of parameters. It is essential to use the strips according to the manufacturer's instructions and be aware of factors that may affect the results, including specific drugs (Table 11.9), the quality of the urine specimen itself and the possibility of false-negative results. There are many different urinalysis test strips available, each testing a different combination of components.

Specific patient preparation

Education

Most patients need advice on hygiene and technique before the procedure to prevent contamination from hands or the genital area (Higgins 2008b) and to ensure that the midstream sample is collected correctly. Midstream urine specimens are indicated in adults and children who are continent and can empty their bladder on request (Gilbert 2006).

Procedure guideline 11.7 Urinalysis: reagent strip procedure

Essential equipment

- Non-sterile disposable gloves
- Apron
- Urine dipsticks, that are in date and have been stored according to the manufacturer's recommendations
- Appropriate urine specimen pot

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

- 2 Wash and dry hands and put on gloves and apron.

To maintain infection control and prevent cross-infection (Fraiese and Bradley 2009, **E**).

Procedure

- 3 If taking the specimen from a urinary catheter, it should be collected using an aseptic technique via the catheter side port. For women, the labia should be separated with cotton wool or a sponge moistened with water, and the vulva should be wiped from the front to the back although disinfectant must never be used. Men should clean the glans penis with soap and water.

To reduce sample contamination (Fraiese and Bradley 2009, **E**; Roche Diagnostics 2010, **C**).

- 4 Obtain a clean specimen of fresh urine from the patient, which is to be analysed within 2 hours from collection. Women should separate the labia. The patient should commence micturition, and when a few millilitres of urine have been passed into the toilet, a container or sterile receptacle should be introduced into the urine stream, and then the remaining urine can pass into the toilet.

Urine that has been stored deteriorates rapidly and can lead to false results (Roche Diagnostics 2010, **C**).

- 5 Check reagent sticks have been stored in accordance with manufacturer's instructions. This is usually a dark dry place in an airtight container.

To ensure reliable results. Tests may depend on enzymic reaction so expired, contaminated or improperly stored strips can give false-positive results such as leucocyte and blood readings (Roche Diagnostics 2010, **C**). Prolonged exposure to the air (nitrous gases) can also affect result accuracy (Roche Diagnostics 2010, **C**).

- 6 Dip the reagent strip into the urine for no longer than 1 second. The strip should be completely immersed in the urine and then removed immediately. Run edge of strip along the container.

To remove any excess urine and prevent mixing of chemicals from adjacent reagent areas (Roche Diagnostics 2010, **C**).

- 7 Hold the stick at an angle.

Urine reagent strips should not be held upright when reading them because urine may run from square to square, mixing various reagents (Roche Diagnostics 2010, **C**).

- 8 Wait the required time before reading the strip against the colour chart, usually 60 seconds (see **Action figure 8**).

The strips must be read at exactly the time interval specified or the reagents will not have time to react, or may be inaccurate (Roche Diagnostics 2010, **C**).

Post-procedure

- 9 Dispose of urine sample appropriately in either sluice or toilet. Dispose of urinalysis stick and gloves in correct wastage bin. Ensure cap to urine reagent strips is replaced immediately and closed tightly.

To ensure strips are in airtight container according to storage guidelines (Roche Diagnostics 2010, **C**).

- 10 Wash and dry hands.

To maintain infection control and prevent cross-infection (Fraiese and Bradley 2009, **E**).

- 11 Document urinalysis readings and inform medical staff of any abnormal readings.

To allow prompt action if change to treatment plan required (NMC 2010, **C**).

Action Figure 8 Compare urinalysis results and document results on appropriate forms.

Post-procedural considerations

When sending a urine specimen to the laboratory, check that the laboratory form is completed and that all relevant information is included. Take care not to contaminate the outside of the container or the request forms (Bishop 2008).

Reagent strips are a quick and easy method of testing urine and can provide valuable information about a patient’s condition. However, patients should be made aware that further tests and investigations may be required if the urine sample indicates any abnormality (Steggall 2007).

Blood glucose

Definition

Blood glucose is the amount of glucose in the blood (Brooker 2010). See Table 11.10 for normal target ranges, which are expressed as millimoles per litre (mmol/L) (NICE 2004).

Normally blood glucose levels stay within narrow limits throughout the day: 4–8 mmol/L. But they are higher after meals and usually lowest in the morning.

Anatomy and physiology

Blood glucose is regulated by insulin and glucagon. Insulin is synthesized and secreted from the beta cells within the islets of Langerhans found in the pancreas (Wallymahmed 2007). It is produced in response to high blood glucose levels (i.e. after meals), promoting the uptake and storage of sugar by fat and muscle tissue as glycogen (Crosser and McDowell 2007). Glucagon is secreted by the alpha cells in response to low blood glucose levels and results in the release of stored sugar back into the blood (Wallymahmed 2007). These processes maintain blood glucose stability within the body (homeostasis) (Crosser and McDowell 2007).

Diabetes mellitus (DM) is a heterogeneous disorder characterized by chronic hyperglycaemia due to lack of insulin or complete insulin deficiency or the body’s resistance to it (Blake and Nathan 2004, WHO/IDF 2006). There are two main types of DM: type 1 and type 2. Type 1 is believed to be triggered by an autoimmune process causing destruction of the beta cells in the pancreas, which produce insulin, resulting in complete loss of insulin production. Type 2 diabetes is characterized by a resistance to insulin (Thornton 2009).

People with type 1 or type 2 diabetes will have total or partial disruption to this normal metabolic regulatory system. Type 1 diabetes normally occurs in the younger population (Gillibrand et al. 2009) and means that they will need replacement-injected insulin to compensate (Crosser and McDowell 2007). Type 2 diabetes is strongly linked to obesity, age and family history (Gillibrand et al. 2009) but can also be a result of steroid use and pancreatic cancer (Schwab and Porter 2007). Both these can result in hyperglycaemia (high blood glucose) which may cause degenerative changes affecting the kidneys, nerves and eyes (Wallymahmed 2007), resulting in blindness, renal failure and neuropathies. Further complications including coronary artery and peripheral vascular disease, stroke, renal disease, central and peripheral

nerve damage, amputations and blindness are also serious consequences of uncontrolled blood glucose (Gillibrand et al. 2009, WHO/IDF 2006).

A diagnosis of diabetes can primarily be based on a fasting blood glucose of more than or equal to 7 mmol/L or a random plasma glucose of more than or equal to 11.1 mmol/L accompanied by symptoms associated with diabetes such as polydipsia, polyuria and weight loss (Blake and Nathan 2004, WHO/IDF 2006). These features of diabetes do not appear until 80% of beta cells are lost and so it is possible to reverse type 2 diabetes if it is picked up early enough (Schwab and Porter 2007).

Furthermore, during infection, major surgery or critical illness such as sepsis, pancreatitis or respiratory distress, counter-regulatory or stress hormones (adrenaline, noradrenaline, cortisol, growth hormone and glucagon) are released causing significant metabolic alterations. These hormones increase insulin resistance that decreases peripheral intake of glucose and also promotes glucogenesis by stimulating glycogen and fat breakdown, causing hyperglycaemia (Crosser and McDowell 2007). For this reason, patients with diabetes may need treatment of insulin or antidiabetic medication during acute illness, in order to replicate this homeostasis or improve the body’s ability to produce insulin or use it.

Hyperglycaemia

Hyperglycaemia is distinctly associated with poor clinical outcomes, increased mortality and extended time of discharge from hospital (Lipska and Kosiborod 2011, Pichardo-Lowden and Gabbay 2012). It is defined as a random blood glucose of more than 11.1 mmol/L (WHO/IDF 2006). When insulin is deficient or absent as in type 1 or 2 diabetes, blood glucose levels will remain high after a meal, in times of illness or stress because glucose is unable to enter most cells (Wallymahmed 2007). Therefore cells are starved of glucose and the body reacts inappropriately by producing stress hormones that cause glycogenolysis (the breakdown of glycogen to release glucose), lipolysis (the breakdown of stored fat into glycerol and fatty acids) and gluconeogenesis (the conversion of glycerol and amino acids into glucose) (D’Hondt 2008, Marieb and Hoehn 2010) (Figure 11.31).

This causes the blood glucose to rise further which results in a number of signs and symptoms. Water reabsorption in the kidneys becomes inhibited, resulting in frequent, large volumes of urine (polyuria). This will cause the person to feel excessive thirst (polydipsia) and may also result in extreme hunger (polyphagia). Polyuria and polydipsia will cause dehydration, a fall in blood pressure and electrolyte imbalance (Marini and Wheeler 2012). Moreover, the subsequent loss of sodium (hyponatraemia) and potassium (hypokalaemia) leads to muscle cramps, nausea, vomiting and diarrhoea, confusion, blurred vision, lethargy, cardiac events, coma and death.

Despite the excessive glucose in the body, the body cannot utilize it, so the body starts to break down its fat and protein stores for energy, which leads to high levels of fatty acids in the blood (lipidaemia) (Marieb and Hoehn 2010). This can also cause sudden and dramatic weight loss. These fatty acids are converted to ketones. They accumulate in the blood more quickly than they can be excreted or used and cause the blood pH to fall, resulting in ketoacidosis. Ketones will also be present in the urine. If ketoacidosis is allowed to continue it can become life threatening, disrupting all physiological processes, including oxygen transportation and heart activity and depression of the nervous system, leading to coma and death (Marieb and Hoehn 2010).

Reasons for hyperglycaemia include:

- inadequate doses of insulin
- stress
- infection/sepsis
- surgery
- medications, for example steroids
- variability in oral or nutritional intake

Table 11.10 Normal target blood glucose ranges

Figure 11.31 Consequences of insulin deficiency.

- nutritional support, for example parenteral nutrition (PN) or enteral nutrition
- critical illness (Marieb and Hoehn 2010).

It has been found that enteral and parenteral feeding contributes to hyperglycaemia both in patients with a diagnosis of diabetes and those without (McKnight and Carter 2008). This is particularly true of patients receiving PN which bypasses the gut and therefore the incretin hormones that also help to maintain glucose homeostasis (McKnight and Carter 2008, Pichardo-Lowden and Gabbay 2012). Hyperglycaemia in response to steroids, for example dexamethasone, is another consideration and some researchers believe that their hypermetabolic action decreases glucose uptake, increases hepatic glucose production and may directly inhibit insulin release (Delaunay et al. 1997, Ogawa et al. 1992, Wallymahmed 2007). For this reason these patients will need blood glucose monitoring and potential changes to their insulin needs or to temporarily commence insulin.

Hypoglycaemia

Hypoglycaemia is described as a blood glucose level that is unable to meet the metabolic needs of the body (Marini and Wheeler 2012), normally lower than 4 mmol/L (Wallymahmed 2007). Hypoglycaemia is an acute complication of diabetes that increases morbidity, mortality and economic costs of diabetes and can decrease quality of life (Fidler et al. 2011, Liu et al. 2012). Often young, healthy individuals can be asymptomatic during this inadequate level of glucose in the blood but early symptoms can be sweating, tremor, weakness, nervousness, tachycardia and hypertension (Wallymahmed 2007), although these depend on not only the absolute blood glucose but also its rate of decline (Tortora and Derrickson 2011). Severe hypoglycaemia can lead to mental disorientation, convulsions, unconsciousness and death and blood glucose less than 3 mmol can start to affect the brain.

The most common causes of hypoglycaemia are missed or delayed meals, not eating enough, exercise without carbohydrate compensation, too much glucose-lowering medication (e.g. insulin) and excessive alcohol (Wallymahmed 2007). Other causes could be infection, muscle and fat depletion (e.g. anorexia), diarrhoea and vomiting, hepatic failure due to tumour or cirrhosis, salicylate poisoning, insulin-secreting tumours, ventilation, congestive heart failure, cerebral vascular accident, concurrent

medications (beta-blockers, adrenaline) and surgery (D'Hondt 2008, Lui et al. 2012, Marini and Wheeler 2012).

There are several ways to reduce hypoglycaemia risk which include frequent monitoring of blood sugars with home blood glucose tests and occasionally continuous glucose monitoring (McCall 2012). Treatment should ideally be the administration of glucose. The route will depend on the consciousness level of the patient, their treatment and their ability to take oral substances (Marini and Wheeler 2012). If they can tolerate an oral or enteral intake, they should be given a fast-acting carbohydrate such as 3–6 glucose tablets, 150 mL sugary fizzy drink or 50–100 mL Lucozade followed by a longer acting carbohydrate such as a sandwich or biscuits. If unconscious or unable to take food and drink then they can receive intramuscular glucagon or intravenous dextrose (Wallymahmed 2007). Blood glucose needs to be checked 5–10 minutes after treatment and then as necessary. Diabetic treatment should not be omitted because of a single episode of hypoglycaemia but, if it remains a consistent problem, treatment should be reviewed (Wallymahmed 2007). There is a three-fold increased risk of severe hypoglycaemia which occurs in both type 1 and type 2 diabetes with tight glucose control and there is therefore a need to individualize therapy and glycaemia goals to minimize this risk (McCall 2012).

Evidence-based approaches

Rationale

Blood glucose monitoring provides an accurate indication of how the body is controlling glucose metabolism and provides feedback to guide clinicians and patients about their treatment adjustments in order to achieve optimal glucose control. In the short term, it can prevent hypo- and hyperglycaemia and in the long term it can significantly reduce the risk of prolonged, life-threatening microvascular complications (Dailey 2011, Lipska and Kosiborod 2011, Rizvi and Saunders 2006, Snell-Bergeon and Wadwa 2012).

Capillary blood glucose monitoring is preferred due to the immediacy of results and its ability to inform us whether blood sugar is high or low, whereas urine testing only indicates instances of high blood sugar (Wallymahmed 2007). Capillary blood glucose monitoring is also referred to as point-of-care testing (POCT).

Indications

Conditions in which blood glucose monitoring will need to take place include the following.

- To make a diagnosis of diabetes indicated by signs and symptoms of polyuria, polydipsia, weight loss for type 1 or weight gain, family history for type 2 (WHO/IDF 2006).
- To monitor and manage the day-to-day treatment of known type 1 and type 2 diabetes (Wallymahmed 2007).
- In acute management of unstable diabetes, that is, evidence of hyperglycaemia, hypoglycaemia, diabetic ketoacidosis, hyperosmolar non-ketotic coma (once severe dehydration is corrected) (Wallymahmed 2007).
- Hospitalized patients with diabetes according to morbidity and treatment, that is, sliding scales, nutritional intake/support (McKnight and Carter 2008, Wallymahmed 2007).
- Initial parenteral and enteral nutritional support of all patients (McKnight and Carter 2008).
- Patients taking steroids and other drugs that cause raised blood glucose (Schwab and Porter 2007).

Contraindications

The following conditions can affect the accuracy of blood glucose monitoring and it may be necessary to obtain a venous sample for more accurate results (MHRA 2011), especially where treatment, e.g. insulin, is due to be initiated on the acquired result.

- Peripheral circulatory failure and severe dehydration, for example diabetic ketoacidosis, hyperosmolar non-ketotic coma, shock, hypotension. These conditions cause peripheral shut-down, which can cause artificially low capillary readings.
- Haematocrit values above 55% may lead to inaccurate levels if the blood glucose level is more than 11 mmol/L.
- Intravenous infusion of ascorbic acid.
- Pre-eclampsia.
- Some renal dialysis treatments.
- *Hyperlipidaemia*: cholesterol levels above 13 mmol/L may lead to artificially raised capillary blood glucose readings.

Principles of care

Although capillary blood glucose monitoring is an essential part of diabetic management, it can have severe consequences if not done correctly (Wallymahmed 2007). The Department of Health issued a hazard warning in 1987 and a safety notice in 1996 highlighting the need for formal training and strict quality control (MHRA 1996), which has been emphasized since by the MHRA (2011).

Blood glucose monitoring needs to be performed regularly enough for patterns to be established on which treatment changes can be based (Walker 2004). 'Regularly' will vary in different circumstances and any unusual situation, for example illness, change of daily routine, hospitalization, will affect diabetes control and therefore require more frequent testing (Walker 2004). Generally people with type 1 diabetes will need to test blood glucose several times a day or more depending on treatment while those with type 2 will require less testing due to a lower risk of such great fluctuations in blood glucose levels (Goldie 2008). Blood glucose monitoring should be individualized dependent on the type of treatment (diet versus oral medication versus insulin), level of haemoglobin A1c and treatment goals.

There is variation in the literature surrounding the frequency of blood glucose monitoring for type 2 diabetes (IDF 2012), although for well-educated patients with type 1 diabetes it is suggested that monitoring four or more times daily is necessary (Minder et al. 2013). With both types of diabetes, more regular testing will be required in certain circumstances, for example illness, steroid treatment, changes in diet, exercise and routine where there is impaired hypoglycaemia awareness, and in the terminal care setting (Minder et al. 2013).

Within the hospital setting, self-monitoring of blood glucose (SMBG) may be appropriate for the competent adult patient who is medically stable and successfully self-managing their diabetes at home (IDF 2012). However, SMBG in the hospital setting would need to be supported by local policy and supportive assessment documentation.

For all patients (irrespective of previous diabetic diagnosis) receiving nutritional support, that is enteral or parenteral feeding, blood glucose levels should be checked once or twice daily (or more if needed) until stable and then weekly (NICE 2008).

Methods of blood glucose testing

Blood glucose testing involves obtaining a drop of capillary blood and putting it on a testing strip that is read by a blood glucose meter (Farmer et al. 2012). Most meters offer the option of using blood from the fingertips, palm of the hand, upper arm, forearm, calf or thigh (Dale 2006). The most commonly used site is the finger tip as the blood from this area responds rapidly to changes in blood glucose level, as does the blood from the palm of the hand, and therefore delivers the most accurate results (Dale 2006, Goldie 2008). However, the fingertips contain nerve endings, which can become sore and less sensitive with frequent testing. The outer parts of the finger are less painful to prick and the thumb and forefinger should be used sparingly due to their continual use in apposition (Goldie 2008). It is important to rotate areas used for blood glucose testing to avoid infection from multiple stabbings, areas becoming toughened and to reduce pain (Roche Diagnostics 2013).

Anticipated patient outcomes

There have been several trials investigating the benefits of tight glycaemic control to near normal levels. D'Hondt (2008) refers to three randomized controlled trials in which intensive insulin treatment was used in hospitalized patients. The trials showed that intensive insulin treatment to achieve tight glycaemic control did result in reductions in length of stay, sepsis, dialysis and hospital mortality and morbidity (Furnary et al. 2000, Krinsley 2004, van den Berghe et al. 2001). Blood glucose testing is integral to achieving this tight control but there is currently no absolute conclusion for the standardization of this treatment (D'Hondt 2008). It does, however, indicate that keeping blood sugar levels as near normal as possible should be the ultimate aim of blood glucose testing.

Accurate blood glucose monitoring and management are vital and poor control and management are known to lead to increased hospital admissions and longer length of stay (NHS Diabetes 2011).

Legal and professional issues

The DH report (MHRA 1996) and a subsequent MHRA alert (2011) highlight that there must be standardization in training, reliability and quality control for blood glucose testing and staff should be updated at appropriate intervals. In order to achieve this, the following aspects must be considered when selecting monitoring devices.

- Equipment is designed for use by non-laboratory staff and is suitable for use in the clinical environment.
- All equipment is compatible and will give reliable results.
- The biochemistry laboratory is involved in the purchase and maintenance of the equipment. This may involve the purchase of one type of device from one company for the whole hospital, to reduce costs and provide standardization.
- The equipment should be easy to use and staff should be involved in the choice of device (Hall 2005).
- The ongoing cost and maintenance of the device need to be considered, including buying strips, control solutions and replacement devices (Hall 2005).
- Written standard operating procedures should be available and kept with the device.

- Training is given to the operators of the equipment and records are kept of this. After training, the following learning outcomes should be demonstrated by the operator:
 - basic principles of measurement
 - expected results in normal and pathological states
 - demonstration of the proper use of the equipment in accordance with the manufacturer's specification
 - demonstration of the consequences of improper use
 - knowledge of operator-dependent steps
 - instruction in the collection of appropriate blood samples
 - health and safety aspects
 - instruction in the importance of complete documentation of all data produced
 - appropriate calibration and quality control techniques
 - practical experience of the procedures, including a series of analyses to satisfy the instructor that the trainee is competent
 - information regarding contraindications
 - information on basic troubleshooting, error messages and potential sources of error (MHRA 2011).

It is a hospital and government directive to keep records of training and quality testing results and the frequency of these quality control tests may vary according to manufacturer or hospital policy (Walker 2004). Independent quality control should be carried out with the collaboration of the biochemistry laboratory and external auditing of quality control should be undertaken, which may be provided by the company providing the equipment.

Pre-procedural considerations

Equipment

Errors can occur in any phase of the testing process: pre-analytic, analytic or post-analytic. Common sources of meter error include patient or methodology interferences, operator mistakes, environmental exposure and device malfunction (Nichols 2011).

All equipment should be checked for expiry dates (according to individual hospital trust policy) and successful calibration, and stored according to manufacturer's guidelines.

- *Blood glucose monitor*: a medical device which measures the concentration of glucose in a human blood sample using a blood glucose test strip.
- *Testing strip*: strip with a small window used to collect a sample of the patient's blood to be inserted into the blood glucose monitor. The strips must be calibrated with the monitor prior to use.
- *Lancet*: a device used to draw out a small amount of blood from the patient for testing of glucose level. Single-use lancets are used to minimize the risk of cross-infection and accidental needlestick injury and set to the correct depth according to the skin turgor (Roche Diagnostics 2013). Disposable lancets are advisable following an outbreak of hepatitis B in French and US hospitals (European Agency for Safety and Health at Work 2010, MHRA 1996, Roche Diagnostics 2013).

The accuracy of glucose meters is a factor for consideration when purchasing or renting glucose meters. This is especially true in the post-operative setting where, in recent years, clinicians have been looking for tight control of glucose to assist in improving recovery and outcomes (Rice et al. 2010). Home glucose meters that have been adopted for use in some hospitals without additional testing may not give the high level of accuracy that anaesthetists require and that is available when using a central laboratory device or an automated blood gas analyser (Rice et al. 2010).

Specific patient preparation

Patients should be advised to wash their hands prior to testing or the test area should be cleaned with soap and water and then dried. Use of alcohol gel should be avoided to ensure non-contamination of the result. The patient should be encouraged to warm their hands before sampling to encourage blood flow and to obtain an adequate amount of blood to cover the test strip (Dale 2006, Wallymahmed 2007).

Procedure guideline 11.8 Blood glucose monitoring

Essential equipment

- Blood glucose monitor
- Test strips
- Control solution
- Single-use safety lancets
- Non-sterile gloves
- Cotton wool/low-linting gauze
- Sharps box

Pre-procedure

Action

- 1 Turn the machine on and ensure the correct date and time are presented on screen, and that there is adequate battery life. Where applicable, enter or scan operator number, e.g. number or bar code on name badge, as per manufacturer's guidelines.

Rationale

To ensure accuracy in the result record and patient safety (Roche Diagnostics 2013, C).

- 2 Check the unit of measure and ensure that it is reading in mmol/L prior to each use.

Units of measure may change from mmol/L to mg/dL, which could result in the meter user thinking that the blood glucose level is higher than it actually is (MHRA 2011, C).

(continued)

Procedure guideline 11.8 Blood glucose monitoring (*continued*)**Action****Rationale**

- 3 Before taking the device to the patient, the monitor and testing strips need to be checked for the following (where applicable to the device. Newer automated systems will self-calibrate when turned on).
 - Testing strips are in date and have not been left exposed to air.
 - The monitor and test strips have been calibrated together.
 - If a new pack of strips is required, the monitor is recalibrated.
 - Internal quality control carried out with both high and low or level 1 and 2 solutions, in accordance with trust and manufacturer's guidelines. Ensure the LOT number is recorded, either manually or via bar code scanning system.
 - Result (pass or fail) of internal quality control is to be recorded in equipment log book and signed. Where an automated device is used, ensure the device is docked in its base unit for the centrally held electronic records to be maintained.
 - The meter has previously been decontaminated per local guidelines and is fit for use.
 - The meter service record is in date according to local policy.
 - That the screen/display is intact and the 'screen safety check' has been completed in accordance with manufacturer's guidelines.

As any device can fail under the right conditions (Nichols 2011, **E**).

- 4 Identify the patient, i.e. verbally and against their hospital identity band, and explain the procedure.

The patient should give consent to the procedure. Explanation may allay any fear or anxieties (NMC 2013, **C**).

- 5 Select a site that is warm, pink and free of any calluses, burns, cuts, scars, bruises or rashes. Avoid skin areas that have evidence of previous punctures. The usual site for lancing is the palmar surface of the distal segment of the third or fourth finger, ideally of the non-dominant hand as they are usually less calloused.

It is important to avoid previous punctures by rotating the site lanced to avoid fingertip soreness and reduce callus formation (WHO 2010, **C**). Fingers on the non-dominant hand and the index finger are generally less calloused. The index finger is also potentially more sensitive to pain due to additional nerve endings. The thumb also may be calloused and has a pulse, indicating arterial presence, and the distance between the skin surface and the bone in the fifth finger also makes it unsuitable for puncture (WHO 2010, **C**). Tips and pads of fingers should be avoided as they are denser with nerve supply and can be more painful (WHO 2010, **C**).

Procedure

- 6 Ask patient to sit or lie down.

To ensure the patient's safety and minimize the risks if they feel faint when blood is taken (Roche Diagnostics 2013, **C**).

- 7 Ask the patient to wash their hands with soap and water and dry thoroughly with low-linting gauze.

To avoid sample contamination (CDC 2013, **C**). Not washing hands can lead to a difference in the glucose concentration, especially with fingers exposed to fruit or a sugar-containing product (Hortensius et al. 2011, **R1b**).

- 8 Wash your hands and put on gloves.

To minimize the risk of cross-infection and contamination (Fraise and Bradley 2009, **E**).

- 9 Take a single-use lancet and, if it has depth settings, ensure the correct setting is used (most commonly middle one).

To minimize the risk of cross-infection and accidental needlestick injury (FDA 2010, **C**; Fraise and Bradley 2009, **E**). The correct depth setting will ensure patient comfort (Roche Diagnostics 2013, **C**).

- 10 Activate the single-use, auto-disabling fingerstick device/lancet or reusable device, as per manufacturer's guidelines, at the chosen site, e.g. the side of the finger. Ensure the site of piercing is rotated (see **Action figure 10**), avoiding frequent use of index finger and thumb. Other areas may be used if finger or palm of hand are unusable.

The fingertip may need 'milking' from palm of hand towards finger to gain a large enough droplet of blood but avoid milking the finger alone.

In settings where assisted monitoring of blood glucose is performed, single-use, auto-disabling fingerstick devices should be used. Although reusable devices may be used in the patient's own environment, they should never be used for more than one person due to the risk of bloodborne viruses (CDC 2013, **C**). The side of the finger is less painful and easier to obtain a hanging droplet of blood. Sites are rotated to avoid infection from multiple stabbings, area becoming toughened and to reduce pain (Roche Diagnostics 2013, **C**).

Milking the finger can cause tissue fluid contamination and a false low reading (Hortensius et al. 2011, **R1b**), cause haemolysis and impede blood flow (WHO 2010, **C**).

- 11 Activate safety-engineered medical device (where applicable and if not automated), dispose of lancet and testing strip in a sharps container.

A cost-effective way to reduce the risk of needlestick injury (European Agency for Safety and Health at Work 2010, **C**; Roche Diagnostics 2013, **C**; Tan et al. 2001, **R1a**).

- 12 Insert testing strip into blood glucose monitor and apply the first drop of blood to the testing strip. Some strips are hydrophilic and are dosed/filled from the side instead of dropping blood directly onto the strip. Ensure that the window on the test strip is entirely covered with blood (see **Action figure 12**).

To ensure accurate results, the window on the test strip needs to be adequately filled as per manufacturer's guidelines (Roche Diagnostics 2013, **C**).

- 13 Place gauze over puncture site, apply firm pressure and monitor for excess bleeding.

To ensure patient safety (Wallymahmed 2007, **E**) and to stop the bleeding (WHO 2010, **C**).

- 14 Remove gloves, place in clinical waste and perform hand hygiene again.

To prevent healthcare-associated infections and spread of antimicrobial resistance (WHO 2013, **C**).

Post-procedure

- 15 Once result is obtained (see **Action figure 15**), document and sign.

To ensure accuracy in record keeping (NMC 2010, **C**; Roche Diagnostics 2013, **C**).

- 16 Where applicable, dock machine.

To ensure centralized records are maintained (Roche Diagnostics 2013, **C**).

- 17 Report any unexpected results.

To ensure appropriate treatment and obtain optimal blood glucose range (Wallymahmed 2007, **E**).

Action Figure 10 Blood glucose taking: Step 1. Take a blood sample from the side of the finger using a lancet, ensuring that the site of piercing is rotated.

Action Figure 12 Blood glucose taking: Step 2. Insert the test strip into the blood glucose monitor and apply the blood to the test strip. Ensure that the window on the test strip is entirely covered with blood.

Action Figure 15 Blood glucose taking: Step 3. Read the result.

Problem-solving table 11.7 Prevention and resolution (Procedure guideline 11.8)

Problem	Cause	Prevention	Action
Inaccurate results.	<p>User error including:</p> <ul style="list-style-type: none"> • inadequate meter calibration • failure to code correctly • poor meter maintenance • incorrect user technique. <p>50% of errors are due to an inadequate amount of blood on the test strip, which can lead to a falsely low reading (Blake and Nathan 2004). Out-of-date or incorrectly stored test strips are other common errors leading to lower glucose levels.</p>	Staff training and education about diabetes are essential in prevention of these errors (Heinemann 2010, Janssen and Delanghe 2010).	Contact colleague to repeat test and, if error persists, report glucose meter to technician and use another machine.

Post-procedural considerations

Immediate care

If a true abnormal blood glucose result is detected then the appropriate action should be taken according to medical advice and hospital policy.

Education of patient and relevant others

Diabetes mellitus is a long-term, often lifelong condition affecting all aspects of a person's life. Ninety-five percent of diabetes care is self-care and all people with type 1 and type 2 diabetes should have access to self-monitoring. Research has found that diabetes self-management education improves quality of life (Thorpe et al. 2013). The nurse has a role in educating and promoting self-management of diabetes and advising patients on the type and frequency of monitoring based on individual clinical need so that patients can monitor and adjust their own treatment (Diabetes UK 2008). NICE and the Department of Health also recommend that people are given annual updates to ensure they are still able to perform tests accurately and learn about any new developments (DH 2008, NICE 2004, NICE 2008). Healthcare professionals should advocate a healthy lifestyle for patients with diabetes, including regulating blood pressure, low-sugar diet and exercise (NICE 2008).

Neurological observations

Definition

Neurological observation is the collection of information about the patient's central nervous system (Mooney and Comerford 2003). Despite advances in neuromonitoring, clinical observation of the patient remains the most sensitive measure of neurological function (Adam and Osbourne 2005).

Anatomy and physiology

The nervous system is the most complex of the body systems, responsible for the co-ordination of all body functions, adapting to changes in internal and external environments. The activities of the nervous system can be grouped into three basic functions (Tortora and Derrickson 2011).

- *Sensory (input)*: detection of internal or external stimuli; this information is carried to the brain and spinal cord through cranial and spinal nerves.

- *Integrative (process)*: analysis of sensory information and deciding on appropriate responses.
- *Motor (output)*: eliciting an appropriate motor response by activating effectors (muscles and glands) through cranial and spinal nerves.

The intricate network of neurones and neuroglia which comprise the nervous system are divided into two main subdivisions: the central nervous system and the peripheral nervous system.

The central nervous system

The central nervous system consists of the brain and spinal cord (Tortora and Derrickson 2011).

The brain

Located within the skull, the brain is the control centre for registering sensations, correlating them with one another and stored information, making decisions and taking actions; it is also the centre for intellect, emotions, behaviour and memories (Tortora and Derrickson 2011). The adult brain consists of four regions: the brainstem, the cerebellum, the diencephalon and the cerebrum (Figure 11.32).

The cerebrum is the largest part of the brain and provides us with the ability to read, write and speak, to make calculations, and to remember the past, plan for the future and imagine things.

The cerebral hemispheres contain the greatest mass of brain tissue. Each hemisphere is subdivided into several lobes named after the bones that cover them: frontal, parietal, temporal and occipital lobes (Figure 11.33). Each of these lobes has a particular function.

- The *frontal lobe* is located at the front of the brain and is associated with cognitive function (orientation, memory, insight, judgement, calculation and abstraction), expressive language (verbal and written) and voluntary motor function (through skeletal muscle).
- The *parietal lobe* is located in the middle section of the brain and is associated with sensory function, including integration of sensory information, awareness of body parts, interpretation of touch, pressure and pain, and recognition of object size, shape and texture.
- The *occipital lobe* is located at the back of the brain and is associated with interpreting visual stimuli and receives impulses from the optic nerve.
- The *temporal lobe* is located in the bottom section of the brain and is primarily associated with hearing, speech, behaviour and memory (Adam and Osbourne 2005, Baumann 2009).

The spinal cord

The spinal cord is a cylindrical mass of nerve tissue encased within the vertical canal of the vertebral column extending from the medulla oblongata of the brainstem to the superior border of the second lumbar vertebra (Tortora and Derrickson 2011). It contains important motor and sensory nerve pathways that exit and enter the cord through anterior and posterior nerve roots and spinal and peripheral nerves, and also mediates reflex activity of the deep tendon reflexes from the spinal nerves (Bickley and Szilagyi 2009). The spinal cord is divided into five segments: cervical, from C1 to C8; thoracic, from T1 to T12; lumbar, from L1 to L5; sacral, from S1 to S5; and coccygeal (Bickley and Szilagyi 2009) (Figure 11.34).

The peripheral nervous system

The peripheral nervous system consists of the 12 pairs of cranial nerves and the 31 pairs of spinal and peripheral nerves (Tortora and Derrickson 2011).

The cranial nerves

Twelve pairs of special nerves called cranial nerves emerge from the brain. They are named according to their distribution and are numbered I to XII in order of their attachment to the brain (Tortora and Derrickson 2011). Cranial nerves II–XII arise from the diencephalon and the brainstem (Table 11.11). Cranial nerves I and II are actually fibre tracts emerging from the brain. Some cranial nerves are limited to general motor or sensory functions whereas others are specialized, producing smell, vision or hearing (I, II, VIII) (Bickley and Szilagyi 2009).

The peripheral nerves

In addition to the cranial nerves, the peripheral nervous system also includes spinal and peripheral nerves that carry impulses to and from the spinal cord. The 31 pairs of spinal nerves are named and numbered in accordance with the region and level of the spinal cord from which they emerge: eight cervical, 12 thoracic, five lumbar, five sacral and one coccygeal. Spinal nerves are typically connected to the spinal cord by a posterior root (containing

sensory fibres) and an anterior root (containing motor fibres) (Tortora and Derrickson 2011).

Related theory

Changes in neurological status can be rapid and dramatic or subtle, developing over minutes, hours, days, weeks or even longer (Aucken and Crawford 1998). The frequency of neurological observations will depend upon the patient's condition and the rapidity with which changes are occurring or expected to occur. Neurological assessment must include (Adam and Osbourne 2005):

- assessment of level of consciousness
- pupil size and reaction to light
- limb assessments (including both motor and sensory function)
- vital signs.

Level of consciousness

Level of consciousness is the most sensitive indicator of neurological deterioration and is therefore the most important aspect of any neurological assessment (Waterhouse 2005). Consciousness is a state of awareness of self and the environment and is dependent upon two components: arousal and awareness (Baumann 2009). These correspond to two brain structures, the reticular activating system (RAS) and the cerebral cortex. Consciousness depends on the interaction between the neurones in the RAS in the brainstem and the neurones in the cerebral cortex (Adam and Osbourne 2005).

Arousal

This is a primitive state managed by the RAS (Figure 11.35). The core of nuclei which make up the RAS extends from the brainstem with projections upwards to the cortex and downwards to the spinal cord. The RAS receives auditory, visual and sensory impulses (such as pain, touch, movement of limbs, bright light or noise), and because of its connections is ideal for governing arousal of the brain as a whole (Adam and Osbourne 2005). Unless inhibited by other areas of the brain, the reticular neurones send a continuous stream of impulses to the cerebral cortex, maintaining the

Figure 11.33 The cerebrum. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

Figure 11.34 External anatomy of the spinal cord and the spinal nerves (posterior view).
Source: Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

cortex in an alert, conscious state; the RAS is selective, however, forwarding only essential information to the cortex and filtering out unnecessary information. Certain drugs have a direct effect on the RAS – alcohol, sleep-inducing drugs and tranquillizers depress the RAS and drugs such as LSD remove the RAS filter system, leading to heightened sensory arousal (Adam and Osbourne 2005).

Awareness

This is the more sophisticated part of consciousness and requires an intact cerebral cortex to interpret sensory input and respond accordingly (Adam and Osbourne 2005).

Assessing consciousness

Consciousness cannot be measured directly but is assessed by observing behaviour in response to different stimuli; the response indicates the level at which the sensory information has been translated within the central nervous system (Adam and Osbourne 2005).

Assessment of arousal focuses on the patient's ability to respond appropriately to verbal or non-verbal stimuli and begins

with verbal stimulus in a normal tone and if there is no response the stimulus is progressively increased, firstly by raising the voice, followed by gently shaking the patient and finally by applying noxious (painful) stimuli (Baumann 2009).

Assessment of awareness is concerned with the patient's orientation to person, place and time; changes in responses that indicate increasing degrees of confusion and disorientation may be the first sign of neurological deterioration (Baumann 2009).

Previous and/or co-existing problems should be considered when assessing levels of consciousness, for example deafness, hemiparesis/hemiplegia. A manifestation of altered consciousness implies an underlying brain dysfunction. Its onset may be sudden, for example following an acute head injury, or it may occur more gradually, such as in hypoglycaemia (Jevon 2008). Similarly, alterations in level of consciousness can vary from slight to severe changes, indicating the degree of brain dysfunction (Aucken and Crawford 1998).

Consciousness ranges on a continuum from alert wakefulness to deep coma with no apparent responsiveness. Therefore, nurses must ensure that families and friends are involved at the initial history taking and throughout care so as to accurately

Table 11.11 Summary of cranial nerves*

Cranial nerve	Components	Principal functions
Olfactory (I)	Special sensory	Olfaction (smell)
Optic (II)	Special sensory	Vision (sight)
Oculomotor (III)	Motor	
	Somatic	Movement of eyeballs and upper eyelid
	Motor (autonomic)	Adjusts lens for near vision (accommodation) Constriction of pupil
Trochlear (IV)	Motor	
	Somatic	Movement of eyeballs
Trigeminal (V)	Mixed	
	Sensory	Touch, pain, and thermal sensations from scalp, face, and oral cavity (including teeth and anterior two-thirds of tongue)
	Motor (branchial)	Chewing and controls middle ear muscle
Abducens (VI)	Motor	
	Somatic	Movement of eyeballs
Facial (VII)	Mixed	
	Sensory	Taste from anterior two-thirds of tongue Touch, pain, and thermal sensations from skin in external ear canal
	Motor (branchial)	Control of muscles of facial expression and middle ear muscle
	Motor (autonomic)	Secretion of tears and saliva
Vestibulocochlear (VIII)	Special sensory	Hearing and equilibrium
Glossopharyngeal (IX)	Mixed	
	Sensory	Taste from posterior one-third of tongue Proprioception in some swallowing muscles Monitors blood pressure and oxygen and carbon dioxide levels in blood Touch, pain, and thermal sensations from skin of external ear and upper pharynx
	Motor (branchial)	Assists in swallowing
	Motor (autonomic)	Secretion of saliva
Vagus (X)	Mixed	
	Sensory	Taste from epiglottis Proprioception from throat and voice box muscles Monitors blood pressure and oxygen and carbon dioxide levels in blood Touch, pain, and thermal sensations from skin of external ear Sensations from thoracic and abdominal organs
	Motor (branchial)	Swallowing, vocalization, and coughing
	Motor (autonomic)	Motility and secretion of gastrointestinal organs Constriction of respiratory passageways Decreases heart rate
Accessory (XI)	Motor	
	Branchial	Movement of head and pectoral girdle
Hypoglossal (XII)	Motor	
	Somatic	Speech, manipulation of food, and swallowing

note any change in neurological symptoms. Terms such as ‘fully conscious’, ‘semi-conscious’ or ‘stuporous’, previously used to describe levels of consciousness, are subjective and open to misinterpretation and therefore level of consciousness should be measured using the Glasgow Coma Scale (GCS) or, during a rapid assessment of an acutely unwell patient, the AVPU scale (see ‘Assessment and recording tools’) (Adam and Osbourne 2005, Jevon 2008).

Application of painful stimuli

Painful stimuli should be employed only if the patient does not respond to firm and clear commands (Jevon and Ewens 2007). The stimulus should be applied in a standard way, increasing from light pressure and being maintained until a response is elicited, for a maximum of 10 seconds to avoid soft tissue injury or causing the patient pain (Adam and Osbourne 2005, Jevon and Ewens 2007). As such, it should only be undertaken by appropriately qualified and experienced professionals.

As the ability to localize pain is lost, various responses may be observed when painful stimuli are applied (Baumann 2009). It is important to note, when applying a painful stimulus, that peripherally it may only elicit a spinal reflex which does not involve cerebral function and, therefore, evaluation of cerebral function requires the application of central stimuli (Jevon and Ewens 2007).

Central stimuli can be applied in the following ways (Baumann 2009, Jevon and Ewens 2007).

- **Trapezium squeeze:** using the thumb and two fingers, hold 5 cm of the trapezius muscle where the neck meets the shoulder and twist the muscle.
- **Supraorbital pressure:** by running a finger along the supraorbital margin (the bony ridge along the top of the eye) a notch is felt. Applying pressure to the notch stimulates the supraorbital nerve and causes an ipsilateral (on that side) sinus headache-type pain. This method should not be used if the facial or cranial bones are unstable, facial fractures are suspected or after facial surgery. Using supraorbital pressure as a painful stimulus may also make the patient grimace and lead to closing the eye rather than eye opening (Fairley et al. 2005).
- **Sternal rub:** using the knuckles of a clenched fist to grind on the centre of the sternum. When applied adequately, marks are left on the skin as sternal tissue is tender and bruises easily.

Please note that because of the risk of bruising, this should not be used for repeated assessment but may be indicated to guide medical decisions about the patient’s management.

If there is no response to central stimuli then a peripheral stimulus should be applied to assess limbs that have not moved (Adam and Osbourne 2005). The patient’s finger should be placed between the assessor’s thumb and a pencil or pen. Pressure is gradually increased over a few seconds until the slightest response is seen. Due to the risk of bruising, pressure should not be applied to the nailbed.

Pupillary activity

Careful examination of the reactions of the pupils to light is an important part of neurological assessment (Table 11.12). The size, shape, equality, reaction to light (in both the eye directly exposed to light [direct] and the eye not directly exposed to it [consensual]) and position of the eyes should be noted as well as whether the eyes are conjugate (moving together) or dysconjugate (not moving together). Pupillary response to light is dependent upon intact afferent (optic nerve) and efferent (oculomotor nerve) function transmitting the light impulse from the retina to the midbrain and the pupillary musculature (Adam and Osbourne 2005). Pupillary pathways are relatively resistant to metabolic insults and therefore response to light is the single most important sign in distinguishing structural from metabolic coma. Impaired pupillary response to light signifies that the midbrain itself may be suffering from pressure exerted by an expanding mass in the brain and is therefore important as a localizing sign; pupillary constriction and dilation are controlled by cranial nerve III (oculomotor) and any changes may indicate pressure on this nerve or brainstem damage (Adam and Osbourne 2005, Fuller 2008).

Limb assessment

Motor function

Damage to any part of the motor nervous system can affect the ability to move. After assessing motor function on one side of the body, the contralateral muscle group should also be evaluated to detect asymmetry. Motor function assessment involves an evaluation of the following.

- Muscle strength
- Muscle tone
- Muscle co-ordination
- Reflexes
- Abnormal movements (Aucken and Crawford 1998, Fuller 2008)

Muscle strength

This involves testing the patient’s muscle strength against the pull of gravity and then against one’s own resistance. Changes

Table 11.12 Examination of pupils

Observation	Pupil size	Pupil reactivity	Possible indication
Pupils equal	Pinpoint	–	Opiates or pontine lesion
	Small	Reactive	Metabolic encephalopathy
	Mid-sized	Fixed	Midbrain lesion
Pupils unequal	Dilated	Reactive	Metabolic lesion
		Unreactive	3rd nerve palsy
	Small	Reactive	Horner’s syndrome

Source: Fuller (2008). Reproduced with permission from Churchill Livingstone.

in motor strength, especially between right and left sides, may indicate imminent neurological failure (Baumann 2009).

Muscle tone

This involves flexing and extending the patient's limbs on both sides and noting how well such movements are resisted; increased resistance would denote increased muscle tone and decreased resistance decreased tone (Baumann 2009).

Muscle co-ordination

Any disease or injury that involves the cerebellum or basal ganglia will affect co-ordination. Assessment of hand and leg co-ordination can be achieved by testing the rapidity and rhythm of alternating movements and point-to-point movements (Baumann 2009).

Reflexes

658 Amongst the most important reflexes are blink, gag and swallow, oculocephalic and plantar.

- *Blink (corneal)*: this is a protective reflex and can be affected by damage to the Vth cranial nerve (trigeminal) and the VIIth cranial nerve (facial). Facial weakness (VIIth cranial nerve) will affect eye closure and absence of the corneal reflex may result in corneal damage (Fuller 2008).
- *Gag and swallow*: damage to the IXth cranial nerve (glossopharyngeal) and Xth cranial nerve (vagus) may impair protective reflexes. These two cranial nerves are always assessed together as their functions overlap. Muscle innervation of the palate is from the vagus, while sensation is supplied by the glossopharyngeal nerves (Aucken and Crawford 1998, Fuller 2008).
- *Oculocephalic*: this reflex is an eye movement that occurs only in patients with a severely decreased level of consciousness (in conscious patients this reflex is not present). When the reflex is present, the patient's eyes will move in the opposite direction from the side to which the head is turned. However, in patients with absent brainstem reflexes, the eyes will appear to remain stationary in the centre. This reflex should not be assessed if there is suspected instability of the cervical spine as the necessary head movement could exacerbate any spinal injury (Baumann 2009).
- *Plantar*: abnormalities of plantar reflex will help to locate the anatomical site of the lesion. Upgoing plantar (extension) reflex is termed 'positive Babinski' (dorsiflexion of the big toe and fanning of the other toes) and indicates an upper motor neurone lesion. Note that upgoing plantar is normal in babies under 1 year of age (Baumann 2009).

Abnormal movements

When carrying out neurological observations, any abnormal movements such as seizures, tics and tremors must be noted.

Sensory functions

Constant sensory input enables an individual to alter responses and behaviour to suit the environment. When disease or injury damages the sensory pathways, the sensory responses are always affected. Any assessment of sensory function should include an evaluation of the following.

- Central and peripheral vision
- Hearing and ability to understand verbal communication
- Superficial sensations (light touch, pain) and deep sensations (muscle and joint pain, muscle and joint position) (Baumann 2009, Fuller 2008)

Visual acuity

The clarity or clearness of vision may be tested with a Snellen chart, which uses decreasing letter size, or newspaper prints, with glasses if worn.

Visual fields

Lesions at different points in the visual pathways affect vision. It should be noted that loss of vision is always described with reference to the visual fields rather than the retinal fields (Weldon 1998).

Vital signs

It is recommended that assessments of vital signs should be made in the following order.

- 1 Respirations
- 2 Temperature
- 3 Blood pressure
- 4 Pulse

Please see relevant sections in this chapter.

Respirations

Of these four vital signs, respiratory patterns give the clearest indication of how the brain is functioning because the complex process of respiration is controlled by more than one area of the brain – the cerebral hemispheres, the cerebellum and the brainstem (Adam and Osbourne 2005, Jevon and Ewens 2007). Any disease or injury that affects these areas may produce respiratory changes. The rate, character and pattern of a patient's respiration must be noted. Abnormal respiratory patterns are listed in Table 11.13.

Table 11.13 Abnormal respiratory patterns

Type	Pattern	Significance
Cheyne–Stokes	Rhythmic waxing and waning of both rate and depth of respirations, alternating regularly with briefer periods of apnoea. Greater than normal respiration, that is 16–24 breaths per minute	May indicate deep cerebral or cerebellar lesions, usually bilateral; may occur with upper brainstem involvement
Central neurogenic hyperventilation	Sustained, regular, rapid respirations, with forced inspiration and expiration	May indicate a lesion of the low midbrain or upper pons areas of the brainstem
Apneustic	Prolonged inspiration with a pause at full inspiration; there may also be expiratory pauses	May indicate a lesion of the lower pons or upper medulla, hypoglycaemia or drug-induced respiratory depression
Cluster breathing	Clusters of irregular respirations alternating with longer periods of apnoea	May indicate a lesion of lower pons or upper medulla
Ataxic breathing	A completely irregular pattern with random deep and shallow respirations; irregular pauses may also appear	May indicate a lesion of the medulla

Constant re-evaluation of the patient's ability to maintain and protect their airway is essential when there is evidence of reduced consciousness or coma (GCS score is less than 8). At this stage, muscles often become flaccid and use of the recovery position may need to be considered. Patients whose neurological function has deteriorated may require adjuncts to protect the airway and possibly artificial ventilation (RCUK 2011). Close liaison with physiotherapists and speech and language therapists is important to minimize the danger of chest infections due to the inability to clear secretions or aspiration.

Temperature

Damage to the hypothalamus, the temperature-regulating centre, may result in grossly fluctuating temperatures (Adam and Osbourne 2005).

Blood pressure and pulse

Hypertension with a widening pulse pressure, bradycardia and a fall in respiratory rate may be indicative of rising intracranial pressure (ICP) and is part of the Cushing's reflex (Adam and Osbourne 2005, Jevon and Ewens 2007). Abnormalities of blood pressure and pulse usually occur late (and may not appear at all in some patients); usually the patient's level of consciousness will have begun to deteriorate before there is any alteration in their vital signs (Adam and Osbourne 2005).

Evidence-based approaches

Rationale

Indications

An accurate neurological assessment is essential in planning appropriate patient care. The information gained from a neurological assessment can be used in the following ways.

- To aid diagnosis (Pentland et al. 2009).
- As a baseline for observations (Meurier et al. 2005, Mooney and Comerford 2003).
- To determine both subtle and rapid changes in an individual's condition (Meurier et al. 2005).
- To monitor neurological status following a neurological procedure or trauma (Mooney and Comerford 2003).
- To observe for deterioration and establish the extent of a traumatic head injury (Walsh 2006).
- To detect life-threatening situations (Alcock et al. 2002).

Frequency of observations

There is no published consensus on how frequently neurological observations should be recorded (Mooney and Comerford 2003, Price 2002). It is therefore impossible to be prescriptive, as the frequency will depend on the patient's presenting condition, medical diagnosis, underlying pathology and possible consequences. Clinicians' professional knowledge and judgement will dictate the necessary timing interval for the assessment. If the patient's condition is deteriorating, observations may need to be carried

out as frequently as every 10–15 minutes for the first few hours and then 1–2-hourly observations for a further 48 hours.

The nurse must be competent to take appropriate action if changes in the patient's neurological status occur, as well as reporting any subtle signs that may indicate deterioration; for example, patients will often become increasingly restless or a previously restless patient may become atypically quiet. It should never be assumed that difficulty to rouse a patient is due to night-time sleep as even a deeply asleep patient with no focal deficit should respond to pain. If the patient requires an increased amount of stimulus to achieve the same response, this may be an indication of subtle deterioration (Table 11.14) (Aucken and Crawford 1998, Waterhouse 2005).

Pre-procedural considerations

Equipment

The following equipment may be used as part of the neurological assessment.

- *Pen torch*: used to assess the reaction of the pupils to light and consensual light reflex (Fairley and Pearce 2006a).
- *Tongue depressor*: a device used to depress the tongue to allow for examination of mouth and throat (Fuller 2008).
- *Patella hammer*: a tendon hammer used to strike the patella tendon below the knee to assess the deep knee jerk/reflex (Fuller 2008).
- *Neuro tips*: a sharp instrument used to apply pressure and test for superficial sensations to pain. Can be replaced by a safety pin or other suitable sharp object (Fuller 2008).
- *Snellen chart*: a letter chart used to measure visual acuity.

Assessment and recording tools

The initial assessment of a patient should include a history (taken from relatives or friends if appropriate), noting changes in mood, intellect, memory and personality, since these may be indicators of a long-standing problem (Baumann 2009).

Assessment of level of consciousness can be carried out using the GCS or the AVPU scale.

Glasgow Coma Scale

The GCS, first developed by Teasdale and Jennett (1974), is a widely used tool to assess level of consciousness and should be used to assess all patients with head injuries (NICE 2007c). It forms a quick, objective and easily interpreted mode of neurological assessment. The GCS measures arousal and awareness, by assessing three different areas of the patient's behaviour: eye opening, verbal response and motor response (Dawes and Durham 2007). Each area is allocated a score, enabling objectivity, ease of recording and comparison between recordings. The total sum provides a score out of 15, whereby a score of 15 indicates a fully alert and responsive patient and a score of 3 (the lowest possible score) indicates unconsciousness (Dawes and Durham 2007). When used consistently, the GCS provides a graphical representation that shows any improvement or deterioration of the patient's conscious level at a glance (Figure 11.36 and Table 11.15).

Table 11.14 Frequency of observations

Category	Frequency	Rationale
All patients diagnosed as suffering from neurological or neurosurgical conditions	At least 4-hourly, affected by the patient's condition	To monitor the condition of the patient so that any necessary action can be instigated
Unconscious patients (including ventilated and anaesthetized)	Frequency indicated by patient's condition	To monitor the condition closely and to detect trends so that appropriate action may be taken

Figure 11.36 The Glasgow Coma Scale.

Table 11.15 Scoring activities of the Glasgow Coma Scale. Scores are added, with the highest score 15 indicating full consciousness

Category	Score	Response
Eye opening		
Spontaneous	4	Eyes open spontaneously without stimulation
To speech	3	Eyes open to verbal stimulation (normal, raised or repeated)
To pain	2	Eyes open with painful/noxious stimuli
None	1	No eye opening regardless of level of stimulation
Verbal response		
Orientated	5	Able to give accurate information regarding time, person and place
Confused	4	Able to answer in sentences using correct language but cannot answer orientation questions appropriately
Inappropriate words	3	Uses incomprehensible words in a random or disorganized fashion
Incomprehensible sounds	2	Makes unintelligible sounds, for example moans and groans
None	1	No verbal response despite verbal or other stimuli
Best motor response		
Obeys commands	6	Obeys and can repeat simple commands, for example arm raise
Localizes to pain	5	Purposeful movement to remove painful stimuli
Normal flexion	4	Withdraws extremity from source of pain, for example flexes arm at elbow without wrist rotation in response to painful stimuli
Abnormal flexion	3	Decorticate posturing (flexion of arms, hyperextension of legs) spontaneously or in response to noxious stimuli
Extension	2	Decerebrate posturing (limbs extended and internally rotated) spontaneously or in response to noxious stimuli
None	1	No response to noxious stimuli. Flaccid limbs

Source: Adapted from Aucken and Crawford (1998), Baumann (2009).

Assessment using the GCS involves three phases (Teasdale and Jennett 1974).

- 1 Eye opening.
- 2 Evaluation of verbal response.
- 3 Evaluation of motor response.

Evaluation of eye opening

Eye opening indicates that the arousal mechanism in the brain is active (Waterhouse 2005). Eye opening may be spontaneous; to speech; to painful stimulus; or not at all. Arousal (eye opening) is always the first measurement undertaken when performing the GCS, as without arousal, cognition cannot occur (Aucken and Crawford 1998).

- *Spontaneous*: the patient is observed to be awake with their eyes open without any speech or touch (allocated a score of 4).
- *To speech*: the patient opens their eyes to loud, clear commands (allocated a score of 3).
- *To pain*: the patient opens their eyes to a painful stimulus (allocated a score of 2).
- *None*: the patient does not open their eyes to painful stimuli (allocated a score of 1) (Fairley et al. 2005, Fairley and Pearce 2006b, Mooney and Comerford 2003, Waterhouse 2005).

A patient with flaccid ocular muscles may lie with their eyes open all the time; this is not a true arousal response and should be recorded as 'none' (Fairley and Pearce 2006b). If a patient's eyes are closed as a result of swelling or facial fractures, eye opening cannot be used to determine a falling conscious level (Fairley et al. 2005). This should be recorded as a 'C' on the chart.

Evaluation of verbal response

- *Orientated*: the patient can correctly identify who they are (person), where they are (place) and the current year (time) (allocated a score of 5).
- *Confused*: the patient's responses to the above questions are incorrect and they are unaware of person, place or time (allocated a score of 4).
- *Inappropriate words*: the patient responds using intelligible words which are unsuitable as conversational responses; swearing is common, as are single word responses (allocated a score of 3).
- *Incomprehensible*: the patient may mumble, moan or groan without recognizable words (allocated a score of 2).
- *Absent*: the patient does not speak or make sounds at all (allocated a score of 1) (Fairley et al. 2005, Fairley and Pearce 2006b, Waterhouse 2005).

The absence of speech may not always indicate a falling level of consciousness; for example, the patient may not speak English (though they can still speak). A patient with an endotracheal tube should be recorded as 'T' on the chart under no response and allocated a score of 1 (Fairley and Pearce 2006b). Likewise, if the patient is dysphasic the best verbal response cannot be determined accurately. The patient may have a motor (expressive) dysphasia, and therefore be able to understand but be unable to find the right word, or a sensory (receptive) dysphasia, being unable to comprehend what is being told to them (Aucken and Crawford 1998, Shah 1999). At times patients with expressive dysphasia may also have receptive problems; therefore it is important to make an early referral to a speech and language therapist. This

should be recorded as a 'D' on the chart under no response and allocated a score of 1 (Fairley and Pearce 2006b).

If a patient cannot follow the instruction due to a language barrier or unconsciousness, observe spontaneous movements and note how strong they appear. Then, if necessary, apply painful stimuli. The nurse should also consider that some patients may need a lot of stimulation to maintain their concentration to answer questions, even though they can answer them correctly. It is, therefore, important to note the amount of stimulation that the patient required as part of the baseline assessment (Aucken and Crawford 1998, Waterhouse 2005).

Evaluation of motor response

Motor response is the most important prognostic aspect of the GCS after traumatic brain injury (Adam and Osbourne 2005). To obtain an accurate picture of brain function, motor response is tested by using the upper limbs because responses in the lower limbs reflect spinal function (Aucken and Crawford 1998, Adam and Osbourne 2005). The patient should be asked to obey a couple of simple commands; for example, they should be asked to squeeze the examiner's hands (both sides) – the nurse should note power in the hands and the patient's ability to release the grip in order to discount a reflex action (Fairley et al. 2005). In addition, the patient should be asked to raise their eyebrows or stick out their tongue with the best motor response recorded (Fairley et al. 2005, Waterhouse 2005). If movement is spontaneous, the nurse should note which limbs move and whether the movement is purposeful. If the patient is able to obey commands they should be allocated a score of 6.

If the patient is unresponsive to simple commands, their response to painful stimuli should be assessed. This may be:

- *localized*: the patient moves their hand to the site of the stimulus – either up beyond the chin or across the midline of the body (allocated a score of 5)
- *normal flexion*: no localization is seen, instead the patient bends their arms at the elbow in response to painful stimuli – this is a rapid response associated with abduction of the shoulder (allocated a score of 4)
- *abnormal flexion*: internal rotation, adduction of the shoulder and flexion of the elbow in response to painful stimuli – this is

much slower than normal flexion and may be accompanied by spastic flexion of the wrist (allocated a score of 3)

- *extension*: no abnormal flexion is seen, the patient has straightening of the elbow joint, adduction and internal rotation of the shoulder, and inward rotation and spastic flexion of the wrist limb in response to painful stimuli (allocated a score of 2)
- *flaccid/none*: no motor response is seen at all in response to painful stimuli (allocated a score of 1) (Fairley et al. 2005, Fairley and Pearce 2006b, Waterhouse 2005).

The AVPU scale

The AVPU scale is a simple, rapid and effective method to assess consciousness, and now forms part of the National Early Warning Score (NEWS) (Royal College of Physicians 2012). It is particularly useful during the rapid assessment of an acutely unwell patient (RCUK 2011).

AVPU is a mnemonic for a simple neurological scoring system which quantifies the response to stimulation and assesses the level of consciousness (Jevon and Ewens 2007); it stands for Alert, response to Voice, response to Pain, Unresponsive. Assessment using the AVPU method is done in sequence and only one outcome is recorded; for example, if the patient responds to voice, it is not necessary to assess the response to pain.

- *Alert*: a fully awake (although not necessarily orientated) patient. Such patients will have spontaneous opening of the eyes, will respond to voice (although may be confused) and will have motor function.
- *Voice*: the patient makes some kind of response when you talk to them, which could be in any of the three component measures of eyes, voice or motor, for example, the patient's eyes open on being asked, 'Are you OK?'. The response could be as little as a grunt, moan, or slight movement of a limb when prompted by voice.
- *Pain*: the patient makes a response to a pain stimulus. A patient who is not alert and who has not responded to voice is likely to exhibit only withdrawal from pain, or even involuntary flexion or extension of the limbs from the pain stimulus.
- *Unresponsive*: this is also commonly referred to as 'unconscious'. This outcome is recorded if the patient does not give any eye, voice or motor response to voice or pain (Royal College of Physicians 2012).

Procedure guideline 11.9 Neurological observations and assessment

Essential equipment

- Pen torch
- Thermometer
- Sphygmomanometer
- Tongue depressor
- Patella hammer
- Neuro tips
- Alcohol handrub

Optional equipment

- Low-linting swabs
- Two test tubes
- Snellen chart
- Ophthalmoscope

Pre-procedure

Action

- 1 Inform the patient of the procedure, whether conscious or not, and explain and discuss the observations.

Rationale

Sense of hearing is frequently unimpaired even in unconscious patients. It is important, as far as is possible, that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

Procedure

- 2 Wash and dry hands.

To minimize the risk of cross-contamination (Fraise and Bradley 2009, **E**).

3 Observe the patient without speech or touch.	To assess eye opening as part of the GCS and level of consciousness as part of the AVPU (Fairley et al. 2005, E ; Royal College of Physicians 2012, C).
4 Talk to the patient. Note whether they are alert and giving their full attention or restless or lethargic and drowsy. Ask the patient who they are, where they are and what day, month and year it is. Also ask them to give details about their family.	To establish whether the patient's level of consciousness is deteriorating. If the patient is becoming disorientated, changes will occur in this order: (a) disorientation as to time (b) disorientation as to place (c) disorientation as to person (Aucken and Crawford 1998, E).
5 Ask the patient to squeeze and release your fingers (both sides should be assessed) and then to stick out their tongue or raise their eyebrows.	To evaluate motor responses and to ensure that the responses are equal and are not reflexive (Baumann 2009, E ; Fairley et al. 2005, E ; Waterhouse 2005, E).
6 If the patient does not respond, apply painful stimuli. Suggested methods have been discussed earlier.	Responses grow less purposeful as the patient's level of consciousness deteriorates. As the condition worsens, the patient may no longer localize pain and respond to it in a purposeful way (Baumann 2009, E).
7 Record the findings precisely, recording the patient's best response. Write exactly what stimulus was used, where it was applied, how much pressure was needed to elicit the response, and how the patient responded.	Vague terms can be easily misinterpreted. Accurate recording will enable continuity of assessment and comply with NMC guidelines (NMC 2010, C ; Waterhouse 2005, E).
8 Extend both hands and ask the patient to squeeze your fingers as hard as possible. Compare grip and strength.	To test grip and ascertain strength. Record best arm in GCS chart to reflect best outcome (Baumann 2009, E).
9 Reduce any external bright light by darkening the room, if necessary, or shield the patient's eyes with your hands.	To allow accurate monitoring of pupil reaction and enable a better view of the eye (Fairley and Pearce 2006a, E).
10 Ask the patient to open their eyes. If the patient cannot do so, hold the eyelids open and note the size, shape and equality of both pupils simultaneously.	To assess the size, shape and equality of the pupils as an indication of brain damage (Waterhouse 2005, E). Normal pupils are round and equal in size with a diameter ranging from 2 to 5 mm (Fairley et al. 2005, E ; Fairley and Pearce 2006a, E).
11 Hold each eyelid open in turn. Shine a bright light into each eye as above, moving from the outer corner of each eye towards the pupil. This should cause the pupil to constrict immediately and cause an immediate and brisk dilation of the pupil once the light is withdrawn.	To assess the direct light reflex of the pupils (Fairley et al. 2005, E ; Fairley and Pearce 2006a, E).
12 Hold both eyelids open but shine the light into one eye only. Both pupils should constrict immediately and immediately and briskly dilate once the light is withdrawn.	To assess consensual light reflex (Fairley et al. 2005, E ; Fairley and Pearce 2006a, E).
13 Record pupillary size (in mm) and reactions on observation chart. Brisk reaction is documented as '+', no reaction as '-', sluggish response of one pupil compared to the other as 'S'.	Accurate recording will enable continuity of assessment and comply with NMC guidelines (Fairley et al. 2005, E ; Fairley and Pearce 2006a, E ; NMC 2010, C).
14 Record unusual eye movements such as nystagmus or deviation to the side.	To assess cranial nerve damage (Waterhouse 2005, E).
15 Note the rate, character and pattern of the patient's respirations.	Respirations are controlled by different areas of the brain. When disease or injury affects these areas, respiratory changes may occur (Adam and Osbourne 2005, E ; Baumann 2009, E ; Jevon and Ewens 2007, E).
16 Take and record the patient's temperature at specified intervals.	Damage to the hypothalamus, the temperature-regulating centre in the brain, will be reflected in grossly abnormal temperatures (Adam and Osbourne 2005, E).
17 Take and record the patient's blood pressure and pulse at specified intervals.	To monitor signs of increased intracranial pressure. Hypertension and bradycardia usually occur late, after the patient's level of consciousness has begun to deteriorate. Call for medical assistance as soon as it is evident that there is a deterioration in the patient's level of consciousness (Adam and Osbourne 2005, E ; Jevon and Ewens 2007, E ; Tortora and Derrickson 2011, E).
18 Ask the patient to close the eyes and hold the arms straight out in front, with palms upwards, for 20–30 seconds. Observe for any sign of weakness or drift.	To show weakness and difference in limbs (Baumann 2009, E ; Waterhouse 2005, E).

(continued)

Procedure guideline 11.9 Neurological observations and assessment (*continued*)

Action	Rationale
19 Stand in front of the patient and extend your hands. Ask the patient to push and pull against your hands. Ask the patient to lie on their back in bed. Place the patient's leg with knee flexed and foot resting on the bed. Instruct the patient to keep the foot down as you attempt to extend the leg. Then instruct the patient to straighten the leg while you offer resistance.	To test arm strength. If one arm drifts downwards or turns inwards, it may indicate hemiparesis. To test flexion and extension strength in the patient's extremities by having the patient push and pull against your resistance (Baumann 2009, E ; Waterhouse 2005, E).
20 Flex and extend all the patient's limbs in turn. Note how well the movements are resisted.	To test muscle tone (Baumann 2009, E).
21 Ask the patient to pat their thigh as fast as possible. Note whether the movements seem slow or clumsy. Ask the patient to turn the hand over and back several times in succession. Evaluate co-ordination. Ask the patient to touch the back of the fingers with the thumb in sequence rapidly.	To assess hand and arm co-ordination. The dominant hand should perform better (Baumann 2009, E ; Bickley and Szilagyi 2009, E).
22 Extend one of your hands towards the patient. Ask the patient to touch your index finger, then their nose, several times in succession. Repeat the test with the patient's eyes closed.	To assess hand and arm co-ordination/cerebellar function (Baumann 2009, E).
23 Ask the patient to place a heel on the opposite knee and slide it down the shin to the foot. Check each leg separately.	To assess leg co-ordination (Fuller 2008, E).
24 Ask the patient to look up or hold the eyelid open. With your hand, approach the eye unexpectedly or touch the eyelashes.	To test the corneal (blink) reflex (Fuller 2008, E).
25 Ask the patient to open the mouth, and hold down the tongue with a tongue depressor. Touch the back of the pharynx, on each side, with a low-linting swab.	To test the gag reflex (Fuller 2008, E).
26 Ask the patient to lie on their back in bed. Place your hand under the knee, raise and flex it. Tap the patellar tendon. Note whether the leg responds.	To assess the deep tendon knee-jerk reflex (Bickley and Szilagyi 2009, E ; Fuller 2008, E).
27 Stroke the lateral aspect of the sole of the patient's foot. If the response is abnormal (Babinski's response), the big toe will dorsiflex and the remaining toes will fan out.	To assess for upper motor neurone lesion (Baumann 2009, E ; Bickley and Szilagyi 2009, E ; Fuller 2008, E).
28 Ask the patient to read something aloud. Check each eye separately. If vision is so poor that the patient is unable to read, ask the patient to count your upraised fingers or distinguish light from dark.	To test for visual acuity (Fuller 2008, E).
29 Occlude one ear with a low-linting swab. Stand a short way from the patient. Whisper numbers into the open ear. Ask for feedback. Repeat for the other ear.	To test hearing and comprehension (Fuller 2008, E).
30 Ask the patient to close the eyes. Using the point of a Neuro tip (sharp instrument for applying pressure), stroke the skin. Use the blunt end occasionally. Ask patient to tell you what is felt. See if the patient can distinguish between sharp and dull sensations.	To test superficial sensations to pain (Fuller 2008, E).
31 Ask the patient to close their eyes. Fill two test tubes with water – one warm, one cold. Touch the patient's skin with each test tube and ask patient to distinguish between them.	To test superficial sensations to temperature (Fuller 2008, E).
32 Stroke a low-linting swab lightly over the patient's skin. Ask the patient to say what they feel.	To test superficial sensations to touch (Fuller 2008, E).
33 Ask the patient to close the eyes. Hold the tip of one of the patient's fingers between your thumb and index finger. Move it up and down and ask the patient to say in which direction it is moving. Repeat with the other hand. For the legs, hold the big toe.	To test proprioception (Bickley and Szilagyi 2009, E). <i>Proprioception</i> is the receipt of information from muscles and tendons in the labyrinth that enables the brain to determine movements and position of the body (Tortora and Derrickson 2011, E).

Post-procedure

34 Document the observation recordings on the patient's observation chart; record only what you see. Do not be influenced by previous observations.	To ensure adequate records and enable continued care of the patient (NMC 2010, C).
35 Report any abnormal findings to medical staff.	To prevent further deterioration and allow timely intervention. E
36 Wash and dry hands or use alcohol handrub.	To minimize the spread of cross-infection (Fraise and Bradley 2009, E).
37 Clean the equipment after use.	To prevent cross-infection (Fraise and Bradley 2009, E).

Problem-solving table 11.8 Prevention and resolution (Procedure guideline 11.9)

Problem	Cause	Prevention	Action
Language difficulties or dysphasia.	Difficulty making accurate assessment of consciousness.	Knowledge of language difficulties.	Use of interpreter for language barrier. Consideration when taking into account overall assessment process.
Patient unable to open eye(s).	Result of swelling.	Unable to prevent.	Does not necessarily indicate a low or falling conscious level.

665

Post-procedural considerations**Documentation**

A validated observation chart is the most common method of monitoring and recording neurological observations. Although the layout may differ from chart to chart, in essence all neurological observation charts measure and record the same clinical information, including the level of consciousness, pupil size and response, motor and sensory response and vital signs (Dawes and Durham 2007).

Observation charts ensure a systematic approach to collecting and analysing essential information regarding a patient's condition. Such charts also act as a means of communication between nurses and other healthcare professionals (Dawes and Durham 2007).

- 12.26** Medication: injection (bolus or push) of intravenous drugs 763
- 12.27** Extravasation management: peripheral cannula 774
- 12.28** Extravasation: performing flush-out following an extravasation 776

Overview

In this chapter the safe, effective and appropriate use of medicines in partnership with the patient will be discussed. This will include prescribing, supply, administration and supporting patients in their own environment to manage their medicines effectively. The terms medicine and drugs will be used interchangeably throughout the chapter and mean the same.

Definitions

Medicines management

'Medicines management in hospitals encompasses the entire way that medicines are selected, procured, delivered, prescribed, administered and reviewed to optimise the contribution that medicines make to producing informed and desired outcomes of patient care' (Audit Commission 2001, p.5).

The Medicines and Healthcare Products Regulatory Agency (MHRA 2004) defines medicines management as 'the clinical, cost-effective and safe use of medicines to ensure patients get the maximum benefit from the medicines they need, while at the same time minimising potential harm'. All Registered Nurses have a professional responsibility with regard to procurement, prescription, supply and disposal of medicines as defined in the NMC *Standards for Medicines Management* (NMC 2010a). They must ensure the patient understands what medicines they are taking, the indication for the medication and any likely side-effects.

Medicinal products and medical devices

The definition of a medicine is:

- any substance or combination of substances presented as having properties for treating or preventing disease in human beings; or
- any substance or combination of substances which may be used in or administered to human beings either with a view to restoring, correcting or modifying physiological functions by exerting a pharmacological, immunological or metabolic action, or to making a medical diagnosis.

The definition of a medical device is any instrument, apparatus, appliance, material or other article, whether used alone or in combination, including the software necessary for its proper application intended by the manufacturer to be used for human beings for the purpose of:

- diagnosis, prevention, monitoring, treatment or alleviation of disease
- diagnosis, monitoring, treatment, alleviation of or compensation for an injury or handicap
- investigation, replacement or modification of the anatomy or of a physiological process
- control of conception

and which does not achieve its principal intended action in or on the human body by pharmacological, immunological or metabolic means, but which may be assisted in its function by such means.

There are three main types of medical device which incorporate or are used to administer a medicinal product.

- Devices which are used to administer medicinal product, e.g. medicine spoon, dropper.
- Devices for administering medicinal products where the device and the medicinal product form a single integral product designed to be used exclusively in the given combination and which are not reusable or refillable, e.g. pre-filled syringe.
- Devices incorporating, as an integral part, a substance which, if used separately, may be considered to be a medicinal product

and which is such that the substance is liable to act upon the body with action ancillary to that of the device, e.g. wound dressings with antimicrobial agents.

Pharmacology

- *Pharmacology* can be defined as the study of the effects of drugs on the function of living systems. Its purpose is to understand what drugs do to living organisms and, more practically, how their effects can be applied to the treatment of diseases (Rang and Dale 2012).
- *Pharmacokinetics* looks at the absorption, distribution, metabolism and excretion of drugs within the body, i.e. what the body does to the drug. When these four factors are considered, with the dose of a drug given, the concentration of drug in the body over a period of time can be determined. Pharmacokinetics is most useful when considered with *pharmacodynamics* which is the study of the mechanisms of action of drugs and other biochemical and physiological effects, i.e. what the drug does to the body (Rang and Dale 2012).
- The *indication* for a drug refers to the use of that drug for treating a particular disease. Drugs often have more than one indication, which means that there is more than one disease for which it could be used. Indications may be diagnostic, prophylactic or for therapeutic purposes.
- A *contraindication* to a medicine is a specific situation in which a medicine should not be used, because it may be harmful to the patient. This could be due to the patient's allergy status, co-morbidities, current disease state or other medicines they are taking.
- A *drug interaction* is when a substance (e.g. another medicine, food) affects the activity of a drug when both are administered together. This action can be synergistic (when the drug's effect is increased) or antagonistic (when the drug's effect is decreased) or a new effect can be produced that neither drug produces on its own. Interactions between drugs are termed drug-drug interactions and interactions between drugs and foods are known as drug-food interactions (Stockley's Drug Interactions: www.medicinescomplete.com). It is important not to forget over-the-counter, herbal and complementary medicines when considering potential interactions.
- *Side-effects* of a medicine are defined as 'any effect that is in addition to its intended primary effect that can be harmful, unpleasant or in some cases beneficial to the patient'. The harmful or unpleasant side-effects are more commonly described as adverse drug reactions (ADRs) (Aronson 2006).

Evidence base for medicines management in practice

Good medicines management is essential to assure high standards in the clinical care of patients. When delivered effectively, it can reduce the risk of medication errors and serious adverse drug reactions and prevent unnecessary delays for the patient at the point of discharge. It also enables the spending on medicines to be more effectively managed (Audit Commission 2001).

All aspects of a medicine's use must be managed with a multidisciplinary approach to ensure it is supported by a strong evidence base and that the safety and well-being of the patient remain paramount (NMC 2015, Shepherd 2002a).

Key principles of medicines management

Legislation

Legislative frameworks, government guidelines and professional regulations govern medicines management in the UK. The primary pieces of legislation are the Medicines Act 1968 and the European Directives and the Misuse of Drugs Act 1971 (HMSO 1971). European Community Council Directives and Regulations and the Medicines Act 1968 (HMSO 1968) regulate

the manufacture, distribution and importation of medicines for human use.

The Medicines Act 1968

The Medicines and Health Care Products Regulatory Agency (MHRA) in the UK and the European Medicines Agency (EMA) are responsible for the licensing procedures for medicinal products. The availability of products is restricted by defining which of the following legal categories they are in:

- prescription-only medicines (POM)
- pharmacy-only medicines (P)
- general sales list medicines (GSL).

Different requirements apply to the sale, supply and labelling of medicines in each category. In hospitals, medicines can be supplied in line with patient-specific directions, from an appropriate practitioner in relation to the medicine, which in most cases will be an instruction on the patient ward drug chart. The legislation also allows the supply of prescription-only medicines to be made under a Patient Group Direction (PGD). A PGD needs to be signed by a doctor and a pharmacist. The regulations permit certain registered professionals to supply or administer under a PGD.

In addition to the above, there are also a range of exemptions from the regulations which allow certain groups of health professionals to sell, supply and administer particular medicines direct to patients. For example, in an emergency and under certain conditions, a pharmacist working in a registered pharmacy can supply a prescription-only medicine to a patient without a prescription if requested by a prescriber or patient (Applebe and Wingfield 2005, RPSGB 2012).

Legal methods for prescribing medicines

The Medicines Act 1968 states that only authorized healthcare practitioners can legally prescribe medicines in the UK. It provides all prescribers with a framework for which medicines require a prescription and which medicines can be available to the public without a prescription and under what circumstances. All medicines administered in hospital must be considered prescription only. This is because administration, whether by a nurse or by a patient to themselves, may only take place in accordance with one or more of the following processes:

- patient-specific direction
- patient medicines administration chart (also called a medicines administration record [MAR])
- Patient Group Direction (PGD)
- Medicines Act exemplar
- standing orders
- homely remedy protocol
- prescription form (NMC 2010a, pp.13–19).

Prescriptions can be handwritten on a chart, a prescription pad or provided electronically. E-prescribing has been defined as the 'utilisation of electronic systems to facilitate and enhance the communication of a prescription or medicine order, aiding the choice, administration and supply of a medicine through knowledge and decision support and providing a robust audit trail for the entire medicines use process' (NHS Connecting for Health 2009, p.9). There are many benefits of e-prescribing systems, summarized in Box 12.1.

A growing number of UK hospitals have introduced e-prescribing systems. One major motivation for this is to improve the safety of medicines used and reduce the current and unacceptable levels of adverse drug events. In a systematic review, nine of the 13 studies demonstrated a significant reduction in prescribing errors for all or some drug types when e-prescribing was used (Reckmann et al. 2009).

Box 12.1 Benefits of e-prescribing systems

The Connecting for Health programme has outlined the benefits of e-prescribing systems as:

- computerized entry and management of prescriptions
- knowledge support, with immediate access to medicines information, for example *British National Formulary*
- decision support, aiding the choice of medicines and other therapies, with alerts such as drug interactions
- computerized links between hospital wards/departments and pharmacies
- ultimately, links to other elements of patients' individual care records
- improvements in existing work processes
- a robust audit trail for the entire medicines use process
- a reduction in the risk of medication errors as a result of several factors, including:
 - more legible prescriptions
 - alerts for contraindications, allergic reactions and drug interactions
 - guidance for inexperienced prescribers
 - improved communication between different departments and care settings
 - reduction in paperwork-related problems, for example fewer lost or illegible prescriptions
 - clearer, and more complete, audit trails of medication administration
 - improved formulary guidance and management and appropriate reminders within care pathways.

Nurse prescribing and Patient Group Directions

As nurses have undertaken increasingly specialized roles, the need for them to have powers to prescribe has become more apparent. The report of the Advisory Committee on Nurse Prescribing (DH 1989) initially recommended a limited nurses' formulary for community nurses and health visitors. The Medicinal Products: Prescription by Nurse, etc. Act 1992 granted the statutory authority for this to occur. The Crown Report (DH 1989) also recommended that doctors and nurses collaborate in drawing up local protocols for the administration of medicines in situations that would benefit specific groups of patients, for example those requiring vaccinations.

The practice of prescribing under group protocols became widespread across the NHS, and they were used to support initiatives such as nurse-led clinics (Lavery et al. 1997, Mallett et al. 1997). The legality of this practice was then questioned. Section 58 of the Medicines Act 1968 states that 'no one should administer any medication (other than to himself) unless he is the appropriate practitioner or a person who is acting according to directions from an appropriate practitioner'. The terms *direction* and *administration* were open to interpretation and how they were used varied across the country (McHale 2002).

Nurse prescribing was therefore reviewed and two further reports were published.

- *Review of Prescribing, Supply and Administration of Medicines. A Report on the Supply and Administration of Medicines under Group Protocols* (DH 1998).
- *Review of Prescribing, Supply and Administration of Medicines. Final Report* (DH 1999).

The first specifically offered guidance about group protocols, including changing the name to Patient Group Directions (PGD) (Box 12.2 and Figure 12.1).

Box 12.2 Patient Group Directions

The legal definition of a Patient Group Direction is 'a written instruction for the supply and/or administration of a licensed medicine (or medicines) in an identified clinical situation signed by a doctor or dentist and a pharmacist' (NPC 2009). It is drawn up locally by doctors, pharmacists and other appropriate professionals and must be approved by the employer, advised by the relevant professional advisory committee. It applies to groups of patients or other service users who may not be individually identified before presentation for treatment (DH 2004). The Health and Safety Commission (HSC) advised that the majority of medication 'should be prescribed and administered on an individual patient specific basis', but that it is appropriate to use PGDs for the supply and administration of medicines in situations where this offers an advantage for patient care (DH 2000b). Shepherd suggests that this means 'where medical staff are either inaccessible or unavailable' (Shepherd 2002b, p.44). The flowchart in Figure 12.1 aims to assist practitioners in deciding the appropriate system for the prescription, supply or administration of medicines. Using a PGD is not a form of prescribing (NICE 2014a).

678

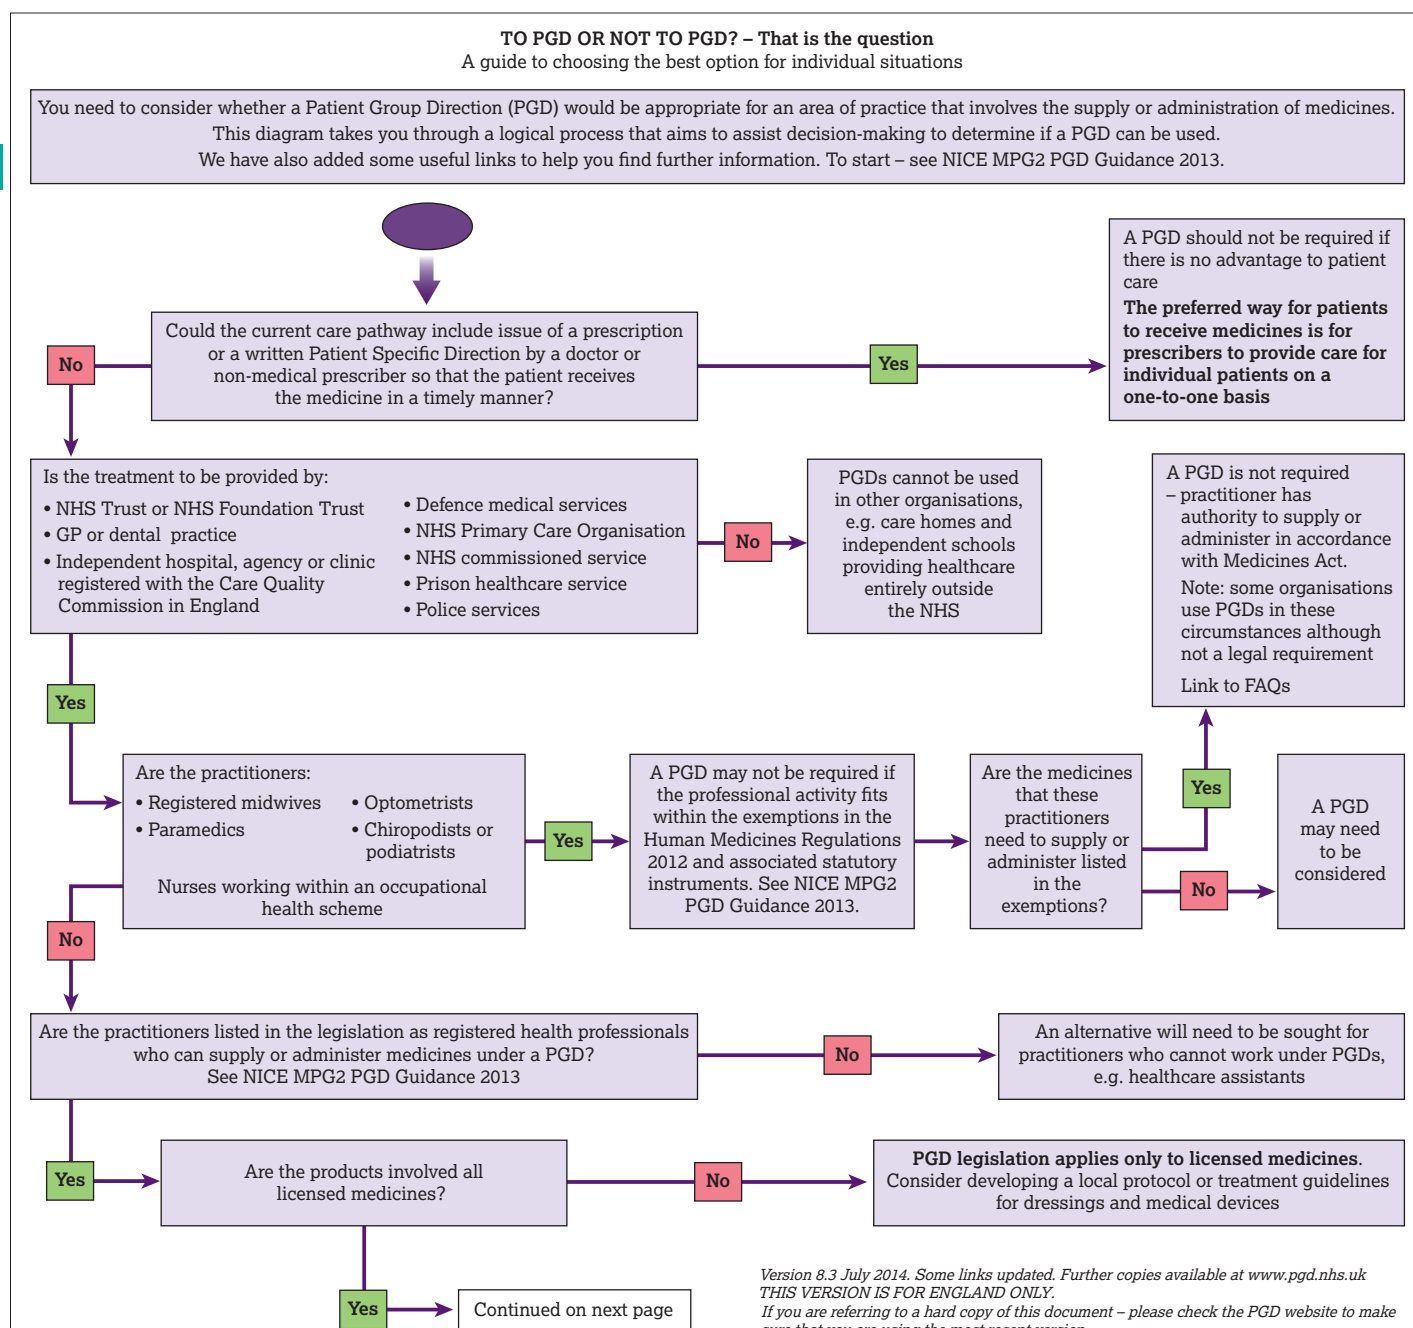

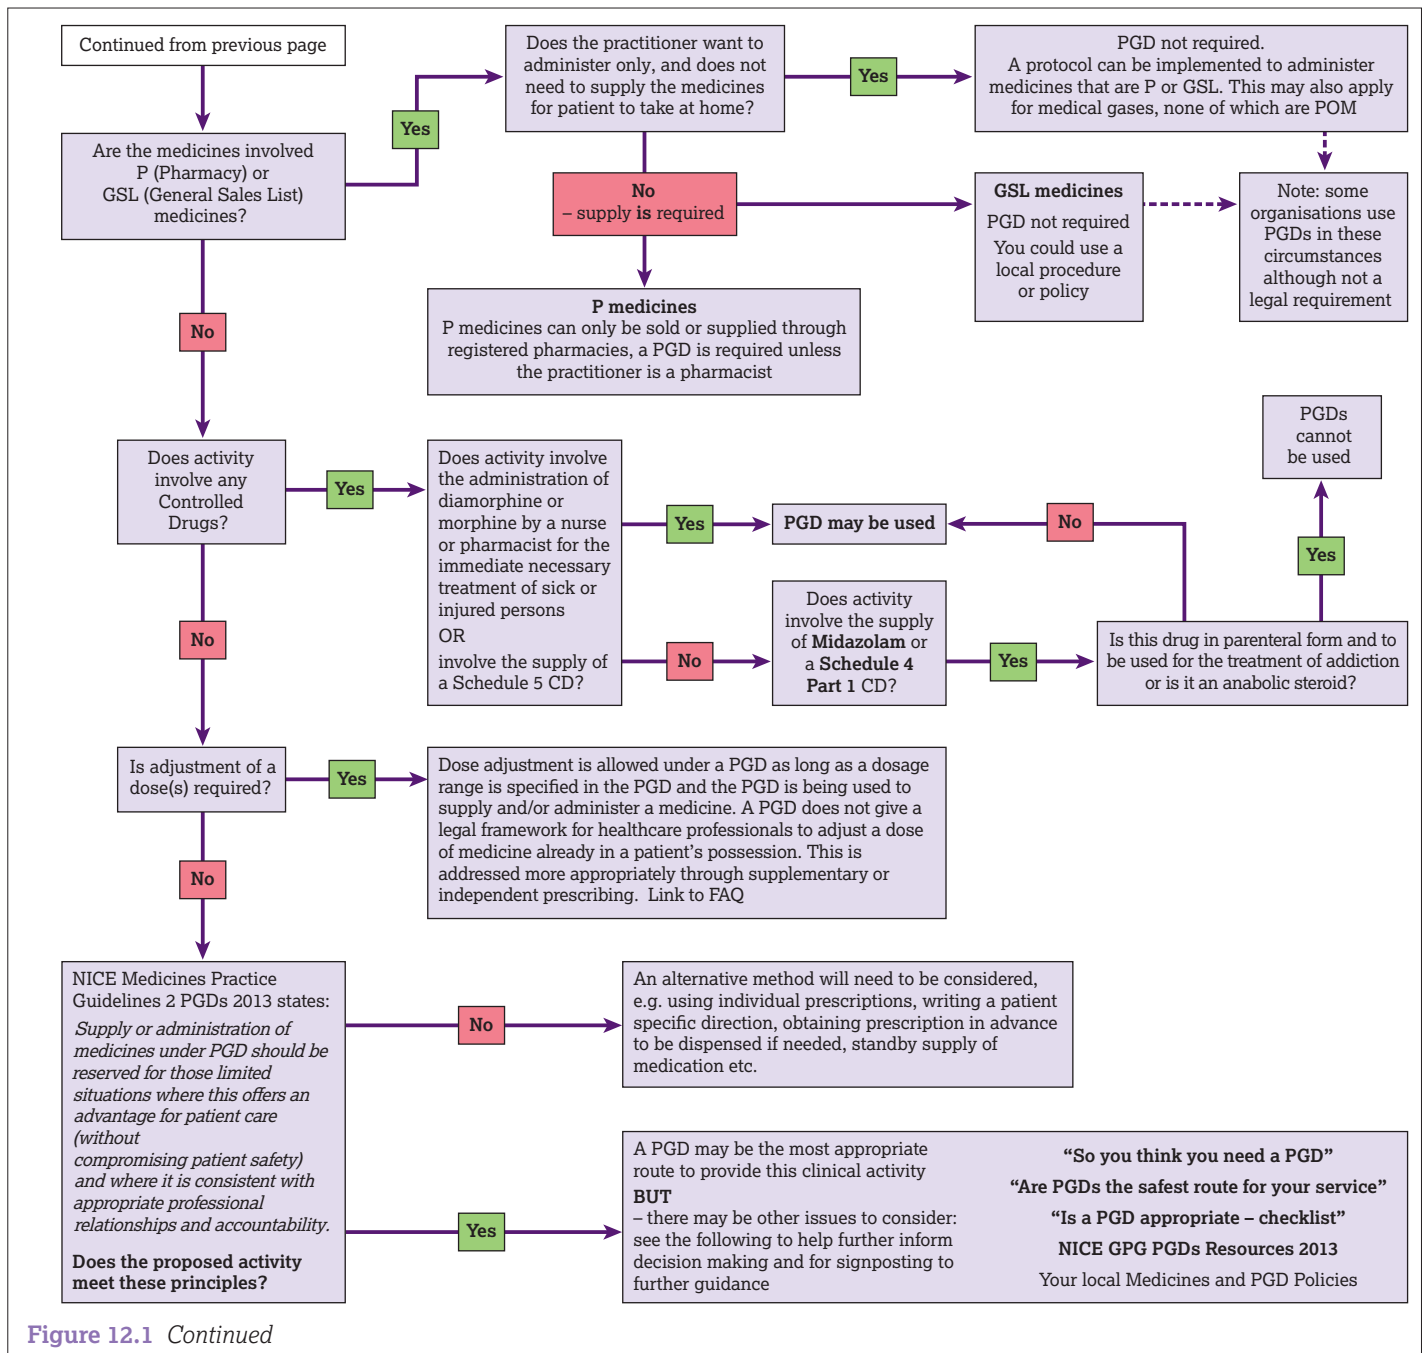

Figure 12.1 Patient Group Directions (PGDs) flowchart. The diagram takes the practitioner through a logical process that aims to assist in determining if a PGD can be used. Source: Patient Group Directions (England) (www.pgd.nhs.uk). Please check the PGD website for the most recent version of this tool and for further resources and guidance relating to PGDs. www.medicinesresources.nhs.uk/en/Communities/NHS/PGDs/PGD-Legislation-Guidance/PGD-Website-Tools/To-PGD-or-not-to-PGD-that-is-the-question/

The second report looked at the existing arrangements for prescribing, supply and administration of medicines and suggested the introduction of a new form of prescribing to be undertaken by non-medical health professionals (DH 2003a). Independent nurse prescribing was initially allowed from an extremely limited formulary (Shuttleworth 2005). It was then extended a number of times until finally, appropriately qualified nurses were allowed to prescribe from the whole *British National Formulary* (BNF).

- *Independent prescribing*: this allows nurses who are registered as independent prescribers to prescribe any licensed medicine (and now unlicensed; DH 2009) for any medical condition (this also includes some controlled drugs; see section on 'Controlled drugs') but only within their own level of experience and competence, and acting in accordance with the NMC *Code* (Public Health England 2006, NMC 2015). Only those who have

undergone appropriate training and are registered with the NMC as an independent prescriber can prescribe (NMC 2006). It must also be considered to be part of that nurse's role.

- *Supplementary prescribing* has been defined as: 'A voluntary prescribing partnership between an independent prescriber and a supplementary prescriber to implement an agreed patient specific clinical management plan with the patient's agreement' (DH 2003a). Amendments to the Prescription Only Medicines Order and the NHS regulations allowed supplementary prescribing by suitably trained nurses from April 2003. Supplementary prescribers prescribe in partnership with a doctor or dentist (the independent prescriber) and are able to prescribe any medicine, including controlled drugs and unlicensed medicines that are listed in an agreed clinical management plan. The plan is drawn up with the patient's agreement, following diagnosis of the patient by an independent prescriber and following

consultation and agreement between the independent and supplementary prescribers (DH 2003a, pp.6 and 7).

The key principles that underpin supplementary prescribing are:

- the importance of communication between prescribing partners
- the need for access to shared patient records
- the patient is treated as a partner in their care and is involved at all stages in decision making, including whether part of their care is delivered via supplementary prescribing (NPC 2003a).

Preparation for both independent nurse prescribing and supplementary prescribing is at least 26 days in length and must follow the standards set out in the NMC *Circular 25/2002* (NMC 2001b). Any preparation must enable independent and supplementary non-medical prescribers to reach the competencies outlined in *Maintaining Competency in Prescribing: An Outline Framework to Help Nurse Prescribers* (NPC 2001), *Maintaining Competency in Prescribing: An Outline Framework to Help Nurse Supplementary Prescribers* (NPC 2003b) and the competences in shared decision making within the Medicines Partnership document (Medicines Partnership Programme 2007).

The addition of prescriptive authority to the nurse role has not only been a positive way of making a service more responsive for service users, but also has helped to meet increasing demands on health services (Bridge et al. 2005). Patients are satisfied with nurse prescribing (Latter et al. 2005) and it is also generally viewed positively by other healthcare professionals (Latter et al. 2010). In 2005 it was estimated that there were 28,000 nurses who were able to prescribe from the limited formulary and 4000 extended prescribers (MHRA 2005). Latter et al. (2010) found that 2–3% of both the nursing and pharmacist workforce are qualified to prescribe medicines independently, in both primary and secondary care settings. A national survey of 246 nurse prescribers concluded that nurse prescribing is largely successful in both practice and policy terms (Latter et al. 2005): this is discussed in more detail in Box 12.3.

A range of competencies and skills are required to ensure quality and safe prescribing; the nurse prescriber:

- identifies main medical condition
- explores patient's presenting symptoms and their management
- explores past medical history, current medication, including over-the-counter (OTC), allergies and family history
- is able to initiate a physical examination
- is able to request and interpret diagnostic tests.

The evidence is that nurses need to be more consistent in the frequency with which they apply these skills (Latter 2008).

Box 12.3 An evaluation of nurse prescribing

- Most nurse prescribers were confident in their prescribing practice.
- Most felt extended prescribing had a positive impact on patient care and enabled them to make better use of their skills.
- Most felt that the limited nurse formulary imposed unhelpful limitations on their practice.
- Nurses were satisfied with the support received from their medical practitioner.
- Patients were positive about their experience of nurse prescribing.
- Doctors were positive about the development of nurse prescribers in their teams.

Unlicensed and 'off-label' medicines

Under European medicines legislation, a medicinal product placed on the market is required to have a marketing authorization (product licence) granted following demonstration of safety, quality and efficacy. However, member states can put in place arrangements to allow an authorized healthcare professional to gain access to an unlicensed medicine, that is, a medicine that does not have a marketing authorization, to meet the special needs of individual patients. In the UK, this occurs via the arrangements for 'specials' manufactured in the UK and the notification scheme for products imported into the UK.

'Specials' can be supplied if there is an order for them, a registered doctor has requested the product and the product will be used for a patient under the care of that doctor and under that doctor's supervision. A 'special' cannot be supplied if an equivalent licensed product is available which will meet the patient's needs. If a 'special' is manufactured in the UK, the manufacturer must hold a manufacturer's (special) licence issued by the MHRA. An unlicensed medicine may also be imported if the importer holds the appropriate wholesaler dealer licence or wholesaler dealer import licence issued by the MHRA. The importer will need to inform the MHRA on each occasion that they intend to import the product. 'Off label' refers to the use of a medicine outside the terms of its licence.

For herbal medicines, there are three possible regulatory routes by which they can reach the market in the UK: as an unlicensed herbal remedy; as a registered traditional herbal medicine (identified as the product container or packaging will include a nine-digit registration number starting with the letters THR) (MHRA 2009); and as a licensed herbal medicine.

Unlicensed medicines can be prescribed by doctors, dentists and nurse independent prescribers (DH 2009). 'Off-label' medicines can be prescribed by doctors, dentists, independent nurse prescribers, independent pharmacist prescribers and independent optometrist prescribers. The MHRA has published advice for prescribers on the use of unlicensed and off-label medicines because the responsibility for prescribing such medicines is potentially greater than for licensed products (Box 12.4).

Nurse independent prescribers can also mix medicines prior to administration and direct others to mix, for example for use within syringe pumps (DH 2009).

As discussed later in this chapter, the MHRA advises that healthcare professionals have a responsibility to help monitor the safety of medicines in clinical use through submission of suspected adverse drug reactions to the MHRA and the Commission on Human Medicines (CHM) via the Yellow Card Scheme (www.yellowcard.mhra.gov.uk). Such reporting is equally important for unlicensed medicines or those used off label as for those that are licensed.

Verbal orders

The NMC (2010a) clearly states that a verbal order is not acceptable on its own. 'In exceptional circumstances, where the medication (NOT including controlled drugs) has been previously prescribed and the prescriber is unable to issue a new prescription, but where changes to the dose are considered necessary, the use of information technology (such as fax or e-mail) may be used but the prescriber must confirm any changes to the original prescription' (NMC 2010a, p.28). This should be followed up by a new prescription, signed by the prescriber confirming the changes, within a maximum of 24 hours. The changes must be authorized before the new dosage is administered (NMC 2010a).

Supply of medicines

Medicines reconciliation

Medicines reconciliation forms part of the medicines management process. It improves patient safety and contributes to the Quality, Innovation, Productivity and Prevention (QIPP) programme by reducing length of stay and the risk of readmission to hospital.

Box 12.4 MHRA advice for prescribers on the use of unlicensed and off-label medicines

- Before prescribing an unlicensed medicine, be satisfied that an alternative, licensed medicine would not meet the patient's needs.
- Before prescribing a medicine off label, be satisfied that such use would better serve the patient's needs than an appropriately licensed alternative.
- Before prescribing an unlicensed medicine or using a medicine off-label:
 - be satisfied that there is a sufficient evidence base and/or experience of using the medicine to show its safety and efficacy
 - take responsibility for prescribing the medicine and for overseeing the patient's care, including monitoring and follow-up
 - record the medicine prescribed and, where common practice is not being followed, the reasons for prescribing this medicine; you may wish to record that you have discussed the issue with the patient.

The MHRA also advises that best practice suggests that:

- you give patients, or those authorizing treatment on their behalf, sufficient information about the proposed treatment, including known serious or common adverse reactions, to enable them to make an informed decision
- where current practice supports the use of a medicine outside the terms of its licence, it may not be necessary to draw attention to the licence when seeking consent. However, it is good practice to give as much information as patients or carers require or which they may see as relevant
- you explain the reasons for prescribing a medicine off label or an unlicensed medicine where there is little evidence to support its use, or where such use of a medicine is innovative.

It has been defined by the Institute for Healthcare Improvement as 'the process of creating the most accurate list possible of all medications the patient is taking – including drug name, dosage, frequency and route – and comparing that list against the physician's admission, transfer, and/or discharge orders, with the goal of providing correct medications to the patient at all transition points within the hospital' (www.ihl.org).

The National Prescribing Centre (NPC) guidance recommends specific competencies required for undertaking medicines reconciliation. These include effective communication skills, technical knowledge of relevant medicines management processes and therapeutic knowledge (NPC 2007b). Medicines reconciliation requires clinical judgement and should only be undertaken by competent healthcare staff. In most hospital settings medicines reconciliation is performed by a member of the pharmacy team who has completed the necessary local accreditation processes deemed essential to perform this role safely and accurately.

Dispensing

Dispensing is defined as 'to label from stock and supply a clinically appropriate medicine to a patient/client/carer usually against a written prescription, for self-administration or administration by another professional and to advise on safe and effective use' (NMC 2010a, p.20). The majority of these activities in hospitals are undertaken by the pharmacy department. They can supply medicines as stock to a ward or for specific patients who are inpatients, daycase patients or outpatients. Pharmacists are professionally accountable for all decisions to supply a medicine and offer advice. As part of this accountability, they must ensure that if any tasks are to be delegated, they are delegated to persons competent to perform them. Nurses may only dispense in exceptional circumstances (NMC 2010a).

A pharmaceutical assessment of a prescription, which is the point at which pharmacists apply their knowledge to establish the safety, quality, efficacy and perhaps cost-effective use of drug treatments specified by a prescriber, must be performed by a pharmacist and must be carried out on every prescription (RPSGB 2007a). Following this assessment, the assembly of the prescription can be delegated to a pharmacy technician or a pharmacy assistant. Once the prescription is assembled, it will be presented for accuracy checking by a pharmacist or a suitably qualified pharmacy technician.

Many pharmacies have also now adopted practices of one-stop dispensing and robotic dispensing. One-stop dispensing involves medicines for inpatients being supplied in a form ready for discharge. Robotic and automated systems can be used to pick and label medicines in order to reduce errors in these areas (RPSGB 2007a).

Use of patient's own drugs

Patients are encouraged to bring their medication into hospital with them to facilitate a comprehensive medicines reconciliation process. This can also be useful if the organization has a policy of using the patient's own drugs.

These medicines remain the property of the patient and should not be destroyed without prior consent from the patient or their representative. If the patient does agree to the destruction of the medicines, they must be sent to the pharmacy for destruction. If the patient does not want the medicines to be stored in the hospital or sent to pharmacy for destruction, they must be sent home with the patient's representative. Patients' medicines should only be used if they can be positively identified, are of a suitable quality and are labelled according to labelling requirements. They should be stored to the same security standards as other medicine stock on the ward. They should be used for the sole use of the patient whose property they remain (RPSGB 2005).

Safe storage of medicines

The report *The Safe and Secure Handling of Medicines: A Team Approach* (RPSGB 2005) details that the responsibility for establishing and maintaining a system for the security of medicines should be that of the senior pharmacist in the hospital. They should do this in consultation with senior nursing staff and appropriate medical staff. The appointed nurse in charge of the area will have the responsibility of ensuring that this system is followed and that the security of medicines is maintained. The nurse in charge may delegate some of these duties but always remains responsible for this task. The safe and secure handling of medicines on the ward is governed by the following principles.

Security

All drugs should be stored in locked cupboards with separate storage for internal medicines, external medicines, controlled drugs and medicines needing refrigeration or storage in a freezer.

Diagnostic reagents, intravenous and topical agents should also be kept separately in individual storage.

Stability

No medicinal preparation should be stored where it may be subject to substantial variations in temperature, for example not in direct sunlight.

The normal temperature ranges for storage are as follows.

- **Cold storage:** products to be stored between 2°C and 8°C. Refrigerators should be placed in an area where the ambient temperature does not affect the temperature control within it. Most refrigerators will function effectively in an environment of 10–32°C. Refrigerators should have a minimum and maximum thermometer fitted which should be read and reset daily (MHRA 2001).

- **Cool storage:** products that need to be stored in a cool place or between 8°C and 15°C. If these temperatures cannot be achieved, these products should be stored in a fridge provided that temperatures below 8°C do not affect the stability of the product. If lower temperatures do affect the stability, it is recommended that they are stored in an area where the temperature will not exceed 18°C (MHRA 2001).
- **Room temperature:** for products that need to be stored at room temperature or not above 25°C (MHRA 2001).

Containers

The type of container used may have been chosen for specific reasons. Therefore all medicines should be stored in the containers in which they were supplied by pharmacy. Medicinal preparations should never be transferred (in bulk) from one container to another except in the pharmacy.

Stock control

A system of stock rotation must be operated (e.g. first in, first out) to ensure that there is no accumulation of old stocks. Only one pack/container of a named medicine should be in use at any one time. A list of stock medicines to be kept on the ward should be regularly reviewed according to usage figures. The medicines to be held on the ward should be discussed between the nurse in charge and a pharmacist with relevant medical staff.

Storage requirements of specific preparations

- **Aerosol containers** should not be stored in direct sunlight or over radiators: there is a risk of explosion if they are heated.
- **Creams** may deteriorate rapidly if subjected to extremes of temperature.
- **Eye drops and ointments** may become contaminated with micro-organisms during use and thus pose a danger to the recipient. Therefore, in hospitals, eye preparations should be discarded 7 days after they are first opened. For use at home, this limit is extended to 28 days.
- **Mixtures** may have a relatively short shelf-life. Most antibiotic mixtures require refrigerated storage and even then have a shelf-life of only 7–14 days. Always check the label for details.
- **Tablets and capsules** are relatively stable but are susceptible to moisture unless correctly packed. They should be stored only in the containers in which they were supplied by the pharmacy.
- **Vaccines** and similar preparations usually require refrigerated storage and may deteriorate rapidly if exposed to heat.

Safe and secure handling of medicines

Handling of medicines is a frequent everyday nursing activity that carries great responsibility.

The effective and safe prescribing, dispensing and administration of medicines to patients demands a partnership between the various health professionals concerned, that is doctors, pharmacists and nurses. The revised Duthie Report, *The Safe and Secure Handling of Medicines: A Team Approach* (RPSGB 2005), defined a medicine as 'a substance administered by mouth, applied to the body or introduced into the body for the purpose of treating or preventing disease, diagnosing disease or ascertaining the existence, degree or extent of a physiological condition, contraception, inducing anaesthesia, or otherwise preventing or interfering with the normal operation of a physiological function' (p.103). It follows from this definition that infusions or injections of sodium chloride 0.9% and water for injection are included, as are all medicinal products covered by the European Directive on Medicines. This report details how the key principles of compliance with legislation, adherence to guidance and safety of patients and staff should be applied to the management and handling of medicines. In order to achieve this, organizations should have in place Standard Operating Procedures (SOPs) for each activity in the medicines trail, also

Box 12.5 Activities defined in the medicines trail

- Prescribing/initiation of treatment
- Procurement/acquisition of medicines
- Manufacture/manipulation of medicines
- Receipt of medicines
- Issue to point of use/dispensing or supply
- Preparation/manipulation of medicines for administration
- Use of medicines/administration
- Removal/disposal of surplus/waste medicines from wards and departments
- Removal/disposal of surplus/waste medicines or related materials from the hospital

indicating clear responsibilities, training, competencies and performance standards for each member of staff. Processes for validation, audit and risk assessment of the activities also need to be included.

The activities defined in the medicines trail are detailed in Box 12.5.

Safe administration of medicines

All nurses who administer medicines must be familiar with and adhere to the *Standards for Medicines Management* (NMC 2010a). The nurse is accountable for the safe administration of medicines which is arguably one of the most common clinical procedures that a nurse will undertake. This can be regarded as the greatest area of risk in nursing practice. To achieve safe administration, the nurse must have a sound knowledge of the therapeutic use, usual dose, side-effects, precautions and contraindications of the drug being administered. If the nurse lacks knowledge of a particular medicine, s/he must not administer the medicine and must seek advice from a senior colleague.

Institutional policies and procedures will assist the nurse to administer drugs safely and a sound working knowledge of these is essential. Medicines administration requires thought and the exercise of professional judgement (NMC 2010a, p.3). There are a number of 'rights' – five rights (Federico 2011, MacDonald 2010), six rights (Potter 2011), eight rights (Bonsell 2011) and nine rights (Elliot & Lui 2010) (see Table 12.1).

Never events

Never events are 'serious, largely preventable patient safety incidents that should not occur if the available preventative measures have been implemented by health care providers' (DH 2012). To be a Never Event, an incident must have clear potential for or has previously caused severe harm, is a known source of risk, there is existing national guidance on how to prevent it and it is largely preventable if the guidance is implemented. Finally it must be easily defined, identified and measured (DH 2012). Occurrence of a Never Event indicates that an organization may not have put the right systems and processes in place to prevent incidents from happening (DH 2012).

For examples of Never Events related to medications, see Box 12.6.

Definition and causes of medication errors

Medication administration errors occur frequently and are more likely to result in serious harm and death than other types of medication errors (Westbrook et al. 2011). Direct observational studies in hospitals estimate error rates in 19–27% of drugs administered to patients (Westbrook et al. 2011). Studies have demonstrated that interruptions are common and that these and other distractions can increase error and accident rates related to drug administration (Relihan et al. 2010, Westbrook et al. 2010) (Box 12.7).

683

Key principles for administration of medicines

Patient identification

When administering a medicine, the nurse must be certain of the identity of the patient to whom the medicine is to be administered (NMC 2010a), i.e. check name, hospital number and date

Box 12.6 List of Never Events related to medications 2012–13

- Wrongly prepared high-risk injectable medications
- Maladministration of a potassium-containing solution
- Wrong route of chemotherapy
- Intravenous administration of epidural medication
- Overdose of midazolam for conscious sedation
- Air embolism
- Misidentification of patients
- Maladministration of insulin
- Opioid overdose in an opioid-naïve patient
- Inappropriate administration of daily oral methotrexate

of birth. To avoid misidentification of patients, staff should check the patient's identity using an identification wristband, following the NPSA (2007b) guidance on the use of a wristband for patient identification.

Patient misidentification can occur at any stage of a patient's journey and, as it is under-reported, its 'true' incidence unknown (Rosenthal 2003). Not identifying the patient correctly can result in the administration of a wrong drug or dose and can sometimes be fatal (Schulmeister 2008). The patient's prescription chart should be taken to the bedside to ensure verification against two

Table 12.2 Types of allergic reactions

Type of reaction	Result of reaction	Example of reaction
Type I IgE-mediated reactions	Urticaria, angio-oedema, anaphylaxis and bronchospasm	Anaphylaxis from beta-lactam antibiotic
Type II IgG/M-mediated cytotoxic reaction	Anaemia, cytopenia and thrombocytopenia	Haemolytic anaemia from penicillin
Type III IgG/M-mediated immune complexes	Vasculitis, lymphadenopathy, fever, arthropathy and rashes Can also be known as serum sickness	Serum sickness from antithymocyte globulin
Type IV Delayed hypersensitivity reactions	Dermatitis, bullous exanthema, maculopapular and pustular xanthemata	Contact dermatitis from topical antihistamine

Source: Adapted from Beijnen and Schellens (2004), Riedl and Casillas (2003).

patient identifiers, e.g. patient name, date of birth and/or hospital number (Grissinger 2008, Gunningberg et al. 2014).

Allergy status

Accurate and up-to-date allergy information is important in reducing medicine-related harm to patients. The patient's allergy status must be up to date at all times. It is the responsibility of all health-care professionals involved in the patient's care to update and document any identified allergies, hypersensitivities, anaphylaxis or drug intolerances (Jevon 2008, Shelton and Shivan 2011).

Allergic reactions are immune mediated and can be classified as in Table 12.2. There are many risk factors that increase the likelihood of an allergic reaction. These can be split into those that are specific to the patient and those that are specific to the drug. The patient-related factors and drug-related factors are listed in Box 12.8 and Box 12.9 respectively.

Although the incidence of true allergic drug reactions is low, the potential morbidity and mortality related to these reactions

Box 12.8 Allergic reactions: patient-related risk factors

- **Immune status:** previous reaction to the same or related compound.
- **Age:** younger adults are more likely to have an allergic reaction than infants or the elderly.
- **Gender:** women are more likely than men to suffer skin reactions.
- **Genetic:** atopic predisposition is more likely to result in a severe reaction and genetic polymorphisms may predispose to drug hypersensitivity, e.g. G6PD deficiency, slow acetylators.
- **Concomitant disease:** viral infections such as HIV and herpes are associated with an increased risk of allergic reactions; cystic fibrosis is associated with an increased risk of allergic reactions to antibiotics, which is thought to be due to the prolonged use in this group of patients.

Source: Mirakian et al. (2009). Reproduced with permission from John Wiley & Sons.

Box 12.9 Allergic reactions: drug-related risk factors

- **Drug chemistry:** some drugs are more likely to cause drug reactions than others. These are high molecular weight compounds, for example insulin. Also, drugs that bind to proteins called haptens, forming complexes that can cause an immune response, for example beta-lactam antibiotics.
- **Route of administration:** the topical route is most likely to cause an allergic reaction, with the oral route being least likely. The intramuscular route is more likely than the intravenous route.
- **Dose:** a large single dose is less likely to cause a reaction than prolonged or frequent doses.

Source: Mirakian et al. (2009). Reproduced with permission from John Wiley & Sons.

can be high, so it is important that drug allergies are accurately diagnosed and treated. The first step towards an accurate diagnosis is a detailed history (Mirakian et al. 2009). Guidance on what information should be collated and accurately recorded is detailed in the British Society for Allergy and Clinical Immunology (BSACI) drug allergy guidelines which can be found at www.bsaci.com and NICE guidance (2014b), and include the following.

- Detailed description of reaction:
 - symptom sequence and duration
 - treatment provided
 - outcome.
- Timing of symptoms in relation to drug administration.
- Has the patient had the suspected drug before this course of treatment?
 - How long had the drug(s) been taken before onset of reaction?
 - When was/were the drug(s) stopped?
 - What was the effect?
- Witness description (patient, relative, doctor).
- Is there a photograph of the reaction?
- Illness for which suspected drug was being taken, that is, underlying illness (this may be the cause of the symptoms, rather than the drug).
- List of all drugs taken at the time of the reaction (including regular medication, OTC and 'alternative' remedies).
- Previous history:
 - other drug reactions
 - other allergies
 - other illnesses (Mirakian et al. 2009, NICE 2014b).

This guideline also gives details on further investigations which may be required in order to accurately diagnose an allergic reaction (Box 12.10). In some cases, desensitization may be considered but this is rarely indicated.

Following an allergic reaction, it is extremely important that the patient is given information regarding what substances they should avoid. This information should be recorded clearly in the patient's medical records, including paper and electronic records. All inpatients should have their allergy indicated by wearing a red-coloured identity band (NPSA 2007b). The allergic drug reaction should also be reported using the Yellow Card Scheme (Mirakian et al. 2009) (see 'Adverse drug reactions', below).

Prior to administering any medication, the nurse must confirm the patient's allergy status and where necessary document any changes.

Medication

The nurse must know the therapeutic uses of the medicine to be administered, its normal dosage, side-effects, precautions and contraindications. If the nurse has concerns regarding the

Box 12.10 Treatment of acute drug reaction

An acute drug reaction must be treated promptly and appropriately.

- 1 Stop the suspected drug.
- 2 Treat the reaction.
- 3 Identify and avoid potential cross-reacting drugs.
- 4 Record precise details of the reaction and its treatment.
- 5 Identify a safe alternative. In some cases this may not be possible so, where the case is less severe, it may be decided to continue with the medication with suppression of the symptoms with, for example, a corticosteroid and an antihistamine.

Also see 'Complications of intravenous injections and infusions'.

Source: Mirakian et al. (2009). Reproduced with permission from John Wiley & Sons.

prescription or the prescription is not clear, the prescriber or pharmacist must be contacted. If weight and/or height are required for calculation of the dose, ensure a recent height or weight has been used.

Calculating the required dose is vital as any miscalculation of medication dosage represents a potential threat to both patient safety and clinical effectiveness (Weeks et al. 2000). Acquisition and maintenance of mathematical competency for nurses in practice is an important issue in prevention of medication errors (Brady et al. 2009) although, when Wright (2010) reviewed studies, she found insufficient evidence to suggest that medication errors are caused by nurses' poor calculation skills. There are a number of computer-based programmes on infection control and IV therapy, infusion pumps (NHSCLU 2009) and medication dosage calculation problem-solving skills (Weeks et al. 2001) which provide information for nurses, facilitate assessment of their competency and can be used as part of induction or mandatory training.

To ensure the patient receives the correct intended treatment, the following checks must be performed:

- correct medicine and formulation selected
- correct dose prepared
- medicine within expiry date
- correct route, administration time and rate if applicable.

If a delivery device is required, ensure that the correct device is used, i.e. vascular access device for intravenous therapy or an epidural catheter for epidural drug administration.

Additional factors to consider

Drug interactions

Consideration should also be given to potential interactions between concomitant drugs and/or food. These interactions can result in an increased effect, causing toxicity, or a decreased effect, resulting in decreased efficacy of the drug. Drug interactions can be divided into pharmacokinetic (Table 12.3) and pharmacodynamic interactions (Table 12.4).

Herbal and complementary medicines have been increasingly used in the UK over recent years and as a result there has been an increase in the reporting of interactions between these agents and conventional drugs. Some of the most common herbal interactions are those involving St John's wort, a popular herbal product used as an antidepressant. Concomitant use should be avoided with, for example, antiepileptics, antivirals, warfarin.

Interactions can also occur between drugs and food. Food can have an effect on drugs by changing gastrointestinal motility or by binding to drugs whilst in transit in the gastrointestinal tract. An example of interactions between food and a drug can be seen with monoamine oxidase inhibitors and tyramine-containing foods such as mature cheese, pickled herring or broad bean pods. Tyramine is a chemical present in certain foods that are rich in protein and can interact with monoamine oxidase inhibitors (MAOIs). As procabazine has mild MAOI properties, it is possible that taking both together could result in a hypertensive reaction which can cause symptoms of raised blood pressure, headache, pounding heart, neck stiffness, sweating, flushing and vomiting. Patients should therefore be advised to avoid tyramine-rich foods

Table 12.3 Types of pharmacokinetic interactions

Type of interaction	Interaction caused by	Example of when to consider in clinical practice
Drug absorption interactions	Changes in the gastrointestinal (GI) pH Adsorption or chelation in the GI tract Changes in GI motility Induction or inhibition of transporter proteins or malabsorption	Allopurinol and mercaptopurine – allopurinol inhibits xanthine oxidase, an enzyme which metabolizes mercaptopurine to an inactive metabolite, thereby resulting in increased mercaptopurine toxicity such as bone marrow suppression. If used together, the mercaptopurine dose should be decreased to a third of the original dose (Baxter 2008)
Drug distribution interactions	Protein binding or inhibition or induction of drug transporter proteins	Therapeutic drug monitoring as drugs that can be displaced in this way can appear subtherapeutic when monitored but doses would not need to be increased (Baxter 2008)
Drug metabolism interactions	Changes in first-pass metabolism, enzyme induction, enzyme inhibition and genetic factors The hepatic cytochrome P450 enzyme system is the major site of drug metabolism and most drug–drug interactions occur at this site	Grapefruit juice can inhibit the cytochrome P450 isoenzyme CYP3A4, thus reducing the metabolism of calcium channel blockers (Baxter 2008)
Drug excretion interactions	Changes in urinary pH, active renal tubular excretion, renal blood flow and biliary excretion or the enterohepatic shunt	Probenecid and penicillin compete for the same active transport systems in the renal tubules. As a result, probenecid reduces the excretion of penicillin which can lead to penicillin toxicity (Baxter 2008)

Table 12.4 Types of pharmacodynamic interactions

Type of interaction	Interaction caused by	Example of when to consider in clinical practice
Additive or synergistic interactions	Two drugs have the same pharmacological effect and therefore the results can be additive	Opioids with benzodiazepines causing increased drowsiness (Baxter 2008)
Antagonistic or opposing interactions	Two drugs have opposing activities	Vitamin K and warfarin resulting in the effects of the anticoagulant being opposed (Baxter 2008)

Source: Beijnen and Schellens (2004). Reproduced with permission from Elsevier.

such as mature and aged cheeses, yeast or meat extracts, pickled fish, salami and heavy red wines (Baxter 2008).

Adverse drug reactions

Although we use drugs to diagnose, prevent or treat disease, no drug is administered without risk. It is important when choosing a drug treatment that consideration is given to the balance between clinical effect and undesired effects. The World Health Organization definition of ADRs is ‘harmful, unintended reactions to medicines that occur at doses normally used for treatment’ (WHO 2008). ADRs can be classified as type A or type B reactions. Type A (‘augmented’) reactions are considered to be an exaggeration of the medicine’s normal effect when given at the usual dose. This category includes unwanted reactions that are predictable from the drug’s pharmacology and are usually dose dependent (e.g. respiratory depression with opioids and bleeding with warfarin) (Rawlins and Thompson 1985). In many instances this type of unwanted effect is reversible and the problem can often be dealt with by reducing the dose (Rang and Dale 2012). Type B (‘bizarre’) reactions are effects that are not pharmacologically predictable and can include hypersensitivity reactions (e.g. anaphylaxis with beta-lactam antibiotics). These cannot be related to the pharmacological action of the drug, are not dose related and therefore cannot be controlled by dose reduction. Type A reactions are more common than type B but type B reactions tend to cause a higher rate of serious illness and mortality (Rawlins and Thompson 1985).

The WHO states that ‘ADRs are among the leading causes of death in many countries. At least 60% of ADRs are preventable and in some countries ADR-related costs, such as hospitalisation, surgery and lost productivity, exceed the cost of the medications’ (WHO 2008).

Although the effect of a drug cannot always be predicted, it is important that when a drug is given to a patient, the risk of harm is minimized by ensuring that prescribed medicines are of good quality, safe, effective and used by the right patient in the right dose at the right time. Consideration should always be given to predisposing factors that drugs or a patient may have which could increase the risk of ADRs, including:

- polypharmacy
- age of the patient
- gender
- co-morbidities, e.g. renal disease
- race
- genetic factors
- allergies
- drug–drug interactions (Koda-Kimble et al. 2005, Walker and Edwards 2003).

Preventing and detecting adverse effects from medicines is termed pharmacovigilance. It is an important aspect for all healthcare professionals to consider in order to identify potential new hazards related to medicines and prevent harm to patients (MHRA 2010a).

Although medicines are widely tested within clinical trials before they become commercially available, trials do not provide information about how different patient populations may respond to the medicines. The only way for this information to be collected is through careful patient monitoring and further collection of data through post-marketing surveillance. In the UK this information is collected through the Yellow Card Scheme which is run by the MHRA and the Commission on Human Medicines (CHM). The scheme is used to collect information from both health professionals and patients about suspected ADRs with prescribed medicines, OTC medicines and herbal medicines. Yellow Cards can be completed by using the MHRA website (www.yellowcard.mhra.gov.uk) or by completing the paper card found in the BNF.

Record of administration

The nurse must document a clear, accurate and immediate record of all medicines administered, intentionally withheld or refused by the patient, ensuring all written entries and signatures are clear and legible (NMC 2010b). If any medication is withheld or refused by a patient, the reasons must be documented.

Single or double checking of medicines

Medicines can be prepared and administered by a single qualified nurse or by two nurses checking (known as double checking). There are certain times when double or second checking is required. It is recommended that for the administration of controlled drugs, a secondary signature is required (NMC 2010a). The NMC *Standards for Medicines Management* also states that ‘wherever possible two registrants should check medication to be administered intravenously, one of whom should also be the registrant who then administers the intravenous medication’ (NMC 2010a, p.34). Where the administration of a medicine requires complex calculations, it is deemed good practice for a second practitioner (a registered professional) to check the calculation independently in order to minimize the risk of error (NMC 2010a).

Jarman et al.’s (2002) review of 129 nurses, using questionnaires and reviewing incidents, both during double checking and then once single checking had been introduced, demonstrated no increase in drug errors following the change. Single checking provided satisfaction for nurses and more effective use of time and the nurses felt that single checking allowed them more autonomy and that it was more beneficial to patients and enabled them to be more responsive to their needs. Armitage (2008) suggested that double checking is a common but inconsistent process. Although often seen to be integral to safe practice, it is often sacrificed when there is a shortage of time or staff (Armitage 2008). He listed the issues with double checking as:

- deference to authority
- reduction of responsibility
- auto-processing (familiarity)
- lack of time (to check properly)
- solutions (how to do it).

Another study viewed independent double checking as an alternative. This is when two nurses check a drug independently of each other. In this study nurses were observed during the setting up of ambulatory chemotherapy pumps. When compared with the old system of double checking, the new system showed no significantly statistical difference in reducing errors in dose, rate or documentation but did show a reduction in errors related to patient identification (Savage and Tripp 2008).

Those nurses who wish or need to have their administration supervised will retain the right to do so until such time as all parties agree that the requested level of proficiency has been achieved. The nurse checking the medicine must be able to justify any action taken and be accountable for the action taken. This is in keeping with the principles of *The Code* (NMC 2015).

Delegation of medicines administration

If a Registered Nurse delegates any aspect of the administration of a medicinal product, they are also accountable for ensuring that the patient or carer/care assistant is competent to carry out the task (NMC 2010a). In delegating to unregistered practitioners, it is the Registered Nurse who must apply the principles of administration and they may then delegate the unregistered practitioner to assist the patient in the ingestion or application of the medicinal product (NMC 2010a, p.33). Student nurses must never administer/supply medicinal products without direct supervision and both the student and Registered Nurse must sign the medication chart or document the administration in the notes (NMC 2010a).

Legal and professional issues

Medicines governance and risk management

A medication incident involves an error in the process of prescribing, dispensing, preparing, administering, monitoring or providing medicine advice, regardless of whether any harm occurred or was possible. This is a broad definition and the majority of errors reported to the National Reporting and Learning Service (NRLS) result in no or low harm (NPSA/NRLS Safety in Doses 2009). Incidents involving medicines were the third largest of all incidents reported to the NRLS. Nearly half of the reports describe incidents involved with the administration or supply of a medicine in a clinical area. The effective and safe prescribing, dispensing and administration of medicines to patients demands partnership between the various health professionals concerned, that is doctors, pharmacists and nurses.

The most frequently reported types of medication incidents accounting for approximately 70% of fatal and serious harms were:

- unclear/wrong dose or frequency
- wrong medicine
- omitted/delayed medicines.

Box 12.11 details seven key actions to improve medication safety.

The Department of Health document *An Organization with a Memory* (DH 2000a) highlighted the importance of reporting and acting on reports of adverse healthcare events and potential adverse events. The document recognizes that the majority of incidents could be avoided if only the lessons of experience were properly learned.

Procedures for reporting and investigating near misses and patient safety incidents should aim to support active learning and ensure that the positive lessons learnt from these events are

Box 12.11 Seven key actions to improve medication safety

- Increase reporting and learning from medication incidents.
- Implement NPSA safer medication practice recommendations.
- Improve staff skills and competencies.
- Minimize dosing errors.
- Ensure medicines are not omitted.
- Ensure the correct medicines are given to the correct patients.
- Document patients' medicine allergy status.

Source: NPSA (2007a). © Crown copyright. Reproduced under the Open Government Licence v2.0. For updates see www.england.nhs.uk/.

embedded into the organization's culture and practices. Learning from incidents is an essential part of integrated governance and risk management.

All employees have a duty to report incidents. It is recognized that fear of reprisal, blame and/or disciplinary action may deter staff from reporting an incident (or potential incident). Creating a learning environment to allow an open 'fair blame' culture for incident reporting is therefore essential.

The NMC believes that all errors and incidents require a thorough and careful investigation at a local level, taking full account of the context, circumstances and position of the practitioner involved. Such incidents require sensitive management and a comprehensive assessment of all the circumstances before a professional and managerial decision is reached on the appropriate way to proceed (NMC 2010a).

The Department of Health NHS Commissioning Board Special Health Authority (the Board Authority) requires the mandatory reporting of specific accidents, incidents and patient safety incidents by all healthcare organizations. All incidents classified as Serious Incidents Requiring Investigation must also be reported to the Commissioners, the Strategic Health Authority and Monitor.

Self-administration of medicines

Evidence-based approaches

Rationale

The Audit Commission report *A Spoonful of Sugar – Medicines Management in NHS Hospitals* (2001) recommended self-administration of medicines by patients. This report detailed how studies have shown that only one-half of patients take their medicines properly when they get home. The National Institute for Health and Clinical Excellence (NICE) published Clinical Guideline 76 on medicines adherence (NICE 2009) which states that between a third and a half of medicines that are prescribed for long-term conditions are not used. This non-adherence has quality and cost implications for the NHS due to wasted medicines and readmissions for patients.

The Audit Commission states that self-administration is beneficial to patients because it empowers the patient and allows them to take medication at the right time, for example analgesics when they are in pain and medicines to be taken before and after food. Self-administration allows patients to take an active role in managing their own care, improves patient compliance and has the potential to reduce admission to hospital due to problems with medicines (Audit Commission 2001). It allows patients to practise taking their medicines in hospital under supervision so that any problems can be dealt with. It has also been found that patients who had administered their own medications in hospital were more likely to report that their overall care was excellent and that they were satisfied with the discharge process than patients who had not (Deeks and Byatt 2000).

The Healthcare Commission report *The Best Medicine – The Management of Medicines in Acute and Specialist Trusts* (2007) states that, where patients are self-administering, it is important that medicines are stored securely in suitable storage near to the bedside, and that procedures and training need to be in place which should cover the assessment process and the patient's suitability for self-administration. Although, by definition, self-administration of medicines shifts the balance of responsibility for this part of care towards the patient, it in no way diminishes the fundamental professional duty of care. It is therefore essential that local policies, procedures and records are adequate to ensure that this duty is, and can be shown to be, discharged. The revised Duthie Report (RPSGB 2005) states that any transfer of responsibility should occur on the basis of an assessment of the patient's ability to manage the tasks involved and with the

patient's consent. The patient's consent should be recorded with the date and time.

The NMC sets out the responsibilities of the nurse regarding the self-administration of medicines. These include viewing the medicines, checking the suitability for reuse, that they have been prescribed, assessment of the patient, what should be documented and how they should be stored (NMC 2010a).

Assessment of patients for self-administration normally results in the allocation of a level of supervision. Examples of levels of supervision can be seen in Table 12.5. All patients should be assessed on a regular basis, using local policies to ensure that the individual patient is able to self-administer. The nurse is responsible for recognizing and acting upon changes in the patient's clinical condition which may affect their ability to self-administer. This information should be documented in their records (NMC 2010b).

Pre-procedural considerations

A medicines reconciliation needs to be carried out with the patient and they will be assessed for their ability to self-administer. Any constraint such as physical or visual handicap must be addressed. Changes in performance status may result from the underlying condition or its treatment, and must be allowed for (NMC 2010a, Shepherd 2002a).

If a compliance aid such as a 'dosette' box is to be used, responsibility for filling and labelling the aid, especially whilst used on the ward, must be agreed and approved by the organization and documented in the patient's notes (NMC 2010a, Shepherd 2002a).

Table 12.5 Examples of levels of supervision for self-administration of medicines

Level of supervision	Role of patient	Role of nurse
Level 1	None	Nurse administers medicine from cabinet Key locked in cabinet and nurse uses master Nurse signs drug administration chart
Level 2	Patient administers medicine with nurse supervision	Cabinet is opened by nurse Nurse supervises patient administration Nurse signs drug administration chart
Level 3	Key kept by patient Patient administers their own medicines	Nurse must check that the appropriate medication was taken and endorse the chart with an identifier to indicate that the patient is self-administering and their initials

Source: NPC (2007a). Reproduced with permission from NICE (www.nice.org.uk).

Procedure guideline 12.1 Medication: self-administration

Essential equipment

- Drugs to be administered
- Recording sheet or book as required by law or hospital policy
- Consent form
- Patient information leaflet explaining the self-administration scheme
- Patient's prescription chart, to check dose, route and so on
- Any protective clothing required by hospital policy for specified drugs, such as antibiotics or cytotoxic drugs

Pre-procedure

Action	Rationale
1 Carry out a medicines reconciliation with the patient on admission by reviewing proposed (inpatient) prescription in liaison with the pharmacist and compare with details given by the patient and medicines in their possession. Any differences should be investigated and highlighted with the medical team.	To ensure an accurate record of all medicines being taken (prescribed or otherwise); dietary supplements, for example multivitamins, herbal remedies, complementary therapies; allergies or hypersensitivities; understanding of current medicines; possible problems with self-administration (Jordan et al. 2003, E ; NMC 2010a, C ; NMC 2010b, C ; NICE/NPSA 2007, C ; Shepherd 2002b, E).
2 Carry out an assessment of the patient's ability to self-administer medication using an assessment form with the criteria in Table 12.6.	Technical patient safety solutions for medicines reconciliation on admission of adults to hospital (NICE/NPSA 2007, C).
3 Consider whether there are any constraints on self-administration and, if so, how they might be overcome. Discuss this with appropriate members of the multidisciplinary team.	To promote successful and safe self-administration and ensure that medicines are dispensed and labelled appropriately for the patient's needs (DH 2003b, C ; NMC 2010a, C ; Shepherd 2002a, E).
4 Following the assessment, a level of supervision will be recommended and entered on the assessment form. The assessment form and the consent will be filed in the patient records. For examples of levels see Table 12.5.	To ensure that the correct level of supervision is selected and communicated to other staff. E

Procedure

- 5 Discuss with the patient their medication and any problems they may be having with the regimen. Document discussions in the care plan. Teach any special skills required, for example correct use of aerosol inhalers. Reassess whether they need any changes to their levels of supervision, either up or down.

To promote the informed commitment and involvement of patients in their own care, where appropriate. To ensure that treatment is received as intended (NMC 2010a, **C**).

Post-procedure

- 6 Check every day that drugs are taken as intended, and that the necessary records are kept.

To ensure that the patient is taking the medication as the nurse continues to take overall responsibility for patient care and well-being. To maintain a record of responsibilities undertaken (NMC 2010a, **C**; NMC 2010b, **C**; NMC 2015, **C**).

- 7 Monitor changes in the patient's prescription.

To ensure that changes are put into effect promptly; drugs are properly relabelled or redispensed; any discontinued drugs are retrieved from the patient (DH 2003b, **C**; NMC 2010a, **C**; Shepherd 2002b, **E**).

- 8 Check when drug supplies are expected to run out and make arrangements for resupply. Order drugs to take out (TTO) as far in advance as possible.

To ensure that drugs are prescribed and dispensed in time to allow uninterrupted treatment and to facilitate planned discharge (DH 2003b, **C**; NMC 2010a, **C**; Shepherd 2002b, **E**).

- 9 Evaluate the effectiveness of the self-administration teaching programme and record any difficulties encountered and interventions made.

To identify further learning and teaching needs and modify care plan accordingly (NMC 2010a, **C**; NMC 2010b, **C**; Shepherd 2002b, **E**, NMC 2015, **C**).

Table 12.6 Assessment form

Assessment criteria	Rationale
• Is the patient willing to participate in self-administration after being given information explaining the scheme with associated time to read and understand it?	Patient's agreement should be recorded with a date and time (RPSGB 2005)
• Has the patient signed a consent form agreeing to self-administration?	Patient's agreement should be recorded with a date and time (RPSGB 2005)
• Is the patient sufficiently well to take part in the scheme?	Patients who are not well enough or who are undergoing surgery will not be able to self-administer until they have recovered and have been reassessed. If frequent changes of drug or dose are expected, immediate self-administration may be undesirable and/or impractical
• Is the patient confused, forgetful or disorientated?	Patients who are confused, forgetful or disorientated will need to have their medicines administered by a nurse in the usual way. This may be assessed by asking relatives or carers or by asking specific questions for assessing state of mind
• Does the patient have a history of drug/alcohol abuse/self-harm?	Patients with this history can self-administer under the supervision of a nurse
• Does the patient self-administer medicines at home?	Patients who are not responsible for self-administering their medicines in the community will need to have their medicines administered by a nurse in the usual way
• Can the patient read the labels on the medicines?	These patients can either self-administer with supervision or have their medicines administered by a nurse. Referral can be made to pharmacy around assessment of labels. Can they be given extra large or Braille labels if necessary?
• Can the patient open the medicine bottles and foil strips?	These patients can either self-administer with supervision or have their medicines administered by a nurse. Referral can be made to pharmacy for assessment and provision of appropriate containers
• Can the patient open the locker where the medicines are stored while they are in hospital?	Patients who cannot open the locker can self-administer with nurse supervision
• Does the patient know what their medicines are for, their dosage, instructions and potential side-effects (Shepherd 2002b)?	Patients who don't know this can be allowed to self-administer with nurse supervision. Re-education can take place in order to achieve full self-administration

Post-procedural considerations

Ongoing care

The nurse must monitor for any changes in the patient's prescription and condition. They must check when drugs supplied are expected to run out and ensure that drugs are ordered along with any TTOs. The effectiveness of the self-administration teaching programme must be evaluated (Shepherd 2002b).

Documentation

Particular care with record keeping is needed in the period of gradual transition from nurse administration to self-administration. Any problems encountered must be addressed (NMC 2010a, NMC 2010b, NMC 2015).

The detail and format of the record may vary according to the patient's needs and performance status, the complexity of treatment, and local circumstances and policy (NMC 2010a, NMC 2010b, NMC 2015).

690

Controlled drugs

Definition

Controlled drugs are those drugs that are listed in Schedule 2 of the Misuse of Drugs Act 1971 and are subject to the controls stipulated in the Act, for example diamorphine, morphine, amphetamines, benzodiazepines. The use of controlled drugs in medicine is permitted by the Misuse of Drugs Regulations and related regulations, as detailed in the next section, Legal and professional issues.

Legal and professional issues

Legislation

Medicines Act 1968

The Act and the regulations made under the Act set out the requirements for the legal sale, supply and administration of medicines. It also allows certain exemptions for the general restrictions on the sale, supply and administration of medicines which, for example, enable midwives to supply and/or administer diamorphine, morphine, pethidine or pentazocine.

A number of healthcare professionals are permitted to supply and/or administer medicines generally in accordance with a PGD. Some of these professional groups, but not all, are permitted to possess, supply or administer controlled drugs in accordance with a PGD under the Misuse of Drugs legislation.

Misuse of Drugs Act 1971

For reasons of public safety, the Misuse of Drugs Act controls the export, import, supply and possession of dangerous or otherwise harmful drugs to prevent abuse as most are potentially addictive or habit forming as well as harmful. The Act dictates what constitutes an unlawful activity. Drugs controlled under the Misuse of Drugs Act 1971 are divided into three classes, A, B and C, for the purposes of establishing the maximum penalties which can be imposed. The Misuse of Drugs Act 1971 also controls the manufacture of controlled drugs. Other regulations of the Act govern safe storage, destruction and supply to known addicts.

Misuse of Drugs (Safe Custody) Regulations 1973

These regulations control the storage of controlled drugs. The level of control of storage depends on the premises in which they are being stored and the schedule of the drug.

Misuse of Drugs Regulations 2001

Under these regulations, controlled drugs are classified into five schedules, each representing a different level of control (Table 12.7). The Schedule in which a CD is placed depends upon

its medicinal or therapeutic benefit balanced against its harm when misused. Schedule 1 CDs are subject to the highest level of control, whereas Schedule 5 CDs are subject to a much lower level of control. A comprehensive list of drugs included within the Schedules is given in the Misuse of Drugs Regulations 2001 and can be accessed at www.opsi.gov.uk.

The requirements of the Act as they apply to nurses working in a hospital with a pharmacy department are described in Table 12.8.

Controlled Drugs (Supervision of Management and Use) Regulations 2006

These regulations set out the requirements for certain NHS bodies and independent hospitals to appoint an accountable officer. The duties and responsibilities of the accountable officer are to improve the management and use of controlled drugs. These regulations also allow the periodic inspection of premises.

Misuse of Drugs and Misuse of Drugs (Safe Custody) (Amendment) Regulations 2007

These regulations give accountable officers authority to nominate persons to witness the destruction of controlled drugs within their organization. They also allow operating department practitioners to order, possess and supply controlled drugs.

In addition, they set out changes to the record keeping for controlled drugs, with requirements for recording in the controlled drug register the person (the patient, patient's representative or a healthcare professional) collecting the Schedule 2 controlled drug. If it is a healthcare professional, there is a requirement for the name and address of that person. Records need to be kept regarding whether proof of identity was requested of the patient or the patient's representative and whether this proof of identity was provided. These requirements also changed midazolam from Schedule 4 to Schedule 3.

Implications of the regulations for nursing practice

Accountability and responsibility

The nurse in charge of an area is responsible for the safe and appropriate management of controlled drugs in that area. Certain tasks such as holding of the keys can be delegated to a Registered Nurse but the overall responsibility remains with the nurse in charge.

Requisition

The nurse in charge of an area is responsible for the requisition of controlled drugs for that area. This task can be delegated to a Registered Nurse but the overall responsibility remains with the nurse in charge. Orders should be written on suitable stationery and must be signed by an authorized signatory. All those who are authorized to order should have a copy of their signatures kept in pharmacy for validation. All stationery which is used to order, return or distribute controlled drugs (CD stationery) must be stored securely, and access to it should be restricted.

Receipt

When controlled drugs are delivered to the ward they must be handed to an appropriate individual and not left unattended. A Registered Nurse in charge should check the order against the requisition, including the number ordered and received, and if all is correct they should sign the 'received by' section of the order book.

The controlled drug should be entered in the controlled drug register, recording the following information: date, number of requisition, quantity, name, formulation and strength of drug, name and signature of person making the entry, name and signature of witness and the balance of stock. The updated balance should be checked against the controlled drugs physically present and that these are the same. The number of units received should be written in words not figures. The controlled drugs will then be placed in the controlled drug cupboard.

Table 12.7 Legal requirements for the schedules of controlled drugs (CDs)

	Schedule 2 Includes opioids and major stimulants, for example amphetamines	Schedule 3 Includes minor stimulants, temazepam, barbiturates, tramadol	Schedule 4 Part I Includes benzodiazepines, zopiclone	Schedule 4 Part II Includes anabolic steroids, growth hormones	Schedule 5 Includes low-dose opioids
Designation	CD	CDs With no register entry	CDs Benzodiazepines	CDs Anabolic steroids	CDs Needing invoice retention
Safe custody	Yes, except quinalbarbitone	Yes, except certain exemptions listed in the Medicines, Ethics and Practices including phenobarbitone	No	No	No
Prescription requirements	Yes	Yes, except temazepam	No	No	No
Requisitions necessary	Yes	Yes	No	No	No
Records to be kept in CD register	Yes	No	No	No	No
Pharmacist must ascertain the identity of the person collecting the CD	Yes	No	No	No	No
Emergency supplies allowed	No	No, except phenobarbitone for epilepsy	Yes	Yes	Yes
Validity of prescription	28 days	28 days	28 days	28 days	6 months
Maximum duration that can be prescribed	30 days as good practice	30 days as good practice	30 days as good practice	30 days as good practice	

Source: DH (2007). © Crown copyright. Reproduced under the Open Government Licence v2.0.
Further details can be found in The Misuse of Drugs and Misuse of Drugs (Safe Custody) (Amendment) (England, Wales and Scotland) Regulations (2014).

Storage/equipment

Controlled drugs should be stored in controlled drug cupboards that conform to British Standard BS2881. If the amount of controlled drugs that are stored is large or in areas where there is not a 24-hour staff presence, a security cabinet that has been evaluated against the SOLD SECURE standard SS304 should be used.

Cupboards should be locked when not in use. The lock must not be common to any other lock in the hospital. Keys must only be available to authorized members of staff and at any time the key holder should be readily identifiable. The cupboard must be dedicated to the storage of controlled drugs. Controlled drugs must be locked away when not in use. There must be arrangements for keeping keys secure, especially in areas that are not operational at all times.

Key holding and access

The nurse in charge is responsible for the controlled drug keys. Key holding may be delegated but the legal responsibility lies with the nurse in charge. The controlled drug keys should be returned to the nurse in charge immediately after use.

For the purpose of stock checking, the key may be handed to an authorized member of pharmacy staff. If keys are lost, the senior nurse, the pharmacy manager and accountable officer must be contacted. Spare keys can be issued to ensure that patient care is not impeded.

Record keeping

Each ward that holds controlled drugs should keep a record of received and administered controlled drugs in a controlled drugs record book (Figure 12.2). The nurse in charge is responsible for keeping the controlled drug record book up to date and in good order.

The controlled drug record book should have sequentially numbered pages, have a separate page for each drug and strength, entries should be in chronological order and in ink. The entries in the controlled drug record book should be signed by a Registered Nurse and then witnessed by a second Registered Nurse. If a second nurse is unavailable, the transaction can be witnessed by another registered practitioner such as a doctor, pharmacist or pharmacy technician.

When the end of a page is reached, the balance should be transferred to another page. The new number should be written on the bottom of the finished page and, as a matter of good practice, the transfer should be witnessed. If a mistake is made in the record book, the mistake should be bracketed so that the original entry is still clear and then signed, dated and witnessed by another nurse or registered professional who will also do the same for the correction.

Stock checks and discrepancies

The stock balance entered in the controlled drug record book should be checked against the amounts in the cupboard. In addition, regular stock checks should be carried out by pharmacy. The nurse in charge is responsible for ensuring that the stock checks are carried out. The stock checks should be carried out by two Registered Nurses. When checking the balance, the record book should be checked against the contents of the cupboard, not the reverse. Packs with unopened tamper-evident seals do not need to be opened during the check. Stock balances of liquid medicines may be checked by visual inspection but the balance must be confirmed to be correct on completion of a bottle. Any discrepancy should be reported to the nurse in charge who should inform the pharmacist. A record should be made in the record book that the

Table 12.8 Summary of legal requirements for handling of controlled drugs (CDs) as they apply to nurses in hospitals with a pharmacy

	Schedule 1: CDs Home Office licence	Schedule 2: CDs subject to full controls	Schedule 3: CDs with no register entry	Schedule 4: CDs anabolic steroids/ benzodiazepines	Schedule 5: CDs needing invoice retention
Drugs in the schedule	Cannabis + derivatives but excluding nabilone, LSD (lysergic acid diethylamide)	Most opioids in common use including: alfentanil; amphetamines; cocaine; diamorphine; methadone; morphine papaveretum; fentanyl; phenoperidine; pethidine; codeine; dihydrocodeine injections; pentazocine	Minor stimulants; barbiturates (but excluding hexobarbitone, thiopentone); diethylpropion; buprenorphine; midazolam; temazepam*, tramadol	Part 1: anabolic steroids, zopiclone Part 2: benzodiazepines	Some preparations containing very low strengths of cocaine; codeine; morphine; pholcodine and some other opioids
692 Ordering	Possession and supply permitted only by special licence from the Secretary of State issued (to a doctor only) for scientific or research purposes	A requisition must be signed in duplicate by the nurse in charge. The requisition must be endorsed to indicate that the drugs have been supplied. Copies should be kept for 2 years	As Schedule 2	No requirement [†]	No requirement [†]
Storage	Must be kept in a suitable locked cupboard to which access is restricted	As Schedule 1	Buprenorphine and diethylpropion: as Schedule 1 drugs. All other drugs, no requirement	No requirement [†]	No requirement [†]
Record keeping	Controlled drug register must be used	As Schedule 1	No requirement [†]	No requirement [†]	No requirement [†]
Prescription	Prescription must include: <ul style="list-style-type: none"> the name and address of patient the drug, the dose, the form of preparation the total quantity of drug or the total number of dosage units to be supplied. This quantity must be stated in words and figures The prescription must be written indelibly and signed and dated by the prescriber	As Schedule 1	As Schedule 1 except for phenobarbitone (this includes all preparations of phenobarbitone and phenobarbitone sodium). Because of its use as an antiepileptic, it does not need to comply with prescription requirements	No requirement [†]	No requirement [†]
Administration to patients	Under special licence only A doctor or dentist or anyone acting on their instructions may administer these drugs to anyone for whom they have been prescribed	A doctor or dentist or anyone acting on their instructions may administer these drugs to anyone for whom they have been prescribed	A doctor or dentist or anyone acting on their instructions may administer these drugs to anyone for whom they have been prescribed	No requirement [†]	No requirement [†]

*Temazepam preparations are exempt from record-keeping and prescription requirements, but are subject to storage requirements.

[†]'No requirement' indicates that the Misuse of Drugs Act 1971 imposes no legal requirements additional to those imposed by the Medicines Act 1968 (HMSO 1968). Figure 12.2 Controlled drugs record book.

stock has been checked with words such as 'check of stock level' and a signature of the Registered Nurse and the witness.

If a discrepancy is found, it should be checked that all requisitions have been entered, that all drugs administered have been entered, that items have not been recorded in the wrong place in the record book, that the drugs have not been placed in the wrong cupboard and that the balances have been added correctly. If an error is found, the nurse in charge should make an entry to correct the balance which should be witnessed. If the error cannot be found, the chief pharmacist and the accountable officer should be contacted immediately.

Archiving

Controlled drug record books should be stored for a minimum of 2 years from the date the last entry was made/date of use.

Administration

Any registered practitioner can administer any drug specified as Schedule 2, 3 and 4 provided they are acting in accordance with the directions of an appropriately qualified prescriber. Two practitioners must be involved in the administration of controlled drugs, and both practitioners should be present during the whole administration procedure (NMC 2010a). The two practitioners should have clearly defined roles. One should be the checker and the other should take responsibility for taking the drug out of the cupboard, preparing and administering the drug. These roles should not be interchangeable during the procedure as this can result in errors. They should both witness the preparation, the controlled drug being administered and the destruction of any surplus drug. An entry should be made in the controlled drug record book recording the following information (see Figure 12.2):

- the date and time the dose was administered
- the name of the patient
- quantity administered
- the name of the controlled drug
- the formulation
- the dose being administered (and any amount being destroyed if only a part vial is required)
- the name and signature of the person administering
- the name and signature of the witness
- the balance in stock (see Procedure guideline 12.2 Medication: controlled drug administration).

Return and disposal including part vials

Unused controlled drug stock should be returned to pharmacy. Controlled drugs that are expired should also be returned to pharmacy for safe destruction. An entry should be made in the relevant page of the record book recording the following information:

- date
- reason for return
- name and signature of Registered Nurse
- name and signature of witness

- quantity removed
- name, form and strength
- the balance remaining.

Disposal of controlled drugs can take place on the ward if a part vial is administered to the patient or if individual doses of controlled drugs were prepared and not administered. If destroying a part vial, the Registered Nurse should record the amount given and the amount wasted under the administration entry in the record book; for example, if the patient is prescribed diamorphine 2.5 mg and only a 5 mg preparation is available, the record should show '2.5 mg given and 2.5 mg wasted'. The entry and destruction should be witnessed by a Registered Nurse or other registered professional. If destroying an unused prepared controlled drug, this should also be recorded in the record book and the entry and destruction witnessed by another registered professional.

Stationery

Controlled drug stationery should be stored in a locked cupboard or drawer. Controlled drug stationery will be issued from pharmacy against a written requisition signed by an appropriate member of staff. Only one requisition book should be in use by a ward. If a new record book is started, the stock balance transfer should be witnessed by a Registered Nurse.

Transport

Controlled drugs should be transferred in a secure, locked or sealed, tamper-evident container. A person collecting controlled drugs should be aware of safe storage and security and the importance of handing over to an authorized person to obtain a signature. They must also have a valid ID badge.

Supply under PGD

When acting in their capacity as such under a PGD, nurses are authorized to supply, or offer to supply, diamorphine and morphine where administration of such drugs is required for the immediate, necessary treatment of sick or injured persons (excluding the treatment of addiction) in any setting. They can also supply or administer any Schedule 3 or 4 controlled drug in accordance with a PGD (except anabolic steroids in Schedule 4 Part 2 and injectable formulations for the purpose of treating a person who is addicted to a drug).

Prescribing

A supplementary prescriber, when acting in accordance with a clinical management plan, can prescribe a controlled drug provided the drug is included in the clinical management plan. Nurse independent prescribers may prescribe any controlled drug listed in Schedules 2–5 for any medical condition, except diamorphine, cocaine and dipipanone for the treatment of addiction (other controlled drugs are prescribable by nurse independent prescribers for the treatment of addiction). The authority to prescribe any controlled drug is given on the basis that nurses must only prescribe within their competence.

Box 12.12 High-dose opiate guidance

- High-strength preparations of morphine or diamorphine (30 mg or above) should be stored in a location separate from lower-strength preparations (10 mg) within the controlled drugs cupboard.
- Awareness should be raised of the similarities of drug packaging, and consider use of alert stickers being attached to high-strength preparations by pharmacy.
- A review of stock levels should be undertaken in all clinical areas where morphine and diamorphine are stored to assess whether high-strength preparations need to be kept on a permanent basis or whether they could be ordered according to specific patient requirements.
- Clear guidance should be provided to ensure that the correct doses of diamorphine and morphine are prepared in the appropriate clinical situation. For example, diamorphine 5 mg and 10 mg ampoules could be used for both bolus administration and patients newly commenced on diamorphine infusions; diamorphine 30 mg ampoules could be reserved for patients already receiving diamorphine infusions and who require higher daily doses.
- Patients should be observed for the first hour after receiving their first dose of diamorphine or morphine injection.
- Naloxone injections should be available in all clinical areas where morphine and diamorphine are stored.

Source: NPSA (2006). © Crown copyright. Reproduced under the Open Government Licence v2.0. For updates see www.england.nhs.uk/.

In response to seven case reports, published between 2000 and 2005, regarding deaths due to the administration of high-dose (30 mg or greater) morphine or diamorphine to patients who had not previously received doses of opiates, the NPSA released a safer practice notice in 2006, *Ensuring Safer Practice with High Dose Ampoules of Morphine and Diamorphine* (NPSA 2006). In line with this safer practice notice, the following guidance should be adhered to (Box 12.12).

Between 2005 and 2008, 4223 incidents were reported to the NRLS involving opioid medicines and the 'wrong/unclear dose or strength' or 'wrong frequency' of medication. As a result, the NPSA released a Rapid Response Report in July 2008. The guidance shown in Box 12.13 has been given.

The NPSA was notified of 498 midazolam patient safety incidents between November 2004 and November 2008 where the dose prescribed or administered to the patient was inappropriate. Three midazolam-related incidents have resulted in death. As a result, the NPSA released a Rapid Response Report in December 2008. The guidance in Box 12.14 has been given.

Box 12.13 Opioid dose/strength guidance

- Confirm any recent opioid dose, formulation, frequency of administration and any other analgesic medicines prescribed for the patient. This may be done, for example, through discussion with the patient or their representative (although not in the case of treatment for addiction), the prescriber or through medication records.
- Where a dose increase is intended, ensure that the calculated dose is safe for the patient (e.g. for oral morphine or oxycodone in adult patients, not normally more than 50% higher than the previous dose).
- Ensure they are familiar with the following characteristics of that medicine and formulation: usual starting dose, frequency of administration, standard dosing increments, symptoms of overdose, common side-effects.

Source: NPSA (2008a). © Crown copyright. Reproduced under the Open Government Licence v2.0. For updates see www.england.nhs.uk/.

Box 12.14 Midazolam guidance

- Ensure that the storage and use of high-strength midazolam (5 mg/mL in 2 mL and 10 mL ampoules, or 2 mg/mL in 5 mL ampoules) are restricted to general anaesthesia, intensive care, palliative medicine and clinical areas/situations where its use has been formally risk assessed, for example, where syringe drivers are used.
- Ensure that in other clinical areas, storage and use of high-strength midazolam are replaced with low-strength midazolam (1 mg/mL in 2 mL or 5 mL ampoules).
- Review therapeutic protocols to ensure that guidance on use of midazolam is clear and that the risks, particularly for the elderly or frail, are fully assessed.
- Ensure that all healthcare practitioners involved directly or participating in sedation techniques have the necessary knowledge, skills and competences.
- Ensure that stocks of flumazenil are available where midazolam is used and that the use of flumazenil is regularly audited as a marker of excessive dosing of midazolam.
- Ensure that sedation is covered by organizational policy and that overall responsibility is assigned to a senior clinician who, in most cases, will be an anaesthetist.

Procedure guideline 12.2 Medication: controlled drug administration*Essential equipment*

- Prescription chart
- Controlled drug record book
- Appropriate medication container, for example medicine pot or syringe
- Red 'Do Not Disturb' medication tabard

*Pre-procedure***Action**

- 1 Apply red tabard.
- 2 Look at the patient's prescription chart: check the name, date of birth, hospital number, allergy status and then read the following.
 - (a) Drug name (generic)

Rationale

To prevent nurse being disturbed during the process. **E**
To ensure that the correct patient is given the correct drug, in the correct formulation, in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, **C**; NMC 2010a, **C**).

- (b) Dose
 - (c) Date and time of administration
 - (d) Frequency
 - (e) Route and method of administration
 - (f) Formulation of oral preparation, e.g. modified release, immediate release
 - (g) Diluent as appropriate
 - (h) Validity of prescription
 - (i) Legible signature and contact details of prescriber.
 - (j) Check when the drug was last administered
- If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.

To ensure the correct formulation is given as many different formulations are available for the same drug. **E**

To ensure prescription is legal (DH 2003b, **C**).

To ensure prescription is legal and complies with hospital policy (DH 2003b, **C**).

To ensure that the patient requires the drug at this time. **E**

To prevent any errors occurring. **E**

Procedure

- | | |
|---|--|
| 3 With the second Registered Nurse, take the keys and open the controlled drug cupboard. Take the ward controlled drug record book that contains the prescribed controlled drug, check the contents page to ascertain and turn to the relevant page headed with the name and strength of the controlled drug. | To check the stock and to enter the details into the controlled drug record book (DH 2003b, C). |
| 4 With the second Registered Nurse, take the correct drug out of the controlled drug cupboard. | To comply with hospital policy and to ensure the patient receives the correct medicine (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). |
| 5 With the second Registered Nurse, check the stock level against the last entry in the ward record book. | To comply with hospital policy (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). |
| 6 With the second Registered Nurse, check the appropriate dose and concentration/strength (e.g. 10 mg in 1 mL or 5 mg in 5 mL) and formulation against the prescription chart and remove the dose from the box/bottle and place into an appropriate container, e.g. medicine pot or syringe. | To comply with hospital policy and to ensure the patient receives the correct dose and strength of medicine (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). |
| 7 Return the remaining stock to the cupboard and lock the cupboard. | To comply with hospital policy (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). |
| 8 Enter the date, dose, new stock level and the patient's name in the ward record book, ensuring that both you and the second Registered Nurse sign the entry (Action figure 8). | To comply with hospital policy (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). |
| NB: May require entry into different sections if the dose is to be made up of different doses, e.g. 70 mg = 1 × 50 mg and 2 × 10 mg). If any is wasted then ensure it is documented correctly, e.g. 5 mg given and 5 mg wasted. | |
| 9 (a) With the second Registered Nurse, take the prepared dose to the patient and check the patient's identity by asking them to verbally identify themselves (where possible) and check the information the patient gives against the identification wristband the patient is wearing. | To prevent error and confirm patient's identity (NPSA 2005, C ; NPSA 2007b, C). |
| (b) Ask the patient if they have any allergies, checking their response against the prescription chart. | |
| (c) Check when the patient last had the medication against the prescription chart. | To ensure that the patient has not already received the medication. E |
| 10 Administer the drug. If given orally, wait until the patient has swallowed the medication. | To ensure the patient receives the medicines (DH 2003b, C). |

Post-procedure

- | | |
|---|--|
| 11 Once the drug has been administered, the prescription chart is signed by the nurse responsible for administering the medication and the Registered Nurse who witnessed the administration. | To comply with hospital policy (DH 2003b, C ; NMC 2010a, C ; NPSA 2006, C). To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NMC 2015, C). |
|---|--|

(continued)

Procedure guideline 12.2 Medication: controlled drug administration (continued)

Action	Rationale
12 Check the patient after administration for effectiveness and/or toxicity.	To ensure that the drug has been effective and to administer a breakthrough dose if necessary. To check that the patient has not experienced any toxicity that may require interventions. E
13 If the drug is given via a syringe pump, return to check the infusion (for rate) and site (for signs of any local complications) and document in the appropriate records.	To ensure that the infusion is infusing at the correct rate and the site is suitable. E

Action Figure 8 Registered Nurses signing controlled drugs record book.

Post-procedural considerations

Ongoing care

Patients should be monitored for signs of adverse effects from opioids and for signs of toxicity. The most common side-effects are constipation, nausea and vomiting and drowsiness. All patients who are prescribed an opioid regularly should be prescribed laxatives concurrently to prevent constipation. Nausea and vomiting should subside after a few days but patients should be prescribed antiemetics and given reassurance. Drowsiness due to opioids should also subside after a few days so if patients experience these symptoms, they should be given reassurance that they will pass in time (Regnard and Hockley 2004).

The warning signs of toxicity due to opioids are:

- pin-point pupils
- confusion

- myoclonus
- hallucinations and nightmares
- respiratory depression.

If patients are showing signs of toxicity, the opioid dose should be reduced or stopped and as-required opioid pain relief given (Regnard and Hockley 2004). Changing to an alternative opioid can also be considered (Regnard and Hockley 2004).

Naloxone, a specific opioid antagonist, has a high affinity for opioid receptors and reverses the effect of opioid analgesics. It is rarely needed but may be required in the case of opioid-induced respiratory depression (with respiration rate of 8 or below).

Care must be taken not to give naloxone to patients who have opioid-induced drowsiness, confusion or hallucinations that are not life threatening as this may risk reversing the opioid analgesic effect (Twycross et al. 2007).

Naloxone should be given in stat doses of 400 micrograms every 2 minutes until respiratory function is satisfactory and doses should be titrated against respiratory function and not the level of consciousness of the patient in order to avoid total reversal of the analgesic effect (Twycross et al. 2007). Registered Nurses administering opioids should be aware of local policy procedures and protocols. Flumazenil is used for reversal of the effects of benzodiazepine toxicity.

Routes of administration

The three basic routes of administration are enteral, parenteral and topical (Table 12.9, Table 12.10). The enteral route uses the gastrointestinal (GI) tract for absorption of drugs. The parenteral route bypasses the GI tract and is associated with all forms of injections. The topical route also bypasses the GI tract and is associated with drugs that are administered to the skin and mucous membranes.

Oral administration

Definition

Medication taken by mouth, that is swallowed by the patient, e.g. liquid, tablets or capsules (Merck Manual 2014), or administered via a feeding tube, for example nasogastric, percutaneous endoscopic gastrostomy (PEG) (Potter 2011). See Figure 12.3.

Table 12.9 Advantages and disadvantages of the routes of administration

Route	Advantages	Disadvantages
Oral	Convenient Easy to administer Least expensive	Compliance Some drugs not suitable for oral route May not be able to swallow or take oral medications
Topical	Easy to apply Local effects	Can stain clothing Local irritation
Injections	Absorbed quickly Avoids gastrointestinal tract	Invasive Pain Complications such as infection May be difficult to self-administer
Site specific, for example eye, ear, nasal, vaginal, rectal, pulmonary	Often for local effects	Discomfort and embarrassment May be difficult to self-administer

697

Table 12.10 Considerations for specific types of administration

Consideration	Rationale
Administer irritant drugs with meals or snacks	To minimize their effect on the gastric mucosa (Jordan et al. 2003, Shepherd 2002a)
Administer drugs that interact with food, or that are destroyed in significant proportions by digestive enzymes, between meals or on an empty stomach	To prevent interference with the absorption of the drug (Jordan et al. 2003, Shepherd 2002a)
Do not break a tablet unless it is scored and appropriate to do so. Break scored tablets with a file or a tablet cutter. Wash after use	Breaking may cause incorrect dosage, gastrointestinal irritation or destruction of a drug in an incompatible pH. To reduce risk of contamination between tablets (DH 2007, Jordan et al. 2003, NMC 2010a, Shepherd 2002a)
Do not interfere with time-release capsules and enteric-coated tablets. Ask patients to swallow these whole and not to chew them	The absorption rate of the drug will be altered (Jordan et al. 2003, Perry 2007)
Sublingual tablets must be placed under the tongue and buccal tablets between gum and cheek	To allow for correct absorption (Perry 2007)
When administering liquids to babies and young children, or when an accurately measured dose in multiples of 1 mL is needed for an adult, an oral syringe should be used in preference to a medicine spoon or measure	An oral syringe is much more accurate than a measure or a 5 mL spoon Use of a syringe makes administration of the correct dose much easier in an unco-operative child Oral syringes are available and are designed to be washable and reused for the same patient. However, in the immunocompromised patient single use only is recommended. Oral syringes must be clearly labelled for oral or enteral use only (DH 2007, NPSA 2007d)
In babies and children especially, correct use of the syringe is very important. The tip should be gently pushed into and towards the side of the mouth. The contents are then <i>slowly</i> discharged towards the inside of the cheek, pausing if necessary to allow the liquid to be swallowed	To prevent injury to the mouth and eliminate the danger of choking the patient (Watt 2003)
If children are unco-operative it may help to place the end of the barrel between the teeth	To get the dose in and to prevent the patient spitting it out (Watt 2003)
When administering gargling medication, throat irrigations should not be warmer than body temperature	Liquid warmer than body temperature may cause discomfort or damage tissue

Figure 12.3 Examples of oral medication.

Oral administration is the most convenient route for drug administration and may result in better compliance (Kelly and Wright 2009). It is usually the safest and least expensive. Due to the widespread use of oral drugs, they are prepared in a variety of dosage forms.

Related theory

Tablets

These come in a great variety of shapes, sizes, colours and types. The formulation may be very simple, presenting as a plain, white, uncoated tablet, or complex, designed with specific therapeutic aims, for example sustained-release preparations. Sugar coatings are used to improve appearance and palatability. In cases where the drug is a gastric irritant or is broken down by gastric acid, an enteric coating may be used; this is designed to allow the tablet to remain intact in the stomach and to pass unchanged into the small bowel where the coating dissolves and the drug is released and absorbed.

Tablets may be formulated specifically to control the rate of release of drug from the tablet as it passes through the GI tract. Terms such as 'sustained release', 'controlled release' and 'modified release' are used by manufacturers to describe these preparations. Tablets may also be formulated specifically to dissolve readily ('soluble' or 'effervescent'), to be chewed or to be held under the tongue ('sublingual') or placed between the gum and inside of the mouth ('buccal'). Unscored or coated tablets should not be crushed or broken, nor should most 'modified-release' tablets, since this can affect the pharmacokinetic profile of the drug and may result in excessive peak plasma concentrations and side-effects (Smyth 2006).

Capsules

These offer a useful method of formulating drugs which are difficult to make into a tablet or are particularly unpalatable.

The capsule shells are usually made of gelatine and the contents of the capsules may be solid, liquid or of a paste-like consistency. The contents do not cause deterioration of the shell. The shell, however, is attacked by the digestive fluids and the contents are then released. Delayed-release capsule formulations also exist. Gastro-resistant capsules are delayed-release capsules that are intended to resist the gastric fluid and to release their active substance or substances in the intestinal fluid (British Pharmacopoeia 2007). If for any reason the capsule is unpalatable or the patient is unable to take it, the contents should not routinely be removed from the shell without first seeking advice from a pharmacist. Removing contents from the capsule could destroy their

properties and cause gastric irritation or premature release of the drug into an incompatible pH (Downie et al. 2003).

Lozenges and pastilles

Lozenges and pastilles are solid, single-dose preparations intended to be sucked to obtain a local or systemic effect to the mouth and/or throat (British Pharmacopoeia 2007).

Linctuses, elixirs and mixtures

Linctuses

These are viscous oral liquids that may contain one or more active ingredients; the solution usually contains a high proportion of sucrose. Linctuses are intended for use in the treatment or relief of cough.

Elixirs

These are clear, flavoured oral liquids containing one or more active ingredients dissolved in a vehicle that usually contains a high proportion of sucrose. A vehicle is a substance usually without therapeutic action used to give bulk for the administration of medicines. If the active drug is sensitive to moisture, it may be formulated as a flavoured powder or granulation and then dissolved in water just before use.

Mixtures

Mixtures are usually aqueous preparations, containing one or more drug, which can be in the form of either a solution or a suspension. Mixtures are normally made up when required as they have a shelf-life of 2 weeks from preparation. Suspended drugs may slowly separate on standing but are easily redispersed by shaking so this should be done before every use.

Drugs suspended, mixed or dispersed in liquids are often referred to as syrups. However, syrups do not contain active ingredients but are used as a vehicle for medications in order to decrease crystallization, increase solubility and provide aromatic and flavouring properties (British Pharmacopoeia 2007).

Evidence-based approaches

Observational studies suggest that medication administration errors for oral medicine range from 3% to 8% (Ho et al. 1997, Taxis et al. 1999) but the rate has been found to be twice as high in mental health patients who have swallowing difficulties (Haw et al. 2007). A proportion of these difficulties are due to an aversion to swallowing tablets, the most common cause being dysphagia (Kelly and Wright 2009). Guidance on medicines management related to dysphagia can be found within the NMC *Standards for Medicines Management* (NMC 2010a). When giving medicines to patients with dysphagia, both the patient and the medicine should be reviewed on a regular basis. If patients cannot swallow tablets then liquid or dispersible medications should be the first consideration (Kelly and Wright 2009). If the oral route is not patient then alternative routes should be used.

Covert drug administration

The NMC recognizes that 'this is a complex issue', as covert drug administration involves the fundamental principles of patient and client autonomy and consent to treatment, which are set out in common law and statute and underpinned by the Human Rights Act 1998 (NMC 2010a). The covert administration of medicines should not be confused with the administration of medicines against someone's will, which in itself may not be deceptive but may be unlawful (NMC 2010a).

Some vulnerable groups of patients, such as those who are confused, may refuse to take medication. Traditionally, in some places, medication has therefore been hidden or disguised in food. The NMC (2001a, 2001b, 2010a) offered the following position statement.

'As a general principle, by disguising medication in food or drink, the patient or client is being led to believe that they

are not receiving medication when in fact they are. The registered nurse, midwife or health visitor will need to be sure that what they are doing is in the best interests of the patient or client and be accountable for this decision.'

Disguising medication in food and drink is acceptable under exceptional circumstances in which covert administration may be considered to prevent a patient, who is incapable of informed consent, from missing out on essential treatment (NMC 2001a, NMC 2010a). The following principles should be followed when making such a decision.

- The medication must be considered essential for the patient's health and well-being.
- The decision to administer medication covertly should be considered only as a contingency in an emergency, not as regular practice.
- The registered practitioner must make the decision only after discussion and with the support of the multiprofessional team and, if appropriate, the patient's relatives, carers or advocates.
- The pharmacist must be involved in these decisions as adding medication to food or drink can alter its pharmacological properties and thereby affect its performance.
- The decision and action taken must be fully documented in the patient's care plan and regularly reviewed.
- Regular attempts should continue to be made to encourage the patient to take the medication voluntarily (NMC 2001a, NMC 2010a, Treloar et al. 2000).

Pre-procedural considerations

Equipment

Medicine pots

Medicine pots (Figure 12.4) allow a dosage form to be taken from its original container for immediate administration to a patient. The person who removes medication from its original container and places it into a medicine pot must oversee the administration of this medication. This responsibility cannot be transferred to someone else.

Figure 12.4 Medicine pot.

Figure 12.5 Tablet splitter.

Tablet splitters

Commercially available tablet splitters (Figure 12.5) may increase the accuracy of tablet splitting when this activity is necessary. Tablets that are unscored, unusually thick or oddly shaped, sugar coated, enteric coated and modified-release tablets are not suitable for splitting. Areas for consideration when using a tablet splitter include the following.

- Can the tablets be split? This must always be discussed with the pharmacy department.
- Do patients have the manual dexterity to use a tablet splitter when at home?
- Will splitting the tablets affect patient adherence when they are at home? Will patients skip or double dose rather than split tablets?
- How will the storage of split tablets affect the stability of the tablets? What about the effect of light and air (Marriott and Nation 2002)?

Tablet crushers

Tablet crushers (Figure 12.6) can be used when a patient has swallowing difficulties and no alternative dosage form exists. Crushing tablets is usually outside the product licence. The Medicines Act 1968 states that unlicensed medicines can only be authorized by a medical or dental practitioner, so if tablets are going to be crushed, there should be discussion and agreement between

Figure 12.6 Tablet crusher.

the prescriber and the person who will administer the medicine. Discussion should also take place with the pharmacist to check that the tablet is suitable for crushing and that the efficacy of the medication is not changed as a result. Tablets that are enteric coated, sustained release or chewable cannot be crushed. Areas for consideration when crushing a tablet include the following.

- Can the tablet be crushed? This must always be discussed with the pharmacy department.
- Will crushing make the tablet unpalatable?
- Will crushing the tablet cause any adverse effects for the patient, for example burning of the oral mucosa?
- Will crushing the tablet result in inaccurate dosing (Kelly and Wright 2009)?

When a tablet crusher is used, water should be added to the crushed tablet and the resulting solution drawn up using an oral syringe. The crusher should then be rinsed and the process repeated. Tablet crushers should be rinsed before and after use to prevent cross-contamination with other medicines (Fair and Proctor 2007, Smyth 2006).

When a tablet crusher has been used, it should be opened and washed under running water, dried with a tissue and left to air dry on a tissue or paper towel.

Monitored dosage systems and compliance aids

Monitored dosage systems and compliance aids, for example dosette boxes (Figure 12.7), are designed to help patients remember when to take their medication. They can also let carers know whether patients have taken their medication. The following should be considered when using these systems.

- They can only be used for tablets and capsules.
- Medicines that are susceptible to moisture should not be put in these systems.
- Light-sensitive medicines should not be put in these systems.
- Medicines that are harmful when handled should not be put in these systems.
- If the patient is on medications that cannot be stored in these systems, precautions should be put in place to ensure that they can cope with two systems.

Figure 12.7 Dosette box.

Figure 12.8 Oral syringe (compliant with NPSA guidance).

- If the patient's drug regimen is not stable, consideration should be given to how easy it will be to make changes to the system.
- As-required medication cannot be placed in these systems.
- These systems comply with labelling and leaflet legislation so they must always be dispensed by a pharmacy department (RPSGB 2007b).

Oral syringes

If a syringe is needed to measure and administer an oral dose, an oral syringe (Figure 12.8) that cannot be attached to intravenous catheters or ports should be used. These syringes are purple in colour. All oral syringes containing oral liquid medicines must be labelled by the person who prepared the syringe with the name and strength of the medicine, the patient name and the time it was prepared. Labelling is unnecessary if the preparation and administration is one uninterrupted process and the labelled syringe does not leave the hands of the person who prepared it. Only one unlabelled syringe should be handled at any one time (NPSA 2007d).

Specific patient preparation

Before administering oral medication, the nurse should assess for:

- the patient's ability to understand the purpose of the medication being administered
- any medication allergies and hypersensitivities
- nil by mouth status
- the patient's ability to swallow the form of medication
- the patient's cough and gag reflexes
- any contraindications to oral medications including nausea and vomiting, absence of bowel sounds/reduced peristalsis, nasogastric suctioning or any circumstance affecting bowel motility or absorption of medication, for example general anaesthesia, GI surgery, inflammatory bowel disease
- any possibility of drug-drug or drug-food interactions
- any pre-administration assessment for specific medications, for example pulse or blood pressure (Chernecky et al. 2002, Potter 2011).

Procedure guideline 12.3 Medication: oral drug administration

Essential equipment

- Drugs to be administered
- Recording sheet or book as required by law or hospital policy
- Patient's prescription chart, to check dose, route and so on
- Glass of water
- Any protective clothing required by hospital policy for specified drugs, such as antibiotics or cytotoxic drugs, for example gloves
- Medicine container (disposable if possible)

Pre-procedure

Action	Rationale
1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
2 Before administering any prescribed drug, check that it is due and has not already been given. Make any required assessments such as pulse, BP or respiration. Check that the information contained in the prescription chart is complete, correct and legible.	To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). These are required to ensure the patient is fit enough to receive medication, for example BP before antihypertensives (Chernecky et al. 2002, E).
3 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p>	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E

Procedure

4 Select the required medication and check the expiry date.	Treatment with medication that is outside the expiry date is dangerous. Drugs deteriorate with storage. The expiry date indicates when a particular drug is no longer pharmacologically efficacious (DH 2003b, C ; NMC 2010a, C).
5 Empty the required dose into a medicine container. Avoid touching the preparation.	To minimize the risk of cross-infection. To minimize the risk of harm to the nurse (DH 2007, C ; Fraise and Bradley 2009, E).
6 Take the medication and the prescription chart to the patient. Check the patient's identity by asking the patient to state their full name and date of birth. If the patient is unable to confirm details then check patient identity band against prescription chart. Check the patient's allergy status by asking them or by checking the nameband.	To ensure that the medication is administered to the correct patient and prevent any errors related to drug allergies (NPSA 2005, C).
7 Evaluate the patient's knowledge of the medication being offered by asking them to tell you what the medication is for and what side-effects to expect. If this knowledge appears to be faulty or incorrect, offer an explanation of the use, action, dose and potential side-effects of the drug or drugs involved.	A patient has a right to information about treatment (NMC 2010a, C ; NMC 2015, C). To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
8 Assist the patient to a sitting position where possible. A side-lying position may also be used if the patient is unable to sit.	To ease swallowing and prevent aspiration (Chernecky et al. 2002, E).
9 Administer the drug as prescribed.	To meet legal requirements and hospital policy (DH 2003b, C ; NMC 2010a, C ; NMC 2010b, C ; NMC 2015, C).

(continued)

Procedure guideline 12.3 Medication: oral drug administration (continued)

Action	Rationale
10 Offer a glass of water, if allowed, assisting the patient where necessary.	To facilitate swallowing of the medication (Chernecky et al. 2002, E ; Jordan et al. 2003, E).
11 Stay with the patient until they have swallowed all the medication.	To ensure that medication has been taken on time (Chernecky et al. 2002, E).
Post-procedure	
12 Record the dose given and sign the prescription chart and in any other place made necessary by legal requirement or hospital policy.	To meet legal requirements and hospital policy (DH 2003b, C ; NMC 2010a, C ; NMC 2010b, C ; NMC 2015, C).

Problem-solving table 12.1 Prevention and resolution (Procedure guideline 12.3)

Problem	Cause	Prevention	Action
Patient vomits when taking or after taking tablets.	Patient suffering from nausea.	Administer antiemetics prior to administration of tablets. These may need to be given via rectal, IM or IV route.	If patient vomits immediately after tablet swallowed then it may be given again (maybe after antiemetics). If patient vomits some time after tablet taken, it may depend on type and frequency of medication as to whether it can be retaken. Patients are advised to retake their medication if they can see a whole tablet in vomit.
Patient unable to swallow tablets.	Patient suffering from dysphagia or has issues swallowing tablets.	Discuss with pharmacy regarding availability of medication in liquid form.	Discuss with prescriber as to administering the medicine in another form or route.

Topical administration**Definition**

Medication applied onto the skin and mucous membranes primarily for its local effects, for example creams, ointments and patches (Potter 2011).

Related theory**Creams**

Creams are emulsions of oil and water and are generally well absorbed into the skin. They are usually more cosmetically acceptable than ointments because they are less greasy and easier to apply (BNF 2014). They may be used as a 'base' in which a variety of drugs may be applied for local therapy (BNF 2014).

Ointments

Ointments are greasy preparations, which are normally anhydrous and insoluble in water, and are more occlusive than creams (BNF 2014). They are absorbed more slowly into the skin and leave a greasy residue. They have similar uses to creams and are particularly suitable for dry, scaly lesions (BNF 2014).

Lotions

Lotions have a cooling effect and may be preferred to ointments or creams for application over a hairy area (BNF 2014).

Pastes

These are stiff preparations containing a high proportion of finely powdered solids such as zinc oxide suspended in ointment. They are less occlusive than ointments and can be used to protect inflamed or excoriated skin (BNF 2014, Potter 2011).

Wound products

See Chapter 15: Wound management.

Evidence-based approaches

The risk of serious effects is generally low but systemic effects can occur if the skin is thin, if drug concentration is high or contact is prolonged (Potter 2011).

Pre-procedural considerations**Specific patient preparation**

The condition of the affected site should be assessed for altered skin integrity as applying medicines to broken skin could cause them to be absorbed too rapidly, resulting in systemic effects (Chernecky et al. 2002, Potter 2011). The affected area must be washed and dried before applying the topical medicines where appropriate, unless the prescription directs otherwise.

Procedure guideline 12.4 Medication: topical applications

Essential equipment

- Disposable plastic apron
- Clean non-sterile gloves
- Sterile topical swabs
- Applicators

Pre-procedure

Action	Rationale
1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
2 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> The correct patient Drug Dose Date and time of administration Route and method of administration Diluent as appropriate Validity of prescription Signature of prescriber The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p>	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C).
3 Explain and discuss the procedure with the patient.	To prevent any errors occurring. E
	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).

Procedure

4 Put on a plastic apron and assist the patient into the required position.	To protect the patient from infection and the nurse from the topical agent as well as allowing access to the affected area of skin. E
5 Close room door or curtains if appropriate.	To ensure patient privacy and dignity. E
6 Expose the area that requires the lotion and where necessary cover the patient with a towel or sheet.	To gain access to affected area and to ensure patient dignity. E
7 Apply gloves and assess the condition of the skin using aseptic technique if the skin is broken.	To prevent local or systemic infection (DH 2007, C ; Fraise and Bradley 2009, E).
8 If the medication is to be rubbed into the skin, the preparation should be placed on a sterile topical swab.	To minimize the risk of cross-infection. To protect the nurse (DH 2007, C ; Fraise and Bradley 2009, E).
9 If the preparation causes staining, advise the patient of this.	To ensure that adequate precautions are taken beforehand such as removal of clothing and to prevent stains (NMC 2015, C).
10 Apply the ointment.	To ensure the medication is applied. E
11 Apply a sterile dressing if required.	To ensure the ointment remains in place (Chernecky et al. 2002, E).

Post-procedure

12 Remove gloves and apron and dispose of waste appropriately.	To ensure safe disposal and prevent reuse of equipment (DH 2005, C ; MHRA 2004, C).
13 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Post-procedural considerations

Educate the patient to inform the nurse if there is any itching, skin colour change or signs of a rash following application.

Complications

Local skin reaction

The skin site may appear inflamed and oedema with blistering indicates that subacute inflammation or eczema has developed from worsening of skin lesions. Patients may also complain of pruritus and tenderness which could indicate slow or impaired healing and should be referred to the prescriber; alternative therapies may be required (Potter 2011).

Transdermal administration

Definition

Medication applied to the outermost layer of the skin, the stratum corneum, usually as an adhesive medicated disc that allows the medication to be absorbed at a slow and constant rate in order to produce a systemic effect (Chernecky et al. 2002).

Related theory

Conventional transdermal systems

These consist of a gel or ointment which is measured and placed directly onto the skin. Drugs that are used in this way include glyceryl trinitrate and oestradiol. Delivering drugs in this way can be messy for patients and can also result in variations of the dose delivered due to the amount applied, the amount of rubbing in of the product, the amount of product transferred onto clothing and so on.

Transdermal patches

A transdermal patch (Figure 12.9) contains a certain amount of drug and delivers it in a quantity which is sufficient to cause the desired pharmacological effect when it crosses the skin and into the systemic system. Drugs which can be delivered in a transdermal system include fentanyl, hyoscine, nicotine and oestradiol (Hillery et al. 2001).

Three types of transdermal patch are available.

Adhesive

These are simply designed patches which consist of a drug-containing adhesive and a backing material. These patches do not provide much control over the rate of delivery and in most cases the stratum corneum controls the rate (Hillery et al. 2001).

Layered or matrix patches

Layered patches consist of a drug-containing matrix, an adhesive layer and a backing material. The drug-containing matrix controls the release of drug from the system (Hillery et al. 2001).

Reservoir

Reservoir patches consist of an enclosed reservoir of drug, a membrane layer, an adhesive layer and a backing material. The membrane layer controls the rate of drug delivery from the reservoir of drug.

Figure 12.9 Transdermal patches.

Evidence-based approaches

The advantages of transdermal systems are the avoidance of the presystemic metabolism, the drug effects can be maintained within the therapeutic window for longer which reduces side-effects and maintains constant dosing, there can be improved patient compliance and drug effects can be stopped with the withdrawal of the patch and avoidance of first-pass metabolism (Hillery et al. 2001). First-pass metabolism occurs when a drug passes through the digestive system and enters the hepatic portal system and the liver before it reaches the rest of the body. The liver metabolizes many drugs, thus reducing their bioavailability before reaching the rest of the circulatory system (Hardman et al. 1996).

A disadvantage of transdermal systems is the limited number of drugs for which the system is suitable; for example, drugs have to have a suitable potency to allow them to absorb across the skin and cause an effect. Tolerance-inducing drugs would need a period during which they were not administered, which is not always possible with transdermal systems. In addition, drugs to be used in transdermal systems cannot be irritating to the skin otherwise they would not be tolerated by patients (Hillery et al. 2001).

Pre-procedural considerations

Specific patient preparation

The condition of the affected site should be assessed for altered skin integrity as applying medicines to broken skin could cause too rapid absorption, resulting in systemic effects (Chernecky et al. 2002, Potter 2011). The affected area must be washed and dried before applying the patch, which should be attached to hairless areas of skin. The upper chest, upper arms and upper back are recommended sites and the distal areas of extremities should be avoided (Chernecky et al. 2002). Patches should not be trimmed or cut.

Procedure guideline 12.5 Medication: transdermal applications

Essential equipment

- Clean non-sterile gloves
- Disposable plastic apron
- Transdermal patch

Pre-procedure

Action

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.

Rationale

To minimize the risk of cross-infection (DH 2007, C; Fraise and Bradley 2009, E).

- 2 Before administering any prescribed drug, look at the patient's prescription chart and check the following.
 - (a) The correct patient
 - (b) Drug
 - (c) Dose
 - (d) Date and time of administration
 - (e) Route and method of administration
 - (f) Diluent as appropriate
 - (g) Validity of prescription
 - (h) Signature of prescriber
 - (i) The prescription is legible

If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.

To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, **C**; NMC 2010a, **C**). To protect the patient from harm (DH 2003b, **C**; NMC 2010a, **C**).

To prevent any errors occurring. **E**

- 3 Explain and discuss the procedure with the patient.

To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, **E**; NMC 2013, **C**; NMC 2015, **C**).

Procedure

- 4 Put on a plastic apron and assist the patient into the required position.

To allow access to the affected area of skin. **E**

- 5 Close room door or curtains if appropriate.

To ensure patient privacy and dignity. **E**

- 6 Expose the area where the patch will be applied and where necessary cover the patient with a towel or sheet.

To gain access to affected area and to ensure patient privacy and dignity. **E**

- 7 Apply gloves and assess the condition of the skin and do not apply to skin that is oily, burnt, cut or irritated in any way.

To prevent local or systemic infection (DH 2007, **C**; Fraise and Bradley 2009, **E**). To prevent local or systemic effects and to ensure the patch will remain in place (DH 2007, **C**; Potter 2011, **E**).

- 8 Where necessary, remove the used patch and fold it in half, adhesive side inwards, place in the original sachet and dispose into clinical waste.

To ensure that the release membrane is not exposed. **E**

- 9 Remove any drug residue from the former site before placing the next patch.

To avoid any skin irritation (Chernecky et al. 2002, **E**).

- 10 Carefully remove the patch from its protective cover and hold it by the edge without touching the adhesive edges.

To ensure the patch will adhere and the medication dose will not be affected (Potter 2011, **E**).

- 11 Apply the patch immediately, pressing firmly with the palm of the hand for up to 10 seconds, making sure the patch sticks well around the edges.

To ensure adequate adhesion and prevent loss of patch which would result in reduced dose and effectiveness (Potter 2011, **E**).

- 12 Date and initial the patch.

To ensure all staff know when it must be changed (Potter 2011, **E**).

Post-procedure

- 13 Remove and dispose of waste in appropriate waste bags.

To ensure safe disposal and prevent reuse of equipment.

- 14 Record the administration on appropriate charts.

To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, **C**; NMC 2010b, **C**).

Post-procedural considerations

Ongoing care

A different skin site should be used each time to avoid skin irritation (Chernecky et al. 2002). After use, the patch still contains substantial quantities of active ingredients which may have harmful effects if they reach the aquatic environment. Hence, after removal, the used patch should be folded in half, adhesive side inwards so that the release membrane is not exposed, placed in the original sachet and then discarded safely out of reach of children. Any used or unused patches should be discarded according to local policy or returned to the

pharmacy. Used patches should not be flushed down the toilet or placed in liquid waste disposal systems (www.medicines.org.uk).

Complications

See 'Topical applications'.

Rectal administration

Definition

These preparations are administered via the rectum which may exert a local effect on the GI mucosa, e.g. anti-inflammatory in

ulcerative colitis or systemic effects, e.g. analgesics or to relieve vomiting (Potter 2011).

Related theory

Suppositories

Suppositories are solid preparations which may contain one or more drug. The drugs are normally ground or sieved and then dissolved or dispersed into a glyceride-type fatty acid or water-soluble base. These suppositories will either melt after insertion into the body or dissolve and mix with the available volume of rectal fluid (Aulton 1988).

Enemas

Enemas are solutions or dispersions of a drug in a small volume of water or oil. These preparations are presented in a small plastic container made of a bulb which contains the drug and an application tube. The bulb can be compressed when the tube has been inserted in the rectum to deliver the drug. Enemas can be difficult for patients to use by themselves compared to suppositories and therefore their use is not as widespread (Aulton 1988).

Evidence-based approaches

The advantages of rectal administration include the following.

- The drug can be administered when the patient cannot use the oral route, for example if the patient is vomiting or is post-operative and therefore either unconscious or unable to ingest via the oral route.
- In some categories of patient, it may be easier to use the rectal route than the oral one as it does not require swallowing, for example children, the elderly.
- The drug may be less suited to the oral route; for example, the oral route can cause severe local GI side-effects. The drug may not be stable after GI administration or it may have an unacceptable taste which makes it unpalatable via the oral route.
- Rarely cause local irritation or side-effects (Chernecky et al. 2002, Potter 2011).

The disadvantages of the rectal route include the following.

- Strong feelings against the rectal route by some patients in some countries and also feelings of discomfort and embarrassment.
- There can be slow and incomplete absorption via the rectal route.
- The development of proctitis has been reported with rectal drug administration.
- Contraindicated in patients who have had rectal surgery or have active rectal bleeding (Chernecky et al. 2002, Downie et al. 2003, Potter 2011).

After a suppository is inserted into the rectum, body temperature melts the suppository so the medication can be distributed. Proper placement is important to promote retention of the medication until it dissolves and is absorbed into the mucosa (Potter 2011).

For further information about the administration of rectal medication, see Chapter 5, Procedure guideline 5.19: Suppository administration.

Vaginal administration

Definition

Medications are inserted into the vaginal canal usually for local effects such as treatment of infections (e.g. *Trichomonas* and *Candida* infections) and contraceptive purposes. They are used less commonly for systemic effects (such as oestrogens and progestones) (Chernecky et al. 2002, Potter 2011).

Related theory

Vaginal preparations can be delivered in a wide variety of dosage forms including pessaries, creams, aerosol foams, gels and tablets (Chernecky et al. 2002, Potter 2011).

Evidence-based approaches

The advantages of the vaginal route include the following.

- The vagina offers a large surface area for drug absorption.
- A rich blood supply ensures a rapid absorption of drug.
- This route can act as an alternative for drugs that cannot be delivered via the oral route (as for suppositories).
- This route can be used when patients cannot take drugs via the oral route (as for suppositories).
- The vaginal route can deliver drug over a controlled period of time, thus avoiding peaks and troughs which result in less toxicity and risk of ineffectiveness.

The disadvantages include the following.

- The route is limited to drugs that are potent molecules and are therefore easily absorbed.
- The vagina can be easily irritated by the use of devices or locally irritating drugs.
- Care must be taken with the use of vaginal devices to ensure they are sterilized and not acting as a growth medium for bacteria.
- The vaginal bioavailability can be affected by hormone levels and can therefore change during menstrual cycles, with age and during pregnancy.
- Leakage can occur with vaginal preparations. This can be alleviated by using the preparation at night.
- This route may not be acceptable to some patients (Hillery et al. 2001).

Pre-procedural considerations

Specific patient preparation

Check patient for any allergies and also whether they have recently given birth or undergone vaginal surgery as this may alter tissue integrity and the level of discomfort. The nurse should also review the patient's willingness and ability to self-administer the medication (Chernecky et al. 2002, Potter 2011).

Procedure guideline 12.6 Medication: vaginal administration

Essential equipment

- Disposable gloves
- Topical swabs
- Disposable sanitary pad
- Lubricating jelly
- Prescription chart
- Warm water

- Pen torch
- Disposable plastic apron

Medicinal products

- Pessary

Pre-procedure**Action****Rationale**

- | | |
|--|--|
| 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. | To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E). |
| 2 Explain and discuss the procedure with the patient. | To ensure that the patient understands the procedure and gives her valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C). |
| 3 Before administering any prescribed drug, look at the patient's prescription chart and check the following.
(a) The correct patient
(b) Drug
(c) Dose
(d) Date and time of administration
(e) Route and method of administration
(f) Diluent as appropriate
(g) Validity of prescription
(h) Signature of prescriber
(i) The prescription is legible

If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber. | To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C).

To prevent any errors occurring. E |
| 4 Select the appropriate pessary and check it with the prescription chart. | To ensure that the correct medication is given to the correct patient at the appropriate time (NMC 2010a, C). |

Procedure

- | | |
|--|---|
| 5 Close room door or curtains, keeping the patient covered as much as possible. | To ensure patient privacy and dignity. E |
| 6 Apply an apron and assist the patient into the appropriate position, either left lateral with buttocks to the edge of the bed or supine with the knees drawn up and legs parted. May require a light source, e.g. lamp or torch. | To facilitate easy access to the vaginal canal, visualize the external genitalia and vaginal canal and facilitate correct insertion of the pessary (manufacturer's instruction, C ; Chernecky et al. 2002, E ; Potter 2011, E). |
| 7 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and put on gloves. | To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E). |
| 8 Clean the area with warm water if necessary. | To remove any previously applied creams (Downie et al. 2003, E). |
| 9 Remove the pessary from the wrapper and apply lubricating jelly to a topical swab and from the swab on to the pessary. Lubricate gloved index finger of dominant hand. | To facilitate insertion of the pessary and ensure the patient's comfort (manufacturer's instruction, C). |
| 10 With non-dominant gloved hand, gently retract labial folds to expose vaginal orifice. | To enable insertion of pessary into correct orifice (Potter 2011, E). |
| 11 Insert the rounded end of the pessary along the posterior vaginal wall and into the top of the vagina (entire length of finger). | To ensure the pessary is inserted into the correct position to ensure equal distribution of medication (Potter 2011, E). To ensure that the pessary is retained and that the medication can reach its maximum efficiency (manufacturer's instruction, C ; Chernecky et al. 2002, E). |
| 12 Wipe away any excess lubricating jelly from the patient's vulval and/or perineal area with a topical swab. | To promote patient comfort (Potter 2011, E). |
| 13 Make the patient comfortable and explain to her that there may be a small amount of discharge and apply a clean sanitary pad. | To absorb any excess discharge (Potter 2011, E). |

Post-procedure

- | | |
|--|---|
| 14 Remove and dispose of gloves and apron safely and in accordance with locally approved procedures. | To ensure safe disposal (DH 2005, C ; MHRA 2004, C). |
| 15 Record the administration on appropriate charts. | To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C). |

Post-procedural considerations

The patient needs to retain the medication so it is recommended that the medication is administered prior to going to bed or the patient should remain supine for 5–10 minutes after instilling the pessary (Chernecky et al. 2002, Potter 2011). It should be explained to the patient that she may also notice a discharge following administration and that it is nothing to be concerned about.

Pulmonary administration

Definition

'Dosage forms introduced into the body via the lungs in an aerosol form to achieve local effects such as to improve bronchodilation or to improve clearance of pulmonary secretions' (Chernecky et al. 2002, Potter 2011). Systemic effects can also be achieved through the pulmonary route, for example volatile anaesthetics (Hillery et al. 2001). Some are inhaled via the mouth, some via the nose and some via nose and mouth (Downie et al. 2003).

Related theory

In order for drugs to reach the lungs, they must be delivered in an aerosol form. The aerosol penetrates the lung airways and the deeper passages of the respiratory tract provide a large surface area for drug absorption and the alveolar-capillary network absorbs medication rapidly (Potter 2011).

There are three ways in which this aerosol can be produced: by nebulizer, by pressurized metered dose inhalers and by drug powder inhalers.

- *Nebulization* involves the passage of air or oxygen driven through a solution of a drug. The resulting fine mist is then inhaled via a facemask (Trounce and Gould 2000). Some antibiotics and bronchodilators may be given in this way (Figure 12.10).
- *Metered dose inhalers* (MDI) involve a drug being suspended in a propellant in a small hand-held aerosol can in the form of a spray, mist or fine powder. Metered doses can then be delivered from the aerosol by the use of a metering valve within the device which is designed to release a fixed volume, for example Ventolin. Steroid medications are often administered by MDI to treat long-term reactive airway disease (Chernecky et al. 2002, Potter 2011) (Figure 12.11).

Figure 12.10 Nebulizer.

Figure 12.11 Metered dose inhaler (MDI).

- *Dry powder inhalers* (DPI) involve a powder being delivered to the lung via a breath-actuated device. Examples of inhalers in this group are the Accuhaler (Figure 12.12) and the Turbohaler (Figure 12.13).

Pre-procedural considerations

Equipment

Nebulizer

The advantage of nebulizers is that they can deliver more drug to the lungs than standard inhalers because of the smaller particles that are generated. They also do not require any co-ordination in order to deliver the drug to the lungs. The disadvantages are that they are expensive, they are not easily portable and the delivery of drug can be difficult to control, for example due to loss in the tubing and mouthpiece.

Metered dose inhaler (MDI)

The advantages of MDIs are that they are convenient, can deliver a fixed dose and are inexpensive. The disadvantage can be the co-ordination needed to use one. In order to be effective, the patient needs to trigger the MDI during a deep slow inhalation and then hold their breath for around 10 seconds. This need for co-ordination between actuation of the dose and inhalation can be removed by using a spacer device (Figure 12.14). The spacer device reduces the speed with which the dose is delivered and the resultant 'cold freon' effect that can occur, which can prevent a patient from continuing to inhale after actuation of the MDI. Spacers are also useful for patients on high-dose inhaled steroids in order to prevent oral candidiasis, for children and patients

Figure 12.12 Accuhaler.

Figure 12.14 Spacer device.

Figure 12.13 Turbohaler.

requiring higher doses, and can improve dose delivery to 15% (Downie et al. 2003). Spacer devices are designed to be compatible with specific inhalers and therefore care should be taken to ensure the correct spacer device is used.

Medication in MDIs is under pressure and so they should not be punctured or stored near heat or in hot conditions (e.g. patients must be informed not to leave their MDI in a hot car) (Chernecky et al. 2002).

Dry powder inhalers (DPI)

Dry powder inhalers are also useful when there are problems with co-ordination. However, they can initiate a cough reflex and patients need to have sufficient breath inhalation to activate the device.

It is also important to remember that because these medications are absorbed rapidly through the pulmonary circulation, most create systemic side-effects (Chernecky et al. 2002, Potter 2011).

Specific patient preparation

Patients who suffer from chronic respiratory disease and require airway management frequently receive inhalational medications. Maximum benefit is obtained only when the correct technique of inhalation is used so it is vital that patients are taught how to use these devices correctly and safely. Periodic checks should be carried out to ensure that efficiency is being maintained. Use of an MDI requires co-ordination during the breathing cycle and impairment of grasp or presence of tremors of the hands interferes with patient ability to depress the canister within the inhaler (Chernecky et al. 2002, Potter 2011). Studies have shown that both adults and children have difficulties with aerosol inhalers and problems include co-ordinating activation and inhalation, too rapid inhalation and too short breaths after inspiration (Hilton 1990). Baseline observations of pulse, respirations and breath sounds should be performed before beginning treatment to use as a comparison during and after treatment (Potter 2011). Patients who are to receive nebulized medicines should be in a sitting position either in bed or a chair (Downie et al. 2003).

Education

Compliance is more likely to be achieved if the patient is well informed. It is the responsibility of the nurse, doctor and pharmacists to ensure that patients have adequate teaching and

demonstration and are monitored at intervals. The patient should know the following.

- About the disease, the purpose of the therapy, how to recognize and report deterioration in the condition.

- How to use and care for the inhaler.
- The dose to be taken.
- The time interval.
- The maximum number of inhalations which should be taken in 24 hours (Downie et al. (2003).

Procedure guideline 12.7 Medication: administration by inhalation using a metered dose inhaler

Essential equipment

- MDI device
- Spacer device

Pre-procedure

Action	Rationale
1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
2 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
3 Correct use of inhalers is essential (see manufacturer's information leaflet) and will be achieved only if this is carefully explained and demonstrated to the patient. If further advice is required, contact the hospital pharmacist.	Incorrect use may result in most of the dose remaining in the mouth and/or being expelled almost immediately. This renders treatment ineffective (Watt 2003, E ; manufacturer's instructions, C).

Procedure

4 Sit the patient in an upright position if possible in the bed or a chair.	To permit full expansion of the diaphragm. E
5 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ul style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E
6 Remove mouthpiece cover from inhaler.	To expose the area for use. E
7 Shake inhaler well for 2–5 seconds.	To ensure mixing of medication in canister (Potter 2011, E).
8 <i>Without a spacer device:</i> Ask patient to take a deep breath and exhale completely, open lips and place inhaler mouthpiece in mouth with opening toward back of throat, closing lips tightly around it. <i>With a spacer device:</i> Insert MDI into end of the spacer device. Ask the patient to exhale and then grasp spacer mouthpiece with teeth and lips while holding inhaler.	Prepares airway to receive medication and directs aerosol towards airway (Potter 2011, E). To enable the medication to reach the airways instead of hitting the back of the throat. The spacer improves delivery of correct dose of inhaled medication. E
9 Ask the patient to tip head back slightly, inhale slowly and deeply through the mouth whilst depressing canister fully.	To allow medication to be distributed to airways during inhalation. E

10 Instruct the patient to breathe in slowly for 2–3 seconds and hold their breath for approximately 10 seconds, then remove MDI from mouth (if not using spacer) before exhaling slowly through pursed lips.	To enable aerosol spray to reach deeper branches of airways (Chernecky et al. 2002, E).
11 Instruct the patient to wait 20–30 seconds between inhalations (if same medication) or 2–5 minutes between inhalations (if different medication). Always administer bronchodilators before steroids.	To ensure that the medication has optimum effect and minimal side-effects. E
12 If steroid medication is administered, ask the patient to rinse their mouth with water approximately 2 minutes after inhaling the dose.	To remove any medication residue from oral cavity area. Steroids may alter the normal flora of the oral mucosa and lead to development of fungal infection (Lilley et al. 2007, E).
Post-procedure	
13 Clean any equipment used and discard all disposable equipment in appropriate containers.	To minimize the risk of infection (Fraise and Bradley 2009, E).
14 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NPSA 2007c, C).

Procedure guideline 12.8 Medication: administration by inhalation using a nebulizer

Essential equipment

- Facemask or mouthpiece
- Nebulizer and tubing

Medicinal products

- Medication required

Pre-procedure

Action

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.
- 2 Explain and discuss the procedure with the patient.
- 3 Sit the patient in an upright position if possible in the bed or a chair.
- 4 Before administering any prescribed drug, look at the patient's prescription chart and check the following.
 - (a) The correct patient
 - (b) Drug
 - (c) Dose
 - (d) Date and time of administration
 - (e) Route and method of administration
 - (f) Diluent as appropriate
 - (g) Validity of prescription
 - (h) Signature of prescriber
 - (i) The prescription is legible

If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.

Rationale

- To minimize the risk of cross-infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).
- To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, **E**; NMC 2013, **C**; NMC 2015, **C**).
- To permit full expansion of the diaphragm and facilitate effective inhalation (Jevon et al. 2010, **E**).
- To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, **C**; NMC 2010a, **C**). To protect the patient from harm (DH 2003b, **C**; NMC 2010a, **C**).

To prevent any errors occurring. **E**

Procedure

- 5 Administer only one drug at a time unless specifically instructed to the contrary.
 - 6 Assemble the nebulizer equipment as per manufacturer's instructions.
- Several drugs used together may cause undesirable reactions or may inactivate each other (Jordan et al. 2003, **E**).
- To ensure correct administration (manufacturer's instructions, **C**).

(continued)

Procedure guideline 12.8 Medication: administration by inhalation using a nebulizer (continued)

Action	Rationale
7 Measure any liquid medication with a syringe. Add the prescribed medication and diluent (if needed) to the nebulizer.	To ensure the correct dose (DH 2007, C).
8 Attach the mouthpiece or facemask via the tubing to medical piped air or oxygen as prescribed.	To ensure it is ready to use when switched on. E
(a) If a patient has a clinical need for supplementary oxygen therapy, oxygen therapy must <i>not</i> be discontinued whilst the nebulizer is in progress. In this situation the drug should be nebulized with oxygen therapy. The patient should receive continuous pulse oximetry for at least the duration of the nebulizer treatment.	To ensure patient maintains their target saturation (Jevon et al. 2010, E).
(b) If a patient is hypercapnic or acidotic (e.g. COPD) the nebulizer should be driven by medical air, not oxygen.	To avoid worsening hypercapnia (NICE 2010, C).
9 Ask the patient to hold the mouthpiece between the lips or apply the facemask and take a slow deep breath.	To promote greater deposition of medication in the airways (Potter 2011, E).
10 After inspiration, the patient should pause briefly and then exhale.	Improves effectiveness of medication. E
11 Turn on the piped air/O ₂ and ensure sufficient mist is formed. A minimum flow rate of 6–8 litres per minute is required.	To ensure effective nebulization of the medication (Downie et al. 2003, E ; Jevon et al. 2010, E).
12 The patient should continue to breathe as above until all the nebulized medication is completed (0.5 mL will remain in chamber).	To ensure all medication has been received. E
13 Optimal nebulization of 4 mL takes approximately 10 minutes.	To ensure it is effective. E .
Post-procedure	
14 If appropriate and prescribed, recommence oxygen therapy at the appropriate dose.	To continue with patient's required therapy (Jevon et al. 2010, E).
15 Clean any equipment used and/or discard all single-use disposable equipment in appropriate containers.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E ; Jevon et al. 2010, E).
16 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Post-procedural considerations

If the nebulizer is marked as single use then it must be discarded after each use. However, nebulizers should not be used for single patient use unless clearly indicated by the manufacturer. If it can be reused, then the nebulizer chamber and mask should be washed in hot soapy water, rinsed thoroughly and dried with paper towels to reduce bacterial contamination and also to prevent any build-up of crystallized medication in the nebulizer (Downie et al. 2003). Spacer devices should be washed, rinsed and allowed to dry naturally on a weekly basis and replaced after 6–12 months (Downie et al. 2003).

Complications

There is a risk of patients developing oral candidiasis when using an MDI. This can be reduced by using a spacer device. Overuse of some inhalers can result in cardiac dysrhythmias and patients may suffer from tachycardia, palpitations, headache, restlessness and insomnia. The doctor should be informed and observations commenced (Potter 2011).

Ophthalmic administration**Definition**

Dosage forms introduced into the eye for local effects, for example, to treat infections, to dilate or constrict the pupil, or to treat eye conditions such as glaucoma (Potter 2011).

Related theory

The topical route is the most popular way to introduce drugs into the eye in the form of eye drops or eye ointment. Most types of drops are instilled into the inferior fornix, the pocket formed by gently pulling on the lower eyelid, as the conjunctiva in this area is less sensitive than that overlying the cornea and will aid the retention of the medication (Jevon et al. 2010).

There are many factors that affect how much of this drug will have an effect on the eye. The eye has a highly selective corneal barrier which can prevent absorption of drug. It also has a tear film which provides an effective clearance mechanism. When an excess volume of fluid is present in the eye, this fluid will either

Figure 12.15 How to instil eye drops.

be spilled onto the cheeks and eyelashes or will enter the nasolacrimal drainage system with a potential for systemic absorption of drug. Drugs also need to be introduced to the eye at a neutral pH, as acidic or alkaline preparations will result in reflex lacrimation which will remove the drug from the eye.

Evidence-based approaches

In order to optimize the effects of topical eye preparations, attempts should be made to ensure that there is proper placement of eye drops and ointments and that the volume applied is kept to a minimum. The number of drops instilled depends on the type of solution used and its purpose. Usually one drop only is ordered and will be sufficient if it is instilled in the correct manner. The exceptions to the 'one drop' rule are as follows.

- *Oil-based solutions:* these are used for lubricating the eyeball. Usually one drop is instilled and repeated as required.
- *Anaesthetic drops:* used to anaesthetize the eye; one drop should be instilled at a time. This is repeated until the drop cannot be felt on the eye.

The dropper should be held as close to the eye as possible without touching the lids or the cornea. This will avoid corneal damage and reduce the risk of cross-infection. If the drop falls from too great a height, it is difficult to control and will be uncomfortable for the patient. The eye should be closed for as long as possible after application, preferably for 1–2 minutes.

Useful properties of eye ointment include:

- longer duration of action than eye drops
- a soothing emollient action
- easy to apply
- long shelf-life (Downie et al. 2003).

Ointments are applied to the upper rim of the inferior fornix using a similar technique to eye drops (Figure 12.15, Figure 12.16). A 2 cm line of ointment should be applied from the nasal canthus outwards. Similarly to the instillation of eye drops, the nozzle should be held approximately 2.5 cm above the eye to avoid contact with the cornea and eyelids (Aldridge 2010, Alexander et al. 2007).

Pre-procedural considerations

Equipment

A variety of droppers and bottles are available for the instillation of eye preparations. These include pipettes, bottles incorporating pipettes, plastic bottles with a dropper attachment and single-dose packs. Pipettes are easy to use but need to be dried and sterilized between doses. Plastic bottles can be squeezed and so avoid the need for a pipette and they are also cheaper than glass

bottles with a dropper. Each patient should have their own individual eye drop container for each eye and single-dose containers should be used for all patients in eye clinics or in accident and emergency departments (BNF 2014).

It is important that eye preparations are sterile before use and attempts are made to reduce microbial contamination. Eye preparations being used at home should be discarded after 4 weeks whereas eye preparations being used in hospital should be discarded after 1 week. If concerns exist around cross-contamination from one eye to another, separate bottles should be issued.

A number of patients experience problems instilling eye medication. This may be due to difficulty aiming eye drops or squeezing the bottle. Aids are available to assist patients with both these problems. Patients will need guidance in how to use any aids (Downie et al. 2003).

If patients are going to use more than one eye drop preparation, they may experience overflow and dilution when one immediately follows the other so they should be advised to leave an interval of at least 5 minutes between the two (BNF 2014). If both drops and ointments are prescribed, the drops should be applied before the ointment as ointment will leave a film on the eye and hamper the absorption of the medication in drop form (Aldridge 2010).

Pharmacological support

Drugs may be given either systemically or topically to exert an effect on the eye (BNF 2014). However, if given systemically, the prescribing doctor needs to take account of the blood–aqueous barrier which exists within the eye. This barrier is selective in allowing drugs to pass into the intraocular fluids. The

Figure 12.16 How to instil eye ointment.

permeability of this barrier may increase during inflammatory conditions or following paracentesis – the removal of excess fluid with a needle or cannula (Andrew 2006).

Medications applied topically meet some resistance at the barrier presented by the lacrimal system (tear film barrier). A further barrier is the cornea which is selectively permeable and only allows the passage of water and not drugs. However, corneal resistance may alter if there is damage to the corneal epithelium (Kirkwood 2006). Many drugs will produce a similar effect on both the healthy and diseased eye.

Drugs for use in the eye are usually classified according to their action.

Mydriatics and cycloplegics

These drugs cause pupil dilation and produce their effects by paralysing the ciliary muscle, stimulating the dilator muscle of the pupil (Figure 12.17) or by a combination of both. They are used mainly for diagnostic purposes and most have an anticholinergic action. The most commonly used preparations are cyclopentolate hydrochloride, tropicamide and atropine (BNF 2014).

714

Miotics

These drugs produce their effects by contracting the ciliary muscle and constricting the pupil (Figure 12.18). They open the inefficient drainage channels in the trabecular meshwork (BNF 2014). Miotics help in the drainage of aqueous humour and are used mainly in the treatment of primary angle-closure glaucoma. An example is pilocarpine (BNF 2014).

Local anaesthetics

These render the eye and the inner surfaces of the lids insensitive. They are used before minor surgery, removal of foreign bodies and tonometry (measurement of intraocular pressure). The most widely used eye anaesthetics are oxybuprocaine and tetracaine (BNF 2014).

Figure 12.17 Effects of mydriatics.

Figure 12.18 Effect of miotics.

Anti-inflammatories

Anti-inflammatory drugs include steroids, antihistamines, lodoxamide and sodium cromoglycate. The most commonly used steroid preparations are dexamethasone, prednisolone and betamethasone (BNF 2014).

Corticosteroid eye drops should be used with caution as they can cause cataract formation or a gradual rise in intraocular pressure in a small percentage of people, particularly if they have a history of glaucoma (Forrester et al. 2002).

Antibacterials/antivirals/antifungals

Antibacterials and antivirals can be used for the active treatment of eye infections or as prophylactic treatment for eye surgery, after removal of a foreign body or following an eye injury. Antibiotic preparations in common use are chloramphenicol, fusidic acid and gentamicin. Aciclovir is the most commonly used antiviral eye preparation and is licensed for local treatment of herpes simplex infections (BNF 2014).

Artificial tears

Artificial tears are used when there is a deficiency in natural tear production. This can be due to a disease process, post radiotherapy treatment, as a side-effect of certain drugs or when the eye-blink reflex is absent. These artificial lubricants commonly contain hypromellose or hydroxyethylcellulose (BNF 2014). Additionally, pilocarpine can be given orally. The severity of the problem and the patient's choice will determine the treatment.

Specific patient preparation

The eye to be treated must be ascertained and the unaffected eye should not be dosed. Ascertain if the patient is wearing contact lenses as contact of the medication with the lens can lead to increased drug absorption, visual distortion and discoloration of the lens (Chernecky et al. 2002). It may be necessary for the patient to remove the lenses and replace them with glasses for the duration of their treatment.

Procedure guideline 12.9 Medication: eye administration

Essential equipment

- Non-sterile powder-free gloves
- Low-linting swabs
- Sterile 0.9% sodium chloride or warm water
- Eye drops at room temperature or eye ointment

Optional equipment

- Eye swab

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient. Ask the patient to explain how their eyes feel, if they are able to.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C). To gain a baseline understanding of current problems or changes the patient is experiencing. E
2 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> The correct patient Drug Dose Date and time of administration Route and method of administration Diluent as appropriate Validity of prescription Signature of prescriber The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E
3 Wash hands and apply well-fitting gloves.	To reduce the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).

Procedure

4 Ask the patient to sit back with neck slightly hyperextended or lie down.	To ensure a position that allows easy access for medication instillation and to avoid excess running down the patient's cheek (Stollery et al. 2005, E). Correct positioning minimizes drainage of eye medication into the tear duct (Potter 2011, E).
5 If there is any discharge, proceed as for eye swabbing (see Chapter 10: Interpreting diagnostic tests). If any crusting or drainage is present around the eye, gently wash away with warm water or 0.9% sodium chloride and a swab. Always wipe clean from inner to outer canthus.	To prevent the introduction of micro-organisms into the lacrimal ducts (Potter 2011, E).
6 Ask the patient to look at the ceiling and carefully pull the skin below the affected eye using a wet swab to expose the conjunctival sac.	To move the sensitive cornea up and away from the conjunctival sac and reduce stimulation of blink reflex (Potter 2011, E).
7 If administering both drops and ointment, administer drops first.	Ointment will leave a film in the eye which may hamper the absorption of medication in drop form (Jevon et al. 2010, E).
8 <i>Either:</i> Administer the prescribed number of drops, holding the eye dropper 1–2 cm above the eye. If the patient blinks or closes their eye, repeat the procedure. <i>Or:</i> Apply a thin stream of ointment evenly along the inner edge of lower eyelid on conjunctiva from the nasal corner outwards. If there is excess medication on the eyelid, gently wipe it from inner to outer canthus.	To provide even distribution of medication across the eye. Therapeutic effect of drug is obtained only when drops enter conjunctival sac (Potter 2011, E). To provide even distribution of medication across the eye and lid margin and reduce the risk of cross-infection, contamination of the tube and trauma to the eye (Fraise and Bradley 2009, E ; Potter 2011, E ; Stollery et al. 2005, E). To avoid excess ointment irritating the surrounding skin (Stollery et al. 2005, E).

(continued)

Procedure guideline 12.9 Medication: eye administration (continued)

Action	Rationale
9 Ask the patient to close their eyes and keep them closed for 1–2 minutes.	To help distribute medication (Aldridge 2010, E ; Potter 2011, E).
10 Explain to the patient that they may have blurred vision for a few minutes after application.	To ensure the patient understands why they have blurred vision and to refrain from driving or operating machinery until their vision returns to normal (Aldridge 2010, E).
Post-procedure	
11 Clean any equipment used and discard all disposable equipment in appropriate containers.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
12 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

716

Post-procedural considerations**Immediate care**

After using any eye medications, any excess medication should be wiped off from inner to outer canthus. If an eye patch is to be worn, it should be secured without putting any pressure on the eye. Patients should be warned not to drive for 1–2 hours, until their vision is clear, after instillation of mydriatics (which dilate the pupil and paralyse the ciliary muscle) (BNF 2014). Patients should be taught how to instil eye medication. If it is difficult for them to do so then it may be necessary for a community nurse to attend and administer the eye medications (Chernecky et al. 2002).

Nasal administration**Definition**

Medication introduced to the cavity of the nose for local or systemic effects (Aldridge 2010).

Related theory

The nasal passages are lined with highly vascular mucous membranes covered with ciliated epithelium which warms and moistens air and traps dust. Medication can be delivered directly to the nasal cavity to relieve local symptoms such as allergic rhinitis in the form of nasal drops or nasal sprays (Aldridge 2010).

The nasal cavity can also be used to allow the delivery of drugs systemically. Examples include sumatriptan for migraine, desmopressin for the treatment of diabetes insipidus and nocturia and fentanyl for the treatment of breakthrough pain.

Evidence-based approaches

The advantages of the delivery of drugs using the nasal route include the large vascular surface of the nasal cavity which allows rapid absorption, the avoidance of first-pass metabolism, the accessibility of the nose, the ease of administration and the fact that this route can be used when patients are unable to swallow. There are some disadvantages to the nasal route, including the presence of mucus which acts as a barrier to absorption and the mucociliary clearance which reduces the time that drugs are held in the nasal cavity. Colds can affect absorption from the nasal cavity, and some drugs may irritate the nasal cavity.

Pre-procedural considerations**Specific patient preparation**

The patient should be encouraged to clear their nostrils by blowing or manually cleaning with a tissue or damp cotton bud to ensure that the drug has access to the nasal mucosa (Aldridge 2010).

Procedure guideline 12.10 Medication: nasal drop administration**Essential equipment**

- Tissues
- Clean non-sterile gloves

Medicinal product

- Nasal spray or drops

Optional equipment

- Cotton bud

Pre-procedure

Action	Rationale
1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).

2 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
3 Before administering any prescribed drug, look at the patient's prescription chart and check the following. (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E
4 Have paper tissues available.	To wipe away secretions and/or medication. E
Procedure	
5 Ask the patient to blow their nose to clear the nasal passages, if appropriate.	To ensure maximum penetration for the medication (Chernecky et al. 2002, E).
6 Place the patient in a supine position and hyperextend the neck (unless clinically contraindicated, for example cervical spondylosis).	To obtain a safe optimum position for insertion of the medication. E
7 Wash hands and put on gloves.	To reduce the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
8 With the non-dominant hand, gently push upward on the end of the patient's nose.	To aid in opening the nostrils. E
9 Avoid touching the external nares with the dropper and instil the drops just inside the nostril of affected side.	To prevent the patient from sneezing. E
10 Ask the patient to sniff back any liquid into the back of the nose or to maintain their position for 2 or 3 minutes.	To ensure full absorption of the medication. E
11 Discard any remaining medication in the dropper into the sink before returning it to the container.	To minimize the risk of cross-infection (Chernecky et al. 2002, E ; DH 2007, C ; Fraise and Bradley 2009, E).
12 Instruct patient not to blow their nose.	To maintain the medication in contact with nasal passages. E
13 Each patient should have their own medication and dropper.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
Post-procedure	
14 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Post-procedural considerations

The patient should be discouraged from sniffing too vigorously post administration as this can cause 'run-off' of the medication down the nasopharynx. This can cause an unpleasant taste in the throat and affect absorption of the medication (Aldridge 2010).

Otic administration

Definition

Medication introduced into the ear for local effects such as treatment of ear infections and softening of ear wax (cerumen) prior to

ear syringing (Aldridge 2010, Chernecky et al. 2002, Nichols and O'Brien 2012).

Related theory

Drugs administered via this route are intended to have a localized effect and act within the anatomy of the ear and auditory canal (Aldridge 2010). Ear preparations can be presented in the form of drops, sprays, ointments and solutions. Certain factors can affect the absorption or action of drugs in the ear, including ear wax and the acidic environment around the ear skin surface.

Evidence-based approaches

Internal ear structures are very sensitive to temperature extremes and so solutions should be administered at room temperature. When drops are instilled cold, patients may experience vertigo, ataxia or nausea (Chernecky et al. 2002, Potter 2011). Solutions should never be forced into the ear canal as medication administered under pressure can injure the eardrum. The ear drop solution should be labelled for the ear it is intended to treat. The dropper should be held as close to the ear as possible without touching to reduce the risk of cross-infection.

Pre-procedural considerations

Specific patient preparation

The nurse should examine the ear, taking note of any discharge, redness, swelling and the amount and texture of any ear wax present as these will give an indication of the general health of the ear (Harkin 2008). The nurse should also discuss with the patient their current level of hearing. It should be explained to the patient that they must lie still as sudden movements could cause injury from the ear dropper.

Procedure guideline 12.11 Medication: ear drop administration

Essential equipment

- Clean non-sterile gloves
- Tissues

Medicinal products

- Ear drops
- Disposable plastic apron

Pre-procedure

Action

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.
- 2 Explain and discuss the procedure with the patient.
- 3 Before administering any prescribed drug, look at the patient's prescription chart and check the following.
 - (a) The correct patient
 - (b) Drug
 - (c) Dose
 - (d) Date and time of administration
 - (e) Route and method of administration
 - (f) Diluent as appropriate
 - (g) Validity of prescription
 - (h) Signature of prescriber
 - (i) The prescription is legible

If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.

Rationale

- To minimize the risk of cross-infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).
- To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, **E**; NMC 2013, **C**; NMC 2015, **C**).
- To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, **C**; NMC 2010a, **C**). To protect the patient from harm (DH 2003b, **C**; NMC 2010a, **C**).
- To prevent any errors occurring. **E**

Procedure

- 4 Ask the patient to lie on their side with the ear to be treated uppermost.

To ensure the best position for insertion of the drops. **E**
- 5 Warm the drops to near body temperature by holding the container in the palm of the hand for a few minutes.

To prevent trauma to the patient (ASHP 1982, **C**; Harkin 2008, **E**; Potter 2011, **E**).
- 6 Wash hands and apply gloves.

To reduce the risk of cross-infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).
- 7 Pull the cartilaginous part of the pinna backwards and upwards (**Action figure 7**).

To prepare the auditory meatus for instillation of the drops (Harkin 2008, **E**).
- 8 If cerumen (ear wax) or drainage occludes outermost portion of the ear canal, wipe out gently with cotton-tipped applicator.

To enable the medication to enter the ear. **E**
- 9 Allow the drop(s) to fall in direction of the external canal. The dropper should not touch the ear.

To ensure that the medication reaches the area requiring therapy. **E**
- 10 Gently massage over tragus to help work in the drops.

To aid the passage of medication into the ear and prevent escape of medication. **E**
- 11 It may be necessary to temporarily place a gauze swab over the ear canal.

To prevent escape of the medication (Chernecky et al. 2002, **E**).

- 12 Request the patient to remain in this position for 2–3 minutes.

To allow the medication to reach the eardrum and be absorbed.
To prevent escape of the medication (Aldridge, 2010, **E**; Potter 2011, **E**).

Post-procedure

- 13 Record the administration on appropriate charts.

To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, **C**; NMC 2010b, **C**).

Action Figure 7 Holding ear for ear drops.

719

Post-procedural considerations

The nurse should ask the patient if there are any changes in order to monitor effectiveness of the intervention. Consideration should also be given to the patient's hearing aids and assistance given to help clean these.

Injections and infusions

Definitions

Injections are sterile solutions, emulsions or suspensions. They are prepared by dissolving, emulsifying or suspending the active ingredient and any added substances in either water for injections or a suitable non-aqueous liquid or in a mixture of these vehicles (British Pharmacopoeia 2007). Box 12.15 lists the types of injections and infusions.

Injections can be described as the act of giving medication by use of a syringe and needle. An infusion is defined as an amount of fluid in excess of 100 mL designated for parenteral infusion because the volume must be administered over a long period of time. However, medications may be given in small volumes (50–100 mL) or over a shorter period (30–60 minutes) (Weinstein and Plumer 2007).

Box 12.15 Types of injections and infusions

- Intradermal injection
- Subcutaneous injection and infusion
- Intramuscular injection
- Intra-arterial injection
- Intraosseous injection
- Intra-articular injection
- Intrathecal injection and infusion
- Intravenous:
 - bolus injection
 - intermittent and continuous infusion

Anatomy and physiology

The skin is made up of two layers: the dermis and epidermis. Within the dermis there is the papillary layer (upper dermal region) which contains capillaries, pain and touch receptors. The reticular layer contains blood vessels, sweat and oil glands. Both collagen and elastic fibres are found throughout the dermis. Collagen fibres are responsible for the toughness of the dermis. The skin also has a rich nerve supply (Marieb and Hoehn 2007).

There are three types of muscles – skeletal, cardiac and smooth. Skeletal muscles are attached to the body's skeleton and are also known as striated muscle because the fibres appear to be striped (Marieb and Hoehn 2007). For specific muscles used for injections, see 'Intramuscular injection site and volume of injection'.

Evidence-based approaches

Medicines should only be administered by injection when no other route is suitable or available. As injections avoid the GI tract, this is described as parenteral administration. Injections would be administered when the medications might be destroyed by the stomach; rapid first-pass metabolism may be extensive; the drug is not absorbed when given orally; precise control over dosage is required; unable to be given by mouth; need to achieve high drug plasma levels (Downie et al. 2003, Ostendorf 2012). There are disadvantages as injections are invasive, cause pain and discomfort, and can put the patient at risk of infection and, in the case of intravenous injections, infiltration and extravasation.

Pre-procedural considerations

Equipment

Ampoule

Ampoules (Figure 12.19) are single-dose glass containers although plastic ampoules are now used for certain products (Downie et al. 2003). They have a wide-ranging capacity and are sealed by heat fusion to exclude any contamination. They have a thin wall which allows rupture of the glass to expose the

Figure 12.19 Ampoules.

contents of liquid or powder. There is a narrow constriction leading to the neck which is often marked with a white ring which indicates the place where the neck can be snapped off (Downie et al. 2003). Ampoule opening devices of various designs are available. Ampoules are available in several sizes from 1 to 20 mL (Ostendorf 2012).

Vials

Vials (Figure 12.20) are glass containers which have a rubber closure which can be penetrated to allow the addition of a diluent to dissolve powder contents and withdrawal of a dose via the needle. The exposed rubber surface is usually covered by a protective pull-off metal or plastic cap which prevents tampering or damage but does not provide sterility (Downie et al. 2003, Ostendorf 2012). The vials may be packaged with a specific transfer needle, and the nurse should follow the manufacturer's instructions in these instances.

Figure 12.20 Vials.

Syringes

Syringes are commonly plastic and disposable, although occasionally a medicine must be administered via a glass syringe, e.g. adenosine. They consist of a graduated barrel and a plunger and a tip. It is the tip that classifies the type of syringe as Luer-Lok or Luer-Slip (Figure 12.21). Syringes come in various sizes from 1 to 60 mL. The choice of syringe is made according to the volume of medication to be administered so it is important to choose the smallest syringe possible to ensure accuracy (Downie et al. 2003, Ostendorf 2012). For Luer-Lok syringes, the needle must be twisted onto the tip and 'locked' into position. This provides security and these syringes are recommended for use with intravenous medicines, especially cytotoxic medications and any medicines administered via a syringe pump. Luer-Slip syringes tend to be used for intramuscular and subcutaneous injections. Insulin syringes are low-dose syringes often calibrated in units and are only used for insulin administration (Downie et al. 2003, Ostendorf 2012, NPSA 2010). They should be stored and distinguished from IV syringes (MHRA 2008a, Reid 2012). Injection pens are pre-filled syringes that contain a disposable cartridge. They provide a convenient delivery method and allow patients to self-administer their medications subcutaneously, e.g. insulin, adrenaline (Ostendorf 2012).

Following intrathecal incidents, the NPSA (2009) issued a safety alert that all spinal (intrathecal) bolus doses and lumbar puncture samples (part A) and all epidural, spinal (intrathecal) and regional anaesthesia infusions and bolus doses (part B) should be performed using syringes, needles and other devices with connectors that *will not* also connect with intravenous equipment.

There are now a number of pre-prepared syringes that contain 0.9% sodium chloride specifically for flushing or ready-to-administer medicines often used in emergency situations.

Needles

A hypodermic needle is composed of three parts (see Figure 12.22):

- the hub which fits onto the tip of a syringe
- the shaft which connects the hub
- the bevel or slanted tip or eye of the needle (different bevels are required depending on use of needle).

Needle sizes are known as gauges, for example 19 G, 21 G (used for intramuscular [IM] injections), 23 G (subcutaneous [SC] injections) and 25 G (intra-dermal injections). This indicates their diameter. The higher the gauge, the finer the needle and selection is made depending on the viscosity of the liquid to be injected (Downie et al. 2003, Ostendorf 2012). Needles vary in length from 10 to 16 mm and selection of length will depend on the size and weight of the patient,

Figure 12.21 Syringes: Luer-Lok and Luer-Slip.

Figure 12.22 Needles.

and the type of tissue into which the drug is to be injected, for example longer for IM and shorter for SC. Each needle is enclosed in a removable plastic guard and then sealed in a sterile pack. Filter needles may be used to prevent drawing up glass and rubber particles into the syringe (Downie et al. 2003, Ostendorf 2012).

There are now a variety of safety needles available to prevent needlestick injury where a plastic guard or sheath slips over the needle after an injection (EU Directive 2010) (Figure 12.23) or the needle retracts into the barrel.

Three categories of needle bevel are available.

- *Regular*: for all intramuscular and subcutaneous injections.
- *Intradermal*: for diagnostic injections and other injections into the epidermis.
- *Short*: rarely used.

Spinal needles

These are used for lumbar punctures, spinal anaesthesia and the administration of intrathecal therapy. There are three types of spinal needles.

- *Quincke*: short bevelled, cutting tip. Insertion results in the needle cutting parallel to the dura fibres.

Figure 12.23 Safety needles.

- *Whitacre*: designed to spread the dural fibres and help reduce the occurrence of post-dural puncture headache. Yields a distinct 'pop' as the pencil point penetrates the dura.
- *Sprotte*: as the fibres of the dura run parallel to the long axis of the spine, if the bevel of the needle is parallel to them, it will part rather than cut them, and therefore leave a smaller hole (Anaesthesia UK 2006, Carson and Serpell 1996).

Now the connectors of spinal needles are designed so they cannot connect with any intravenous equipment (NPSA 2009) (Figure 12.24).

Medication preparation

Medicines presented as liquids can be drawn up directly from the vial or ampoule. If the medicine has been presented in a powder form it will need to be reconstituted. This is usually done using water for injections but some medications will require special diluents which are often supplied with the medication. When adding diluent to a powder, for example 2 mL to a 100 mg vial, the final volume will exceed 2 mL although this is usually not of any consequence if the total dose is to be administered (Downie et al. 2003). In order to ensure that the correct volume is withdrawn, it will be necessary to perform a calculation.

721

Figure 12.24 Lumbar puncture needle and intrathecal syringe.

Medication calculations

The drug volume required from stock strength:

$$\frac{\text{Strength required}}{\text{Stock strength}} \times \text{volume of stock solution} = \text{volume required}$$

What you want/what you have got \times volume of stock solution

Displacement values

Displacement values are when you take a drug and dissolve it in a solution, e.g. water. The resulting solution will have a greater volume than before. Displacement value volumes can vary from drug to drug and may be so small that the increased volume is not considered in calculating doses (Lapham and Agar 2003). However, the total volume may be increased significantly and, if this is not taken into account when calculating a dose, errors in dosage may occur, particularly when small doses are involved, e.g. for neonates (Lapham and Agar 2003). Displacement volumes may be stated in the relevant drug information sheets.

To calculate dose using displacement volumes:

$$\text{Volume to be added} = \text{diluent volume} - \text{displacement volume}$$

It is important to note that the 'use of calculators to determine the volume or quantity of medication should not act as a substitute for arithmetical knowledge and skill' (NMC 2010a).

Single-dose preparations

The volume of the injection in a single-dose container is sufficient to permit the withdrawal and administration of the nominal dose using a normal technique.

Multidose preparations

Multidose aqueous injections contain a suitable antimicrobial preservative at an appropriate concentration except when the preparation itself has adequate antimicrobial properties. When it is necessary to present a preparation for parenteral use in a multidose container, the precautions to be taken for its administration and more particularly for its storage between successive withdrawals are given.

Parenteral infusions

Parenteral infusions are sterile, aqueous solutions or emulsions with water; they are free from pyrogens and are usually made isotonic with blood. They are principally intended for administration in large volume. Parenteral infusions do not contain any added antimicrobial preservative (British Pharmacopoeia 2007, Hillery et al. 2001).

Specific patient preparation

Reducing pain of injections

Patients are often afraid of receiving injections because they perceive the injection will be painful (Downie et al. 2003). Torrence (1989) listed a number of factors that cause pain.

- The needle.
- The chemical composition of the drug/solution.
- The technique.
- The speed of the injection.
- The volume of drug.

Applying manual pressure to an injection site before performing an injection can be an effective means of reducing pain intensity (Chung et al. 2002). A small study carried out by Chan (2001) showed that administering subcutaneous heparin slowly (over 30 seconds rather than 10) can reduce site pain intensity as well as bruising. Pain may also be reduced when using retractable needles (Lamblot et al. 2011).

Other ways of reducing pain during injections are covered in Box 12.16.

Box 12.16 Reducing the pain of injections

- Correct length and gauge of needle (use smallest possible).
- Correct site.
- Correct angle (90° for IM).
- Correct volume (no more than 3 mL at a site for IM).
- Rotate sites to prevent formation of indurations or abscesses.
- Consider using ice, freezing spray or topical local anaesthetic to numb the skin.
- Listen to views of the experienced patient.
- Explain the benefits of the injection.
- Positioning of the patient so that the muscles are relaxed.
- Use distraction.
- If appropriate, ask the patient to turn their foot inwards (IM).
- Insert and remove the needle smoothly and quickly.
- Hold the syringe steady once the needle is in the tissue to prevent tissue damage.
- Inject medication slowly but smoothly.

Source: Adapted from Dickerson (1992), Downie et al. (2003), Potter (2011).

Procedure guideline 12.12 Medication: single-dose ampoule: solution preparation

Essential equipment

- Medication ampoule
- Needle
- Syringe
- Sterile topical swab
- Sharps container
- Ampoule opening aid

Pre-procedure

Action

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.
- 2 Inspect the solution for cloudiness or particulate matter. If this is present, discard and follow hospital guidelines on action to take; for example, return drug to pharmacy.

Rationale

- To prevent contamination of medication and equipment (DH 2007, C).
- To prevent the patient from receiving an unstable or contaminated drug (NPSA 2007d, C).

Procedure

3 Tap the neck of the ampoule gently.	To ensure that all the solution is in the bottom of the ampoule (NPSA 2007d, C).
4 Cover the neck of the ampoule with a sterile topical swab and snap it open. If there is any difficulty, a file or ampoule opening aid may be required.	To minimize the risk of contamination. To prevent aerosol formation or contact with the drug which could lead to a sensitivity reaction. To reduce the risk of injury to the nurse (NPSA 2007d, C).
5 Inspect the solution for glass fragments; if present, discard.	To minimize the risk of injection of foreign matter into the patient (NPSA 2007d, C).
6 Open packaging and attach the needle onto the syringe.	To assemble equipment. E
7 Withdraw the required amount of solution, tilting the ampoule if necessary.	To avoid drawing in any air (NPSA 2007d, C).
8 Replace the sheath on the needle using one-handed scooping method (Figure 12.25) and tap the syringe to dislodge any air bubbles. Expel air (replacing the sheath should not be confused with resheathing used needles). Or: An alternative to expelling the air with the needle sheath in place would be to use the ampoule or vial to receive any air and/or drug.	To prevent needlestick injury and aerosol formation (NPSA 2007d, C). To ensure that the correct amount of drug is in the syringe (NPSA 2007d, C).
9 Attach a new needle if required (and discard used needle into appropriate sharps container) or attach a plastic end cap or insert syringe into the syringe packet.	To reduce the risk of contamination of the syringe tip. To avoid tracking medications through superficial tissues and to ensure that the correct size of needle is used for intramuscular or subcutaneous injection. To reduce the risk of injury to the nurse (NPSA 2007d, C).
10 Attach a label to the syringe.	To ensure practitioner can identify medication in syringe (NPSA 2007d, C).
11 Keep all ampoules/vials and diluents in the tray with the syringe	To enable checking at the bedside. E

Figure 12.25 Scooping.

Procedure guideline 12.13 Medication: single-dose ampoule: powder preparation

1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To prevent contamination of medication and equipment (DH 2007, C).
2 Open packaging and attach needle to the syringe.	To assemble the equipment. E

(continued)

Procedure guideline 12.13 Medication: single-dose ampoule: powder preparation (continued)

Action	Rationale
Procedure	
3 Open the diluent and draw up required volume.	To ensure the correct volume of diluent. E
4 Tap the neck of the ampoule gently.	To ensure that any powder lodged here falls to the bottom of the ampoule (NPSA 2007d, C).
5 Cover the neck of the ampoule with a sterile topical swab and snap it open. If there is any difficulty, an ampoule opening device may be required.	To minimize the risk of contamination. To prevent contact with the drug which could cause a sensitivity reaction. To prevent injury to the nurse (NPSA 2007d, C).
6 Inject the correct diluent slowly into the powder within the ampoule.	To ensure that the powder is thoroughly wet before agitation and is not released into the atmosphere (NPSA 2007d, C).
7 Agitate the ampoule.	To dissolve the drug (NPSA 2007d, C).
8 Inspect the contents.	To detect any glass fragments or any other particulate matter. If present, continue agitation or discard as appropriate (NPSA 2007d, C).
9 When the solution is clear, withdraw the prescribed amount, tilting the ampoule if necessary.	To ensure the powder is dissolved and has formed a solution with the diluent. To avoid drawing in air (NPSA 2007d, C).
10 Replace the sheath on the needle using a one-handed scooping method (see Figure 12.26) and tap the syringe to dislodge any air bubbles. Expel air.	To prevent aerosol formation. To ensure that the correct amount of drug is in the syringe (NPSA 2007d, C).
11 Attach a new needle if required (and discard used needle into appropriate sharps container) or attach a plastic end cap or insert syringe into the syringe packet.	To reduce the risk of contamination of the syringe tip. To avoid possible trauma to the patient if the needle has barbed (become bent/hooked), to avoid tracking medications through superficial tissues and to ensure that the correct size of needle is used for intramuscular or subcutaneous injection. To reduce the risk of injury to the nurse (NPSA 2007d, C).
12 Attach a label to the syringe.	To ensure practitioner can identify medication in syringe (NPSA 2007d, C).
13 Keep all ampoules/vials and diluents in the tray with the syringe.	To enable checking at the bedside. E

Procedure guideline 12.14 Medication: multidose-vial: powder preparation using a venting needle**Essential equipment**

- Medication ampoule
- Diluent
- Needles ×2
- Syringe
- Alcohol swab

Pre-procedure

Action	Rationale
1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To prevent contamination of medication and equipment (DH 2007, C).
2 Open packaging and attach needle to the syringe.	To assemble the equipment. E

Procedure

3 Open the diluent and draw up required volume.	To ensure the correct volume of diluent. E
4 Remove the tamper-evident seal on the vial and clean the rubber septum with alcohol swab and let it air dry for at least 30 seconds.	To prevent bacterial contamination of the drug, as the plastic lid prevents damage but does not ensure sterility (NPSA 2007d, C).
5 Insert a 21 G needle into the cap to vent the bottle (Action figure 5a).	To prevent pressure differentials, which can cause separation of needle and syringe (NPSA 2007d, C).
6 Insert the needle bevel up, at an angle of 45–60°. Before completing the insertion of the needle tip, lift the needle to 90° and proceed (Action figure 6).	To minimize the risk of coring when inserting the needle into the cap. E
7 Inject the correct diluent slowly into the powder within the ampoule.	To ensure that the powder is thoroughly wet before it is mixed and is not released into the atmosphere (NPSA 2007d, C).
8 Remove the needle and the syringe.	To enable adequate mixing of the solution. E
9 Place a sterile topical swab over the venting needle (see Action figure 5b) and gently swirl to dissolve the powder.	To prevent contamination of the drug or the atmosphere. To mix the diluent with the powder and dissolve the drug (NPSA 2007d, C).

Action Figure 5 Suggested method of vial reconstitution to avoid environmental exposure. (a) When reconstituting vial, insert a second needle to allow air to escape when adding diluent for injection. (b) When gently swirling the vial to dissolve the powder, push in second needle up to Luer connection and cover with a sterile swab. (c) To remove reconstituted solution, insert syringe needle and then invert vial. Ensuring that tip of second needle is above fluid, withdraw the solution. (d) Remove air from syringe without spraying into the atmosphere by injecting air back into vial.

Action Figure 6 Method to minimize coring.

Procedure guideline 12.15 Medication: multidose vial: powder preparation using equilibrium method*Essential equipment*

- Medication vial
- Diluent
- Needle
- Syringe
- Alcohol swab

*Pre-procedure***Action****Rationale**

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.
- 2 Open packaging and attach needle to the syringe.

To prevent contamination of medication and equipment (DH 2007, **C**).

To assemble the equipment. **E**

Procedure

- 3 Open the diluent and draw up required volume.
- 4 Remove the tamper-evident seal on the vial and clean the rubber septum with an alcohol swab and let it air dry for at least 30 seconds.
- 5 Inject the diluent into the vial. Keeping the tip of the needle above the level of the solution in the vial, release the plunger. The syringe will fill with air which has been displaced by the solution.
- 6 With the syringe and needle still in place, gently swirl the vial to dissolve all the powder.
- 7 Inspect the solution for cloudiness or particulate matter. If this is present, discard. Follow hospital guidelines on what action to take; for example, return drug to pharmacy.
- 8 Invert the vial. Keep the needle in the solution and slowly depress the plunger to push the air into the vial.

To ensure the correct volume of diluent. **E**

To prevent bacterial contamination of the drug, as the plastic lid prevents damage but does not ensure sterility (NPSA 2007d, **C**).

To prevent bacterial contamination of the drug (NPSA 2007d, **C**).

To mix the diluent with the powder and dissolve the drug (NPSA 2007d, **C**).

To prevent patient from receiving an unstable or contaminated drug (NPSA 2007d, **C**).

To create an equilibrium in the vial (NPSA 2007d, **C**).

- 9 Release the plunger so that the solution flows back into the syringe (if a large volume of solution is to be withdrawn, use a push-pull technique).
- 10 Inject the diluent into the vial. Keeping the tip of the needle above the level of the solution in the vial, release the plunger. The syringe will fill with the air which has been displaced by the solution.
- 11 Withdraw the prescribed amount of solution, and inspect for pieces of rubber which may have 'cored out' of the cap (see **Action figure 5c** in Procedure guideline 12.14).
- 12 Remove air from syringe without spraying into the atmosphere by injecting air back into the vial (see **Action figure 5d** in Procedure guideline 12.14) or replace the sheath on the needle using a one-handed scooping method (see Figure 12.26) and tap the syringe to dislodge any air bubbles.
- 13 Attach a new needle if required (and discard used needle into appropriate sharps container) or attach a plastic end cap or insert syringe into the syringe packet.

To create an equilibrium in the vial (NPSA 2007d, **C**).

This 'equilibrium method' helps to minimize the build-up of pressure in the vial (NPSA 2007d, **C**).

To ensure that the correct amount of drug is in the syringe (NPSA 2007d, **C**). To prevent the injection of foreign matter into the patient (NPSA 2007d, **C**).

To reduce risk of contamination of practitioner.

To prevent aerosol formation (NPSA 2007d, **C**).

- 14 Attach a label to the syringe.

To reduce the risk of contamination of the syringe tip. To avoid possible trauma to the patient if the needle has barbed (become bent/hooked), to avoid tracking medications through superficial tissues and to ensure that the correct size of needle is used for intramuscular or subcutaneous injection. To reduce the risk of injury to the nurse (NPSA 2007d, **C**).

To ensure practitioner can identify medication in syringe (NPSA 2007d, **C**).

- 15 Keep all ampoules/vials and diluents in the tray with the syringe.

To enable checking at the bedside. **E**

Procedure guideline 12.16 Medication: injection administration

Essential equipment

- Clean tray or receiver in which to place drug and equipment
- 21 G needle(s) to ease reconstitution and drawing up, 23 G if from a glass ampoule
- 21, 23 or 25 G needle, size dependent on route of administration
- Syringe(s) of appropriate size for amount of drug to be given
- Swabs saturated with isopropyl alcohol 70%
- Sterile topical swab, if drug is presented in ampoule form
- Drug(s) to be administered
- Patient's prescription chart, to check dose, route and so on
- Recording sheet or book as required by law or hospital policy
- Any protective clothing required by hospital policy for specified drugs, such as antibiotics or cytotoxic drugs, such as goggles or gloves

Pre-procedure

Action	Rationale
1 Collect and check all equipment.	To prevent delays and enable full concentration on the procedure. E .
2 Check that the packaging of all equipment is intact.	To ensure sterility. If the seal is damaged, discard (NPSA 2007d, C).
3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To prevent contamination of medication and equipment (DH 2007, C).

Procedure

4 Prepare needle(s), syringe(s) and so on, on a tray or receiver.	To contain all items in a clean area. E
5 Inspect all equipment.	To check that none is damaged; if so, discard or report to MHRA. C
6 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
7 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ul style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C).
8 Check all details with another nurse if required by hospital policy.	To prevent any errors occurring. E
9 Select the drug in the appropriate volume, dilution or dosage and check the expiry date.	To minimize any risk of error (NMC 2010a, C).
10 Proceed with the preparation of the drug, using protective clothing if advisable.	To reduce wastage. Treatment with medication that is outside the expiry date is dangerous. Drugs deteriorate with storage. The expiry date indicates when a particular drug is no longer pharmacologically efficacious (NPSA 2007d, C).
11 Take the prepared dose to the patient and close the door or curtains as appropriate.	To protect practitioner during preparation (NPSA 2007d, C).
12 Check patient's identity.	To ensure patient privacy and dignity. E
13 Evaluate the patient's knowledge of the medication being offered. If this knowledge appears to be faulty or incorrect, offer an explanation of the use, action, dose and potential side-effects of the drug or drugs involved.	To prevent error and confirm patient's identity (NPSA 2005, C).
14 Administer the drug as prescribed.	A patient has a right to information about treatment (NMC 2010a, C).
	To ensure patient receives treatment. E

(continued)

Procedure guideline 12.16 Medication: injection administration (continued)	
Action	Rationale
Post-procedure	
15 Dispose of all equipment in the appropriate waste containers/sharps bins.	To ensure safe disposal of all equipment.
16 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NPSA 2007d, C).

Methods for injection or infusion

There are a number of routes for injection or infusion (see Box 12.15). The selection may be pre-determined, for example intra-arterial, intra-articular injections. The choice of other routes will normally depend on the desired therapeutic effect and the patient's safety and comfort.

Intra-arterial

This special technique allows the delivery of a high concentration of drug to the tissues or organ supplied by a particular artery if the medications are rapidly metabolized or systematically toxic (Downie et al. 2003). This route can be used for the administration of chemotherapy and vasodilators and for diagnostic purposes. Injection of drugs into an artery is a rare and hazardous procedure. The introduction of the cannula or catheter must be performed with care as the vessel may go into spasm, causing pain and occlusion. This could result in necrosis of an organ or part of a limb.

Intra-articular

In inflammatory conditions of the joints, corticosteroids are given by intra-articular injection to relieve inflammation and increase joint mobility (Downie et al. 2003).

Intrathecal administration of medication

Definition

Intrathecal administration is the administration of drugs into the central nervous system (CNS) via the cerebrospinal fluid. This is usually achieved using a lumbar puncture (Polovich et al. 2014, Stanley 2002, Wilkes and Barton Burke 2011).

Related theory

Medications can be administered intrathecally if they have poor lipid solubility and therefore do not pass the blood–brain barrier (Downie et al. 2003). Only medication specially prepared for the intrathecal route should be used; doses should be carefully calculated and are usually much smaller than would be given by intramuscular or intravenous injection. Water-soluble antibiotics are administered by the intrathecal route to achieve adequate concentrations in the cerebrospinal fluid (CSF) in the treatment of meningitis. Other medicines administered via this route include antifungal agents, opioids, cytotoxic therapy and radiopaque substances (used in the diagnosis of spinal lesions) (Downie et al. 2003).

The advantage of this route is that it allows direct access to the CNS of drugs which do not normally cross the blood–brain barrier in sufficient amounts and thus ensures constant levels of the drug in this area. The main disadvantage is that it requires a standard lumbar puncture before the drug can be injected, and this may need to be performed on a daily to weekly basis (Wilkes and Barton Burke 2011). Although this can be quick and easy to perform, it can be distressing for the patient, and could even result in CNS trauma and infection. It may also only reach the epidural or subdural spaces and therefore the concentrations in the ventricles

may not be therapeutic (Wilkes and Barton Burke 2011). However, central instillation of the drug into the ventricle can be achieved via an Ommaya reservoir (Figure 12.26), which is surgically implanted through the cranium (Weinstein and Plumer 2007, Wilkes and Barton Burke 2011). It carries more risks but provides permanent access and can be inserted under local or general anaesthetic (Wilkes and Barton Burke 2011). Doses of intraventricular drugs tend to be lower than those given intrathecally.

Evidence-based approaches

Rationale

Indications

Intrathecal administration has proved to be of benefit in prophylactic treatment in cases of leukaemias and some lymphomas, where the CNS may provide a sanctuary site for tumour cells not reached during systemic chemotherapy (Wilkes and Barton Burke 2011). It has no place in the treatment of CNS metastases of solid tumours (Wilkes and Barton Burke 2011). Water-soluble antibiotics are administered by the intrathecal route in the treatment of meningitis, and radiopaque substances are administered for the diagnosis of spinal lesions (Downie et al. 2003).

Principles of care

Preparation of the drug must be performed using aseptic technique to reduce the risk of infection. The drug should be free from preservatives to reduce neurotoxicity. Cerebrospinal fluid removal and volumes of medications should not be more than 2 mL/min.

Legal and professional issues

Chemotherapy administered using this route has the potential to cause great harm (Sewell et al. 2002) and has been associated with the deaths of at least 13 patients since 1985. The risks of intrathecal chemotherapy have been well documented in An

Figure 12.26 Ommaya reservoir.

Organization with a Memory (DH 2000a) and the government set a target to eliminate the incidents of patients dying or being paralysed by maladministered intrathecal injections by the end of 2001 (DH 2000a). Two reports on injection errors (Toft 2001) gave rise to the publication of the national guidance for the safe administration of intrathecal chemotherapy.

Following the publication of the guidance, all UK trusts that undertake to administer intrathecal cytotoxic chemotherapy (ITC) must ensure safe practice guidelines have been introduced and that they are fully compliant with the *Updated National Guidance on the Safe Administration of Intrathecal Chemotherapy* (DH 2008). The key requirements of the guidance are noted in Box 12.17.

The Chief Executive must identify a 'designated lead' who in turn must ensure the appropriate induction, training and continuing professional development of designated personnel authorized to administer intrathecal chemotherapy. A register of these personnel must be kept along with details of certain competency-based tasks such as prescribing, dispensing, issuing, checking and administration. It is important to keep up to date with relevant safety alerts concerning intrathecal therapy which may be issued by the Department of Health agencies such as the Medicines and Healthcare Products Regulatory Agency (MHRA) or National Patient Safety Agency (NPSA). Such reports have highlighted concerns over the risk of neurological injury due to implantable drug pumps for intrathecal therapy (MHRA 2008b) and the storage of vinca alkaloid minibags (NPSA 2008b). More recently, the NPSA published two alerts to ensure that all needles, syringes and other devices used for intrathecal administration of medication cannot be attached to any intravenous equipment to prevent maladministered injections (NPSA 2012).

Intradermal injection

Definition

An intradermal injection is given into the dermis of the skin just below the epidermis where the blood supply is reduced and drug absorption can occur slowly (Chernecky et al. 2002). The intradermal route provides a local rather than systemic effect and is used primarily for administering small amounts of local anaesthetic and skin testing, for example allergy or tuberculin testing (Potter 2011).

Evidence-based approaches

Observation of the skin for an inflammatory reaction is a priority, so the best sites are those that are lowly pigmented, thinly keratinized and hairless. Chosen sites are the inner forearms and the scapulae. The injection site most commonly used for skin testing is the medial forearm area as this allows for easy inspection (Downie et al. 2003). Volumes of 0.5 mL or less should be used (Chernecky et al. 2002).

Box 12.17 Summary – requirements of intrathecal guidance

- Only trained, designated personnel whose names are recorded on the appropriate intrathecal register are authorized to prescribe, dispense, check or administer intrathecal chemotherapy.
- All staff involved in the intrathecal chemotherapy process must undertake a formal competency-based induction programme that is appropriate to their role and annual training must be provided for all professional staff to remain on the register.
- Staff involved with intrathecal chemotherapy must use this policy in conjunction with the national guidance HSC 2008/001 and the Rapid Response Report NPSA/2008/RRR004 relating to intravenous vinca alkaloid administration.
- Staff are given an annual date-expiring certificate on satisfactory completion of their training.
- Intrathecal chemotherapy must be prescribed by a consultant, associate specialist, specialist registrar, staff grade or ST3 grade doctor only and they must be on the register.
- Intrathecal chemotherapy drugs must be issued and received by designated staff only. Any such products not used must be returned to pharmacy at the end of the intrathecal chemotherapy session.
- In adults, intravenous drugs must be administered BEFORE intrathecal drugs are issued (or once intravenous continuous infusions have been started).
- Children receiving intrathecal therapy under general anaesthetic will have their intrathecal treatment first in theatre. Intravenous drugs (excluding vinca alkaloids) may be given later in day care or on the ward, but never in theatre.
- Intrathecal chemotherapy should always be administered in a designated area, within normal working hours; out-of-hours administration must only occur in exceptional circumstances.
- Checks must be made by medical, nursing and pharmacy staff at relevant stages throughout the prescribing, preparation and administration process.
- This guidance predominantly relates to treatment given intrathecally, by lumbar puncture (i.e. via spinal injection) but is also relevant to intraventricular chemotherapy (i.e. via injection into the ventricles of the brain).

Pre-procedural considerations

Equipment

The injections are best performed using a 25 or 27 G needle inserted at a 10–15° angle, bevel up, just under the epidermis. Usually a TB (tuberculosis) or 1 mL syringe is used to ensure accuracy of dose.

Procedure guideline 12.17 Medication: intradermal injection

Essential equipment

- Needle 25–27 G
- 1 mL syringe containing medication
- Alcohol swab

- Non-sterile gloves
- Apron

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E; NMC 2013, C; NMC 2015, C).

(continued)

Procedure guideline 12.17 Medication: intradermal injection (continued)

Action	Rationale
<p>2 Before administering any prescribed drug, look at the patient's prescription chart and check the following.</p> <ul style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p> <p>Prepare medication as described in Procedure guidelines 12.12, 12.13, 12.14, 12.15.</p>	<p>To ensure that the patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C; NMC 2010a, C). To protect the patient from harm (DH 2003b, C; NMC 2010a, C).</p> <p>To prevent any errors occurring. E</p>

Procedure

3 Apply apron, close the curtains or door and assist the patient into the required position. Wash hands.	To ensure patient privacy and dignity. E To allow access to the appropriate injection site (Workman 1999, E).
4 Remove appropriate garments to expose the injection site.	To gain access for injection (Workman 1999, E).
5 Assess the injection site for signs of inflammation, oedema, infection and skin lesions.	To promote effectiveness of administration (Workman 1999, E). To reduce the risk of infection (Fraise and Bradley 2009, E ; Workman 1999, E). To avoid skin lesions and avoid possible trauma to the patient (Workman 1999, E).
6 Choose the correct needle size and attach the needle.	To minimize the risk of missing the subcutaneous tissue and any ensuing pain (Workman 1999, E).
7 Apply gloves and clean the injection site with a swab saturated with isopropyl alcohol 70% and apply gloves.	To reduce the number of pathogens introduced into the skin by the needle at the time of insertion. (For further information on this action see 'Skin preparation'.)
8 Remove the needle sheath and hold syringe with the dominant hand with the bevel of needle pointing up.	To facilitate needle placement (Ostendorf 2012, E).
9 With the non-dominant hand, stretch skin over the site with forefinger and thumb.	To facilitate the needle piercing the skin more easily (Ostendorf 2012, E).
10 With the needle almost against the patient's skin, insert the needle into the skin at an angle of 10–15° and advance through the epidermis so the needle tip can be seen through the skin.	To ensure the needle tip is in the dermis (Ostendorf 2012, E).
11 Inject medication slowly. It is not necessary to aspirate as the dermis is relatively avascular.	To minimize the discomfort at site (Ostendorf 2012, E).
12 While injecting medication, a bleb (resembling a mosquito bite) will form (Action figure 12).	To indicate medication is in dermis (Ostendorf 2012, E).
13 Withdraw the needle rapidly and apply pressure gently. Do not massage the site.	To prevent dispersing medication into underlying tissue layers and altering test results (Chernecky et al. 2002, E ; Ostendorf 2012, E).

Post-procedure

14 Where appropriate, activate safety device. Ensure that all sharps and non-sharp waste are disposed of safely and in accordance with locally approved procedures. For example, sharps into sharps bin and syringes into an orange clinical waste bag.	To ensure safe disposal and to avoid laceration or other injury to staff (DH 2005, C ; EU 2010, C ; MHRA 2004, C).
15 Record the administration on appropriate sheets.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NPSA 2007d, C).

Action Figure 12 Intradermal bleb.

Subcutaneous injection

Definition

These are given beneath the epidermis into the loose fat and connective tissue underlying the dermis and are used for administering small doses of non-irritating water-soluble substances such as insulin or heparin (Downie et al. 2003).

Related theory

Subcutaneous tissue is not richly supplied with blood vessels and so medication is absorbed more slowly than when given intramuscularly. The rate of absorption is influenced by factors that affect blood flow to tissues such as physical exercise or local application of hot or cold compresses (Ostendorf 2012). Other conditions can prevent or delay absorption due to an impaired blood flow so in these conditions, subcutaneous injections are contraindicated, for example circulatory shock, occlusive vascular disease (Ostendorf 2012).

Evidence-based approaches

Injection sites

Sites recommended are the abdomen in the umbilical region, the lateral or posterior aspect of the lower part of the upper arm, the thighs (under the greater trochanter rather than mid thigh) and the buttocks (Downie et al. 2003) (Figure 12.27). It has been found that the amount of subcutaneous tissue varies more than was previously thought; this is particularly significant for administration of insulin as inadvertent intramuscular administration can result in rapid absorption and hypoglycaemic episodes (King 2003). Rotation of sites can decrease the likelihood of irritation and ensure improved absorption. If using the abdominal area then try to inject each subsequent injection 2.5 cm from the previous one (Chernecky et al. 2002). Injection sites should be free of infection, skin lesions, scars, birthmarks, bony prominences and large underlying muscles or nerves (Ostendorf 2012).

The skin should be gently pinched into a fold to elevate the subcutaneous tissue which lifts the adipose tissue away from the underlying muscle (FIT 2011). The practice of aspirating to ensure a blood vessel has not been pierced is no longer recommended as it has been shown that this is unlikely to occur (Ostendorf 2012, Peragallo-Dittko 1997). The maximum volume tolerable using this route for injection is 2 mL and drugs should be highly soluble to prevent irritation (Downie et al. 2003).

Pre-procedural considerations

Equipment

Injections are usually given using a 25 G needle. To ensure medication reaches the subcutaneous tissue, the rule is: if you can grasp 2 inches of tissue, insert the needle at a 90° angle; for 1 inch, insert needle at a 45° angle (Chernecky et al. 2002, Ostendorf 2012). With the introduction of shorter needles (4–8 mm), it is recommended that insulin injections be given at an angle of 90° (FIT 2011, King

2003). The length of the needle should be selected by pinching the skin tissue and selecting a needle one-half the width of the skinfold (Chernecky et al. 2002, FIT 2011). Shorter needles should also be used at a 45° angle in children and underweight adults.

Specific patient preparation

It has been stated that it is not necessary to use an alcohol swab to clean the skin prior to administration of injections providing the skin is socially clean (FIT 2011). If unsure or in immunocompromised patients, the skin should be prepared using an antiseptic swab (Dann 1969, Downie et al. 2003, FIT 2011).

Figure 12.27 Sites recommended for subcutaneous injection. Source: Adapted from Elkin et al. (2007).

Procedure guideline 12.18 Medication: subcutaneous injection*Essential equipment*

- Gloves and apron
- Alcohol swab
- Needle
- Syringe containing prepared medication
- Sterile gauze

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
2 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> The correct patient Drug Dose Date and time of administration Route and method of administration Diluent as appropriate Validity of prescription Signature of prescriber The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p> <p>Prepare medication as described in Procedure guidelines 12.12, 12.13, 12.14 and 12.15.</p>	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C).
3 Wash hands and apply an apron.	To prevent any errors occurring. E To prevent contamination of medication and equipment (DH 2007, C). To prevent possible cross-contamination (Fraise and Bradley 2009, E).

Procedure

4 Close the curtains or door and assist the patient into the required position.	To ensure patient's privacy and dignity. E To allow access to the appropriate injection site (Ostendorf 2012, E).
5 Remove appropriate garments to expose the injection site.	To gain access for injection. E
6 Assess the injection site for signs of inflammation, oedema, infection and skin lesions.	To promote effectiveness of administration (Ostendorf 2012, E). To reduce the risk of infection (Fraise and Bradley 2009, E ; Workman 1999, E). To avoid skin lesions and possible trauma to the patient (Ostendorf 2012, E).
7 Wash and dry hands and apply non-sterile gloves.	To prevent contamination of medication and equipment (DH 2007, C). To prevent possible cross-contamination (Fraise and Bradley 2009, E).
8 Pinch the skin and select the correct needle size (this is commonly a 23 G needle).	To minimize the risk of missing the subcutaneous tissue and any ensuing pain (FIT 2011, C ; Ostendorf 2012, E).
9 Where appropriate, clean the injection site with a swab saturated with isopropyl alcohol 70%.	To reduce the number of pathogens introduced into the skin by the needle at the time of insertion (FIT 2011, C). (For further information on this action see 'Skin preparation')
10 Remove the needle sheath.	To prepare the syringe for use. E
11 Gently pinch the skin up into a fold.	To elevate the subcutaneous tissue, and lift the adipose tissue away from the underlying muscle (FIT 2011, C ; Ostendorf 2012, E).
12 Hold the syringe between thumb and forefinger of dominant hand as if grasping a dart.	To enable a quick smooth injection (Ostendorf 2012, E).

13 Insert the needle into the skin at an angle of 45° and release the grasped skin (unless administering insulin when an angle of 90° should be used). Inject the drug slowly over 10–30 seconds.	Injecting medication into compressed tissue irritates nerve fibres and causes the patient discomfort (Ostendorf 2012, E). The introduction of shorter insulin needles makes 90° the more appropriate angle (FIT 2011, C ; Trounce and Gould 2000, E).
14 Withdraw the needle rapidly. Apply gentle pressure with sterile gauze. Do not massage area.	To aid absorption. Massage can injure underlying tissue (Ostendorf 2012, E).
Post-procedure	
15 Ensure that all sharps and non-sharp waste are disposed of safely and in accordance with locally approved procedures.	To ensure safe disposal and to avoid laceration or other injury to staff (DH, 2005b, C ; MHRA, 2004, C).
16 Record the administration on appropriate sheets.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NPSA 2007d, C).

Post-procedural considerations

Education of patient and relevant others

Patients often have to administer their own subcutaneous injections, for example insulin for diabetics. The nurse must teach the patient how to prepare and administer self-injection, including aspects such as equipment, storage, hand washing, injection technique, rotation of sites and safe disposal of equipment and sharps (FIT 2011, Ostendorf 2012).

Complications

Medications collecting within the tissues can cause sterile abscesses, which appear as hardened, painful lumps (Ostendorf 2012) or in rare cases lipohypertrophy (wasting of the subcutaneous tissue at injection sites) can develop (FIT 2011). The nurse must monitor and report these and avoid using these areas for further injections (FIT 2011).

Subcutaneous infusion

Definition

Continuous infusion of fluids or medication into the subcutaneous tissues (Ostendorf 2012).

Evidence-based approaches

Methods for subcutaneous infusions of fluids (hypodermoclysis)

Hypodermoclysis is a method of infusing fluid into subcutaneous tissue that is easier than administering intravenous fluids (Sasson and Shvartzman 2001). Subcutaneous fluids can be given to maintain adequate hydration in patients with mild or moderate dehydration (Scales 2011, Walsh 2005) and have been shown to be as effective as the intravenous route for replacing fluid and electrolytes (Barton et al. 2004, Barua and Bhowmick 2005, Luk et al. 2008). The use of this route is generally limited to palliative care or elderly patients (Scales 2011, Walsh 2005). It is not recommended for patients needing rapid administration of fluids, and is also contraindicated in patients with clotting disorders or who have problems with fluid overload (such as those with cardiac failure) (Mei and Auerhahn 2009, Walsh 2005).

A volume of 1000–2000 mL can be given over 24 hours; this can be given as a continuous infusion, over a number of hours (such as overnight) or as intermittent boluses (Moriarty and Hudson 2001, Scales 2011, Walsh 2005). More than one site can be used if greater volumes are required. It is recommended that electrolyte-containing fluids such as sodium chloride 0.9% or dextrose saline

be used although 5% glucose has also been used (Hypodermoclysis Working Group 1998, Sasson and Shvartzman 2001).

Advantages of this route include the following.

- Side-effects are few and not generally significant.
- It is a relatively easy procedure which can be carried out at home, reducing the need for hospitalization.
- May be set up and administered by nurses in almost any setting.
- Low cost.
- Less likely to cause fluid overload.
- Intravenous access can be problematic in elderly or debilitated patients; avoidance of this can reduce anxiety and distress (Mei and Auerhahn 2009, Scales 2011).

Side-effects of subcutaneous fluid administration include pain, bruising, local oedema, erythema and local inflammation, which can be reduced by changing the site of infusion (Mei and Auerhahn 2009, Scales 2011).

Hyaluronidase is an enzyme which temporarily increases the permeability of subcutaneous connective tissue by degrading hyaluronic acid and has been shown to increase the dispersion and absorption of co-administered molecules (Thomas et al. 2009). It can be given as a subcutaneous injection before commencing fluids or added to infusion bags (Sasson and Shvartzman 2001). A randomized study compared absorption and side-effects of administration of subcutaneous fluids with or without hyaluronidase. No significant differences were found although patients not receiving hyaluronidase showed an increase in the size of the limb in which the fluid had been administered, but no differences in pain or local discomfort were found so no clear benefit to the use of hyaluronidase was demonstrated (Constans et al. 1991). Most agree that it is not necessary to use hyaluronidase if the infusion rate is 1 mL/min or less (Mei and Auerhahn 2009).

Methods for subcutaneous infusions of drugs

This may be the route of choice in patients with problems such as vomiting, diarrhoea or dysphagia and who are unable to tolerate drugs by the oral route; patients with bowel obstruction whose gut absorption may be impaired may also benefit. It is also commonly used for patients who are dying and no longer able to manage medication orally (Dickman et al. 2007, Dychter et al. 2012, Menahem and Shvartzman 2010, Ostendorf 2012). Continuous subcutaneous infusion of insulin is used in a small number of diabetic patients, particularly when adequate control cannot be achieved with multiple daily insulin doses. Such patients need to be under the care of a multidisciplinary team familiar with the use of such infusions (NICE 2003).

Infusions of a single drug, such as an antiemetic or analgesic, do not generally cause problems with stability. The drug should be diluted with a suitable diluent (sodium chloride is recommended for most drugs) and given over 12–24 hours (Dickman et al. 2007). The use of a combination of drugs can be problematic; there is anecdotal evidence regarding combinations of drugs but not many pharmaceutical studies confirming compatibility. Combinations of up to four drugs have been reported but if compatibility is uncertain, it may be best to use a second syringe pump. It is also important to ensure that the diluent used is compatible with all the drugs in the infusion. It is recommended that infusions are not exposed to direct sunlight or to increased temperatures as drug instability may result (Dickman et al. 2007). Hyaluronidase may be used to enhance the pharmacokinetics of drugs such as subcutaneous morphine (Menahem and Shvartzman 2010, Thomas et al. 2009).

Pre-procedural considerations

734 Equipment

Access devices

Research has shown that the use of peripheral cannulas rather than steel winged infusion devices results in sites remaining viable for longer (Torre 2002). Incidence of needlestick injuries may also be reduced (Dawkins et al. 2000). It is now recommended that subcutaneous infusion be given via a plastic cannula. Administration of infusions of drugs or fluids requires the insertion of a 25 G winged infusion set or a 24 G cannula (RCN 2010, Scales 2011). These should be inserted at an angle of 45° and secured with a transparent dressing to enable inspection of the site. This may also be appropriate for patients not receiving a continuous infusion but requiring frequent subcutaneous injections; this is common practice in palliative care in order to reduce the number of needles inserted into the patient and the subsequent trauma caused.

Syringe driver/pump

A syringe driver/pump is a portable battery-operated infusion device. It is used to deliver drugs at a predetermined rate via the appropriate parenteral route (e.g. subcutaneous) and is suitable for symptom management and palliative care (Dickman et al. 2007, Quinn 2008). It should be used for patients who are unable to tolerate oral medication, for example, in nausea and vomiting, dysphagia, intestinal obstruction, local disease or sometimes in intractable pain which is unrelieved by oral medications and where rapid dose titration is required. Drugs administered by subcutaneous infusion include opioid analgesics, antiemetics, anxiolytic sedatives, corticosteroids, non-steroidal anti-inflammatory drugs and anticholinergic drugs (Dickman et al. 2007, Dychter et al. 2012).

Examples include the Graseby MS16A (calibrated in millimetres per hour) and MS26 (calibrated in millimetres per day) syringe drivers (currently being phased out of use) and the McKinley T34 syringe pump (mL/h). Other types are available and nurses should follow the manufacturer's instruction manual for details of their use.

Most sizes and brands of plastic syringes can be used with these devices; however, it is recommended to use Luer-Lok syringes to avoid leakage or accidental disconnection.

The advantages of the syringe driver are as follows.

- It avoids the necessity of intermittent injections.
- Mixtures of drugs may be administered.
- Infusion timing is accurate, which is particularly advantageous in the community where it is not possible to constantly monitor the rate.
- The device is lightweight and compact, allowing mobility and independence.
- Rate can be increased.
- Simple calculations of dosage are required over a 12- or 24-hour period.
- It allows patients to spend more time at home with their symptoms managed effectively.

The disadvantages are as follows.

- The patient may become psychologically dependent on the device.
- Inflammation or infection may occur at the insertion site of the subcutaneous cannula.
- The rate calculation differs between certain syringe drivers which can be confusing for the nurse.
- The alarm system of some devices operates only if the plunger is obstructed. It does not alert the nurse if the flow is too rapid or too slow (Dickman et al. 2007).

Specific patient preparation

Infusion sites

Choice of site should be based on both thickness of subcutaneous tissue and patient convenience. Sites recommended for subcutaneous infusion of drugs or fluids are the lateral aspects of the upper arms and thighs, the abdomen, the chest and the scapula (Walsh 2005). If the patient is ambulant then the chest or abdomen is the preferred site (Dickman et al. 2007). The following areas should not be used.

- Lymphoedematous areas, as absorption may be impaired and infection may be introduced.
- Sites over bony prominences, as there may be insufficient subcutaneous tissue.
- Previously irradiated skin areas, as absorption may be impaired.
- Sites near a joint, as movement may cause the cannula to become dislodged.
- Any areas of inflamed, infected or broken skin (Mitten 2001, Ostendorf 2012).

Rotation of the site every 3 days should be routine in order to minimize site reactions although in some patients this may not be feasible so the infusion site must be monitored regularly and the device resited as necessary (Dickman et al. 2007).

Procedure guideline 12.19 Medication: subcutaneous infusion of fluids

Essential equipment

- Clinically clean receiver or tray
- Sharps box
- Isopropyl alcohol 70% swab
- Transparent adhesive dressing
- Winged infusion set or 24 G cannula
- Infusion fluid
- Administration set
- Apron
- Non-sterile gloves

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
2 Before administering any prescribed fluid, check that it is due and has not already been given.	To protect the patient from harm (NPSA 2007d, C).
3 Before administering any prescribed fluid, look at the patient's prescription chart and check the following. (a) The correct patient (b) Drug/fluid (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the correct patient is given the correct fluid in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E
4 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the necessary equipment.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).

Procedure

5 Check the name and volume of infusion fluid against the prescription chart.	To ensure that the correct type and quantity of fluid are administered (NMC 2010a, C ; NPSA 2007d, C).
6 Check the expiry date of the infusion bag.	To prevent an ineffective or toxic compound being administered to the patient (NPSA 2007d, C).
7 Check that the packaging is intact and inspect the container and contents in a good light for cracks, punctures or air bubbles.	To check that no contamination of the infusion container has occurred (NPSA 2007d, C).
8 Inspect the fluid for discoloration, haziness and crystalline or particulate matter. If this occurs, discard.	To prevent any toxic or foreign matter being infused into the patient (NPSA 2007d, C). To detect any incompatibility or degradation (NPSA 2007d, C).
9 Establish the correct drip rate setting using the correct calculation.	To monitor rate and ensure fluid is infused safely (Pickstone 1999, E).
10 Place the infusion bag and administration set in a clean receptacle. Wash hands and proceed to the patient.	To minimize the risk of contamination (Loveday et al. 2014, C).
11 Check the identity of the patient against the prescription chart, and with the patient.	To minimize the risk of error and ensure the correct fluid is administered to the correct patient (NMC 2010a, C ; NPSA 2007d, C).
12 Place the infusion bag on a flat surface, remove the seal and insert the spike of the administration set fully into the infusion bag port.	To prevent puncturing the side of the infusion and to reduce the risk of contamination (DH 2007, C).
13 Hang the infusion bag from a drip stand.	To allow gravity flow. E
14 Open the roller clamp and allow the fluid through the set to prime it. Close clamp.	To remove air from the set. E
15 Apply apron and assist the patient into a comfortable position.	To ensure patient comfort during the procedure. E
16 Expose the chosen site for infusion.	To expose the area. E
17 Apply gloves and clean the chosen site with a swab saturated with 70% isopropyl alcohol. Wait until the alcohol evaporates.	To reduce the risk of infection and prevent stinging sensation on insertion of needle (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
18 Grasp the skin firmly.	To elevate the subcutaneous tissue. E

(continued)

Procedure guideline 12.19 Medication: subcutaneous infusion of fluids (*continued*)

Action	Rationale
19 Insert the infusion needle into the skin at an angle of 45°, bevel up, and release the grasped skin. (If using a cannula, remove the stylet.)	To gain access to the subcutaneous tissue (Walsh 2005, E).
20 Connect the administration set to the device.	To commence the infusion. E
21 Apply transparent dressing to secure infusion device.	To prevent movement and reduce the risk of mechanical phlebitis and infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C ; Weinstein and Plumer 2007, E).
22 Open the roller clamp and adjust until the flow rate is achieved. The rate is usually 1 mL/min per site by gravity.	To ensure the correct rate is set. E

Post-procedure

23 Complete the patient's prescription chart and other hospital and/or legally required documents.	To comply with local drug administration policies and provide a record in the event of any queries (NMC 2010b, C). To prevent any duplication of treatment (NMC 2010a, C).
24 Monitor the patient for any infusion- or site-related complications and document these in the patient's notes.	To detect complications promptly (Sasson and Shvartzman 2001, E).
25 Ask the patient to report any pain or tenderness at the infusion site.	To ascertain whether there are any problems that may require nursing care and refer to medical staff where appropriate. E .
26 Discard waste, making sure that it is placed in the correct containers, for example sharps into a designated receptacle.	To ensure safe disposal and avoid injury to staff. To prevent reuse of equipment (DH 2005, C ; MHRA 2004, C).

Procedure guideline 12.20 Medication: subcutaneous administration using a McKinley T34 syringe pump**Essential equipment**

- Clinically clean receiver or tray containing the prepared drug
- Syringe pump
- Battery (PP3 size, 9 volt alkaline)
- Plastic peripheral cannulas (e.g. 24 G) and microbore extension set (100 cm) with needle-free Y connector injection site (or 100 cm winged infusion set)
- Luer-Lok syringe of suitable size (minimum size 20 mL)
- Swab saturated with isopropyl alcohol 70%
- Transparent adhesive dressing
- Drugs and diluent
- Needle (to draw up drug)
- Drug additive label
- Patient's prescription chart
- Recording chart or book as required by law or hospital policy
- Sharps box
- Apron
- Non-sterile gloves

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
2 Before administering any prescribed drug, check that it is due and has not already been given.	To protect the patient from harm (NPSA 2007d, C).
3 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration 	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C).

<ul style="list-style-type: none"> (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p>	To prevent any errors occurring. E
4 Calculate and check dosage of drugs required over a 24-hour period.	To establish correct dosages of drugs (Pickstone 1999, E).
5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the necessary equipment.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
Procedure	
6 Check the name, strength and volume of subcutaneous drug(s) against the prescription chart.	To ensure that the correct type and quantity of fluid are administered (NMC 2010a, C ; NPSA 2007d, C).
7 Check the expiry date of the drug(s).	To prevent an ineffective or toxic compound being administered to the patient (NPSA 2007d, C).
8 Check that the packaging is intact and inspect the container and contents in a good light for cracks, punctures, air bubbles.	To check that no contamination of the infusion container has occurred (NPSA 2007d, C).
9 Check the identity and amount of drug to be prepared. Consider: <ul style="list-style-type: none"> (a) compatibility of drugs (b) stability of mixture over the prescription time (c) any special directions for dilution, for example pH, optimum concentration (d) sensitivity to external factors such as light (e) any anticipated allergic reaction. <p>If any doubts exist about the listed points, consult the pharmacist or appropriate reference works.</p>	To minimize any risk of error. To ensure safe and effective administration of the drug (NPSA 2007d, C). To enable anticipation of toxicities and the nursing implications of these (NPSA 2007d, C).
10 Prepare medication as described in Procedure guidelines 12.12, 12.13, 12.14, 12.15. Using a Luer-Lok syringe, draw up drugs required with diluent to measure a total volume (this will depend on type of syringe pump used). See Box 12.18 for McKinley T34 recommended volumes and Action figure 10 for a McKinley T34 syringe pump.	To ensure accuracy and avoid any infusion errors. To ensure the drug is prepared correctly (NPSA 2007d, C).
11 Inspect the fluid for discoloration, haziness and crystalline or particulate matter. If this occurs, discard and re-evaluate drug compatibility. <i>Note:</i> This can occur even if the mixture is theoretically compatible, thus making vigilance essential.	To prevent any toxic or foreign matter being infused into the patient (NPSA 2007d, C). To detect any incompatibility or degradation (NPSA 2007d, C).
12 Establish the correct rate setting of the pump using the correct calculation.	To monitor rate and ensure drug is infused safely (Dickman et al. 2007, E ; Pickstone 1999, E).
13 Complete the drug additive label and fix it onto the syringe without obscuring the markings.	To identify which drug has been added, when and by whom and be able to visually inspect the amount in the syringe (NPSA 2007d, C).
14 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
15 Connect prepared syringe to a 100 cm microbore driver set with needle-free Y connector injection site.	This length of tubing allows patient greater freedom of movement. E
16 Prime the infusion by gently depressing the plunger of the syringe until the fluid is visible at the end of the infusion set. Priming the infusion set after calculation will reduce the delivery time by approximately half an hour for the first infusion. Do not alter previously calculated rate setting despite volume reduction in barrel of syringe.	This removes extraneous air from the system. E Ensures patient receives drugs immediately and accurately. E

(continued)

Procedure guideline 12.20 Medication: subcutaneous administration using a McKinley T34 syringe pump (continued)

Action	Rationale
17 Place the syringe and infusion set in a clean receptacle. Wash hands and proceed to the patient.	To minimize the risk of contamination (Loveday et al. 2014, C).
18 Check the identity of the patient against the prescription chart, syringe drug additive label and with the patient if possible.	To minimize the risk of error and ensure the correct drug is administered to the correct patient (NMC 2010a, C ; NPSA 2007d, C).
19 Apply apron and assist the patient into a comfortable position.	To aid patient comfort. E
20 Expose the chosen site for infusion.	To gain access to the site. E
21 Apply gloves and clean the chosen site with a swab saturated with 70% isopropyl alcohol. Wait until the alcohol evaporates.	To reduce the risk of infection and prevent stinging sensation on insertion of needle (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
22 Grasp the skin firmly.	To elevate the subcutaneous tissue. E
23 Insert the infusion needle into the skin at an angle of 45° and release the grasped skin. (If using a cannula, remove the stylet and connect the extension set.)	Positioning shallower than 45° may shorten the life of the infusion site. E
24 Apply transparent dressing to secure infusion device.	To prevent movement and reduce the risk of mechanical phlebitis and infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C ; Weinstein and Plumer 2007, E).
25 Check that the infusion set and syringe are securely connected.	To ensure that there is no disconnection so that the drug(s) are administered correctly. E
26 Connect the syringe to the syringe pump.	To ensure the syringe is connected correctly to the syringe pump. E
27 Press the >Back key to adjust the actuator to accommodate the syringe. Lift the barrel arm and ensure the syringe is loaded correctly. If not loaded into the barrel, collar and plunger correctly, this will be identified on the LED screen.	To ensure the syringe is in the correct position (manufacturer's instructions, C).
28 The pump will detect size and brand of syringe. Check and confirm by pressing YES key.	To enable the pump mechanism to operate correctly (manufacturer's instructions, C).
29 Set a new programme for each syringe.	To clear previous programme and reduce risk of error (manufacturer's instructions, C).
30 Pump measures deliverable volume in syringe.	To check the volume is as required. E
31 Press YES to confirm volume to be infused. Press YES to confirm infusion duration. Pump displays rate calculated on volume and duration set by user. Then press YES to confirm.	To complete set-up of device (manufacturer's instructions, C).
32 Secure in the clear Perspex lock box (for syringes 30 mL or larger only).	To ensure extra security and minimize the risk of errors in infusional rates. E
Post-procedure	
33 Discard waste, making sure that it is placed in the correct containers, for example sharps into a designated receptacle.	To ensure safe disposal and avoid injury to staff. To prevent reuse of equipment (DH 2005, C ; MHRA 2004, C).
34 Complete the patient's prescription chart and other hospital and/or legally required documents. This should include infusion device serial number and infusion device and site checks.	To comply with local drug administration policies and ensure the safe administration and monitoring of the infused drug and accurate records. To provide a record in the event of any queries (NMC 2010b, C). To prevent any duplication of treatment (NMC 2010a, C).
35 Monitor the patient for any infusion-related complications.	To detect complications promptly (Dickman et al. 2007, E ; Dougherty 2002, E ; MHRA 2010b, C ; Pickstone 1999, E ; Quinn 2000, E).
36 Ask the patient to report any pain and tenderness at the infusion site and if they experience any change in their symptoms or have new symptoms.	To ascertain whether there are any problems that may require nursing care and refer to medical staff where appropriate. E

Action Figure 10 McKinley T34 syringe pump.

Problem-solving table 12.2 Prevention and resolution (Procedure guideline 12.20)

Problem	Cause	Prevention	Action
Precipitation or cloudiness in the syringe.	Indicates incompatibility.	Check compatibility prior to mixing. Use http://book.pallcare.info for up-to-date advice.	Remove syringe, dispose of contents and prepare a new syringe.

739

Post-procedural considerations

Ongoing care

Accurate documentation of the site, rate, flow, start time and drugs used is imperative in order to avoid confusion and errors amongst staff (Dickman et al. 2007, Dougherty 2002, MHRA 2010b, NMC 2010a, NMC 2010b, Quinn 2000, Sasson and Shvartzman 2001). Sites and tubing will need to be changed every 1–4 days.

The frequency of checks should be as follows.

- At start of infusion – record date, time, start volume, infusion rate setting, name of person setting up infusion.
- Based upon the type of infusion and patient's condition; however, at a minimum these should be carried out 15 minutes and 1 hour after the initial set-up and thereafter a minimum of every 4 hours.
- Device must be checked at the start of each shift and/or when setting up an infusion.

Infusion device and infusion checks

- Check and record the date, time, rate and volume remaining and that the battery/syringe pump is working.
- Record any reasons for changing of the drug, dose, rate setting of syringe pump or site.
- Check subcutaneous site for:
 - pain/discomfort
 - swelling/induration
 - erythema
 - leakage of fluid
 - bleeding.

Box 12.18 Volumes for syringe pumps

- 10 mL syringe must be drawn up to 10 mL (approx. rate = 0.42 mL per 24 hours)
- 20 mL syringe must be drawn up to 17 mL (approx. rate = 0.71 mL per 24 hours)
- 30 mL syringe must be drawn up to 22 mL (approx. rate = 0.92 mL per 24 hours)
- 60 mL syringe must be drawn up to 32 mL (approx. rate = 1.33 mL per 24 hours)

Complications

Skin reactions

Some drugs are particularly likely to cause irritation and may need to be diluted in a greater volume of diluent; cyclizine and levomepromazine are amongst these. This may result in skin sites that break down rapidly or site reactions. The following methods can help to prevent this.

- Check compatibility of drugs and diluents and consider changing the drug combination.
- Dilute the solution as much as possible or change the diluent.
- Rotate the site at least every 72 hours.
- Use of a non-metal cannula.
- Use a different site cleanser.
- Change the dressing used.
- Consider adding dexamethasone 1 mg to the pump; this may be helpful but is not currently recommended for routine use. Care should also be taken as dexamethasone is incompatible with a number of drug combinations (Dickman et al. 2007).

Intramuscular injections

Definition

An intramuscular injection deposits medication into deep muscle tissue under the subcutaneous tissue (Chernecky et al. 2002). The vascularity of muscle aids the rapid absorption of medication (Ostendorf 2012).

Evidence-based approaches

Site and volume of injection

Selecting the site requires correct identification of the muscle groups by using landmarks to identify the correct anatomical features (Hunter 2008). Choice will be influenced by the patient's physical condition and age. Intramuscular injections should be given into the densest part of the muscle (Pope 2002). An active patient will probably have a greater muscle mass than older or emaciated patients (Hunter 2008).

The injectable volume will depend on the muscle bed. In children, injectable volumes should be halved because muscle mass is less (Workman 1999). However, it appears that it is the medicine rather than just the volume that affects how a patient tolerates the injection. Malkin (2008) uses Botox injections as an

example where a volume of 1–3 mL can be injected into facial muscle groups, supporting the view that tolerance of the drug is more important than the volume.

Current research evidence suggests that there are five sites that can be utilized for the administration of intramuscular injections (Rodger and King 2000, Tortora and Derrickson 2011).

- The *ventrogluteal site* (Figure 12.28a) is relatively free of major nerves and blood vessels and the muscle is large and well defined, making it easy to locate (Greenway 2004). It is located by placing the palm of the hand on the patient's opposite greater trochanter (right hand on left hip). The index finger is then extended to the anterior superior iliac spine to make a V. Injection in the centre of the V will ensure the injection is given into the gluteus medius muscle (Hunter 2008). This is the site of choice for intramuscular injections (Rodger and King 2000) and used for antibiotics, antiemetics, deep intramuscular and Z-track injections in oil, narcotics and sedatives. Up to 2.5 mL can be safely injected into the ventrogluteal site (Rodger and King 2000).
- The *deltoid site* (Figure 12.28b) has the advantage of being easily accessible whether the patient is standing, sitting or lying down. It is found by visualizing a triangle where the horizontal line is located 2.5–5 cm below the acromial process and mid-point of the lateral aspect of the arm, in line with the axilla to form the apex (Hunter 2008). The injection is then given 2.5 cm

down from the acromial process, avoiding the radial and brachial nerves. Owing to the small area of this site, the number and volume of injections which can be given into it are limited. Drugs such as narcotics, sedatives and vaccines, which are usually small in volume, tend to be administered into the deltoid site (Workman 1999). Rodger and King (2000) state that the maximum volume that should be administered at this site is 1 mL.

- The *dorsogluteal site* (Figure 12.28c) or upper outer quadrant is the traditional site of choice and is used for deep intramuscular and Z-track injections. It is located by using imaginary lines to divide the buttocks into four quarters. However, this site carries the danger of the needle hitting the sciatic nerve and the superior gluteal arteries (Workman 1999). The gluteus muscle has the lowest drug absorption rate and this can result in a build-up in the tissues, increasing the risk of overdose (Malkin 2008). The muscle mass is also likely to have atrophied in elderly, non-ambulant and emaciated patients. Finally, it appears that there is a risk that the medication will not reach the muscle due to the amount of subcutaneous tissue in this area (Greenway 2004) and so it is not recommended for routine immunizations due to the poor absorption and risk of nerve injury (Public Health England 2006, WHO 2004). In adults, up to 4 mL can be safely injected into this site (Rodger and King 2000).
- The *rectus femoris site* (Figure 12.28d) is a well-defined muscle found by measuring a hand's breadth from the greater

trochanter and the knee joint, which identifies the middle third of the quadriceps muscle (Hunter 2008). It is used for antiemetics, narcotics, sedatives, injections in oil, deep intramuscular and Z-track injections. It is rarely used by nurses, but is easily accessed for self-administration of injections or for infants (Workman 1999). 1–5 mL can be injected (1–3 mL in children).

- The *vastus lateralis* site (Figure 12.28d) is used for deep intramuscular and Z-track injections. One of the advantages of this site is its ease of access and, more importantly, there are no major blood vessels or significant nerve structures associated with this site. It is the better option in the obese patient (Nisbet 2006). Up to 5 mL can be safely injected (Rodger and King 2000).

There is debate over which site to use. The two recommended are the vastus lateralis and the ventrogluteal, but most nurses tend to use the dorsogluteal as it is more familiar (Greenway 2004).

Rate of administration

It is recommended that the plunger is depressed at a rate of 10 seconds per millilitre.

Technique

The syringe should be held like a pen to insert with a dart-like motion. Aspiration is still an accepted part of an IM injection to ensure that the medication does not enter the capillaries or is inadvertently given intravenously (Hunter 2008), but there is no evidence to support this. The Z-track method reduces the leakage of medication through the subcutaneous tissue and decreases skin lesions at the injection site and may hurt less.

It involves pulling the skin downwards or laterally of the injection site and inserting the needle at a 90° angle to the skin, which moves the cutaneous and subcutaneous tissues by approximately 2–3 cm (Antipuesto 2010, Take 5 2006). The injection is given and the needle withdrawn, while releasing the retracted skin at the same time. This manoeuvre seals off the puncture track.

Pre-procedural considerations

Equipment

The most common size of needle is 21 G (23 G may also be used in a thin patient) but it does depend on the viscosity of the medication. The important aspect of the needle is the length. The correct use of needle length will result in fewer adverse events and reduce complications of abscess, pain and bruising (Malkin 2008). Needles should be long enough to penetrate the muscle and still allow a quarter of the needle to remain external to the skin (Workman 1999). Lenz (1983) states that when choosing the correct needle length for intramuscular injections, it is important to assess the muscle mass of the injection site, the amount of subcutaneous fat and the weight of the patient. It may be necessary to calibrate the

BMI to calculate body fat (Public Health England 2006). Without such an assessment, most injections intended for gluteal muscle are deposited in the gluteal fat. The following are suggested as ways of determining the most suitable size of needle to use.

Deltoid and vastus lateralis muscles

The muscle to be used should be grasped between the thumb and forefinger to determine the depth of the muscle mass or the amount of subcutaneous fat at the injection site.

Gluteal muscles

The layer of fat and skin above the muscle should be gently lifted with the thumb and forefinger for the same reasons as before.

The patient's weight indicates the length of needle to use.

- | | |
|----------------|--------------|
| • Children | 16 mm needle |
| • 31.5–40.0 kg | 25 mm needle |
| • 40.5–90.0 kg | 25 mm needle |
| • 90 kg | 38 mm needle |

Remember women have more subcutaneous tissue than men so a longer needle will be needed (Pope 2002).

Specific patient preparation

Skin preparation

There are differences in opinion regarding skin cleaning prior to subcutaneous or intramuscular injections. Previous studies have suggested that cleaning with an alcohol swab is not always necessary, as not cleaning the site does not result in infections and may predispose the skin to hardening (Dann 1969, Koivistov and Felig 1978, Workman 1999).

Dann (1969), in a study over a period of 6 years involving more than 5000 injections, found no single case of local and/or systemic infection. Koivistov and Felig (1978) concluded that whilst skin preparations did reduce skin bacterial count, they are not necessary to prevent infections at the injection site. Some hospitals accept that if the patient is physically clean and the nurse maintains a high standard of hand hygiene and asepsis during the procedure, skin disinfection is not necessary (Workman 1999).

In the immunosuppressed patient, the skin should be cleaned as such patients may become infected by inoculation of a relatively small number of pathogens (Downie et al. 2003). The practice at the Royal Marsden Hospital is to clean the skin prior to injection in order to reduce the risk of contamination from the patient's skin flora. The skin is cleaned using an 'alcohol swab' (containing 70% isopropyl alcohol) for 30 seconds and then allowed to dry. If the skin is not dry before proceeding, skin cleaning is ineffective and the antiseptic may cause irritation by being injected into the tissues (Downie et al. 2003).

Procedure guideline 12.21 Medication: intramuscular injection

Essential equipment

- 70% Alcohol swab
- Needle
- Syringe containing prepared IM medication
- Clinically clean receiver or tray containing prepared drug
- Apron
- Non-sterile gloves

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, **E**; NMC 2013, **C**; NMC 2015, **C**).

(continued)

Procedure guideline 12.21 Medication: intramuscular injection (continued)

Action	Rationale
<p>2 Before administering any prescribed drug, look at the patient's prescription chart and check the following.</p> <ul style="list-style-type: none"> (a) The correct patient (b) Drug (c) Dose (d) Date and time of administration (e) Route and method of administration (f) Diluent as appropriate (g) Validity of prescription (h) Signature of prescriber (i) The prescription is legible <p>If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.</p> <p>Prepare medication as described in Procedure guidelines 12.12, 12.13, 12.14 and 12.15.</p>	<p>To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C; NMC 2010a, C). To protect the patient from harm (DH 2003b, C; NMC 2010a, C).</p> <p>To prevent any errors occurring. E</p>
Procedure	
3 Apply apron, close the curtains or door and assist the patient into the required position. Wash hands.	<p>To ensure patient privacy and dignity. E</p> <p>To allow access to the injection site and to ensure the designated muscle group is flexed and therefore relaxed (Workman 1999, E).</p>
4 Remove the appropriate garment to expose the injection site.	To gain access for injection (Workman 1999, E).
5 Apply gloves and assess the injection site for signs of inflammation, oedema, infection and skin lesions.	<p>To promote effectiveness of administration (Workman 1999, E). To reduce the risk of infection (Fraise and Bradley 2009, E; Workman 1999, E).</p> <p>To avoid skin lesions and avoid possible trauma to the patient (Ostendorf 2012, E; Workman 1999, E).</p>
6 Clean the injection site with a swab saturated with isopropyl alcohol 70% for 30 seconds and allow to dry for 30 seconds (Workman 1999).	To reduce the number of pathogens introduced into the skin by the needle at the time of insertion and to prevent stinging sensation if alcohol is taken into the tissues upon needle entry (Antipuesto 2010, E ; Hunter 2008, E). (For further information on this action see 'Skin preparation'.)
7 With the non-dominant hand, stretch the skin slightly around the injection site.	To displace the underlying subcutaneous tissues, facilitate the insertion of the needle and reduce the sensitivity of nerve endings (Antipuesto 2010, E ; Hunter 2008, E).
8 Holding the syringe in the dominant hand like a dart, inform the patient and quickly plunge the needle at an angle of 90° into the skin until about 1 cm of the needle is left showing.	To ensure that the needle penetrates the muscle (Hunter 2008, E ; Workman 1999, E).
9 Pull back the plunger. If no blood is aspirated, depress the plunger at approximately 1 mL every 10 seconds and inject the drug slowly. If blood appears, withdraw the needle completely, replace it and begin again. Explain to the patient what has occurred.	<p>To confirm that the needle is in the correct position and not in a vein (Antipuesto 2010, E). This allows time for the muscle fibres to expand and absorb the solution (Hunter 2008, E; Workman 1999, E).</p> <p>To prevent pain and ensure even distribution of the drug (Ostendorf 2012, E).</p>
10 Wait 10 seconds before withdrawing the needle.	To allow the medication to diffuse into the tissue (Ostendorf 2012, E ; Workman 1999, E).
11 Withdraw the needle rapidly. Apply gentle pressure to any bleeding point but do not massage the site.	To ensure that the injected medication is not forced out of the tissues (Antipuesto 2010, E).
12 Apply a small plaster over the puncture site.	To prevent tissue injury and haematoma formation (Ostendorf 2012, E).
Post-procedure	
13 Where appropriate, activate safety device. Ensure that all sharps and non-sharp waste are disposed of safely and in accordance with locally approved procedures, for example put sharps into sharps bin and syringes into orange clinical waste bag.	To ensure safe disposal and to avoid laceration or other injury to staff (DH 2005, C ; EU 2010, C ; MHRA 2004, C).
14 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C ; NPSA 2007d, C).

Intraosseous administration

Definition

Intraosseous administration of medications generally involves delivery via the medullary cavity of a long bone and has been used for decades (Vizcarra and Clum 2010).

Related theory

This route is used for emergency or short-term treatment when access by the vascular route is difficult or cannot be achieved and the patient's condition is considered life threatening (Resuscitation Council 2010) as it provides rapid systemic action of medications and fluids, but it is more rapidly and easily achieved than other forms of central venous access. Unlike the peripheral vessels, the medullary cavity does not collapse in the presence of hypovolaemia or circulatory failure. It acts like a rigid vein, making it an ideal site in a situation where circulatory access is urgently required (e.g. clinical shock or cardiac arrest). The onset of action of medications administered via the intraosseous (IO) route is almost as rapid as conventional central venous delivery and considerably quicker than those given by the peripheral vessel. Medications can be delivered as a bolus injection or continuous infusion. The IO route can also be used to obtain bone marrow samples for some emergency testing (e.g. cross-match).

The preferred sites are the proximal or distal tibia or the proximal humerus (Resuscitation Council 2010). Any drug administered intravenously can be administered via the intraosseous route. Common indications for use of the IO device are cardiac arrest, circulatory collapse, hypovolaemic shock, respiratory arrest, major trauma and emergency clinical situations (all advocated after two attempts at IV access or after 2 minutes of trying). However, this list is not exhaustive and administration may be based on the clinical judgement of the competent practitioner (Vizcarra and Clum 2010).

Contraindications include (Resuscitation Council 2010, Vizcarra and Clum 2010):

- suspected fracture of the tibia, femur or humeral head
- known previous orthopaedic procedure on the selected limb
- an extremity that is significantly compromised due to a pre-existing medical condition
- inability to locate anatomical landmarks
- previous IO in the same site within the last 48 hours
- local infection in the proposed insertion site
- prosthesis
- known thrombocytopenia (ideally platelets >50, but in an emergency IO access may be required irrespective of the platelet count).

Table 12.11 Intraosseous needle selection

Needle size	Patient weight
15 mm	3–39 kg
25 mm	≥40 kg
45 mm	≥40 kg and excessive tissue, e.g. bariatric

Medications that can be infused via the IO route include adrenaline, amiodarone, calcium chloride, sodium bicarbonate and magnesium (Resuscitation Council 2010). Fluids and blood products can also be given via the IO route but need the application of pressure to achieve reasonable flow rates, ideally using a pressure bag.

Pre-procedural considerations

Equipment

There are three types of device.

- *Manual* (hollow needle with removable trocar) which is manually inserted into the medullary space using pressure and twisting of the device.
- *Impact driven* (spring-loaded device with hollow needle and removable trocar); spring-loaded device triggers penetration into the sternum or the medullary space of the tibia.
- *Powered drill* (battery-operated drill with a hollow needle and removable stylet); the device drills the needle to the appropriate depth in the intraosseous space (Vizcarra and Clum 2010).

Vizcarra and Clum (2010) report success rates of 55–93% for sternal access (although rates increase with experience) whereas the drill device has success rates of 97%.

Intraosseous needles are available in three sizes. The size of the needle is dependent on the weight of the patient and clinical judgement (see Table 12.11).

Specific patient preparation

As this method of administration is often used in an emergency, there may not be time to prepare the patient. However, the clinician inserting the IO device must select the most appropriate site and it is suggested that the proximal tibia is the preferred insertion site.

Legal and professional issues

Any attempt at IO access is undertaken by a clinical practitioner who has undergone education, training and assessment. This is usually carried out by the resuscitation officer.

Procedure guideline 12.22 Inserting an intraosseous needle

Essential equipment

- Intraosseous needle
- Power driver
- Connector
- Dressing pack
- Sterile gloves
- Needle

- Syringe (10 mL)

Medicinal products

- 0.9% sodium chloride
- Lidocaine 2%
- Chlorhexidine 2% in 70% alcohol sponge

Pre-procedure

Action

- 1 Approach the patient in a confident manner and explain the procedure to the patient/family whilst gaining consent.
- 2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, apply an apron and assemble the necessary equipment.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**; NMC 2015, **C**). In a cardiac arrest, it may not be possible to gain consent. **E**

To minimize the risk of infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).

(continued)

Procedure guideline 12.22 Inserting an intraosseous needle (*continued*)

Action	Rationale
3 Assess the patient and the patient's limb to determine what size IO needle is required (Action figure 3).	To ensure that the correct needle is selected (Vizcarra and Clum 2010, E).
4 Obtain assistance as required.	To maintain safety. E
Procedure	
5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and apply gloves.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
6 Inspect needle set package to ensure sterility and then open the sterile pack and all packaging.	To ensure device is safe to use and reduce the risk of complications. E
7 Draw up a syringe of 0.9% sodium chloride (10 mL).	To prepare for priming. E
8 Connect the 10 mL syringe to the EZ-connect and prime with 0.9% sodium chloride. If lidocaine 2% is indicated, prime the set with the lidocaine.	To prepare for administration and remove air from the set. E
9 Leave the syringe connected to the EZ-connect.	To prepare for administration once sited. E
10 Connect the needle set to the driver, leaving the needle cap on until ready to insert.	To prepare for insertion. E
11 Palpate the site to locate the appropriate anatomical landmarks for the needle set placement (Action figure 11).	To ensure the IO is placed in the correct position for optimal drug administration and minimization of tissue damage (Vizcarra and Clum 2010, E).
12 Select the insertion site. For the proximal tibia it is approximately 2 cm below the patella and approximately 2 cm (depending on patient's anatomy) medial to the tibial tuberosity along the flat aspect of the tibia.	To ensure the optimal site for insertion. E
13 Wash hands and apply gloves.	To minimize the risk of infection (Fraise and Bradley 2009, E).
14 Clean the site using 2% chlorhexidine in 70% alcohol and allow the site to air dry (Action figure 14).	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
15 Stabilize the insertion site, keeping hand and fingers away from the needle.	To guard against unexpected patient movement and avoid a sharps injury. E
16 Remove the needle cap (Action figure 16).	To prepare for insertion. E
17 Identify the two (2) markings on the needle. The distal mark should be visible once the needle is inserted into the skin. The proximal mark is the maximum insertion point.	To ensure that the insertion landmarks are identified. E
18 Insert the EZ-IO needle through the skin at a 90° angle to the bone until bone is reached (Action figure 18). The distal mark on the needle should be visible. If not, consider using another size needle or site.	To ensure that the needle reaches the medullary space. E
19 Press the driver trigger whilst applying minimal pressure, driving through the bone until a give is heard or felt. Allow the driver to do the work.	To ensure that no excess pressure is applied and that the needle is inserted within the bone. E
20 Release the driver trigger when the proximal mark on the needle at the hub end is level with the skin.	To ensure that the needle reaches the medullary space. E
21 Remove the EZ-IO power driver from the needle set while stabilizing the needle hub.	To prepare for drug or fluid administration. E
22 Hold the base of the needle hub with one hand whilst turning the upper part of the needle counterclockwise.	To remove the stylet and prepare for fluid or drug administration. E
23 Remove the stylet from the needle (Action figure 23).	To prepare the needle for drug or fluid administration. E
24 Dispose of the stylet into a sharps container immediately.	To ensure safe disposal and avoid injury to staff (DH 2005, C ; HSE 2013, C ; MHRA 2004, C ; NHS Employers 2007, E).
25 Confirm placement by: (a) ensuring the catheter is firmly seated and does not move (b) blood at the catheter hub (c) aspiration of marrow from the catheter.	To ensure the needle is in the correct position. E
26 Apply the EZ-stabilizer dressing.	To secure the IO port and prevent dislodgement. E
27 Connect the primed EZ-connect with the exposed Luer-Lok hub and flush with the designated solution (Action figure 27).	To ensure patency of the EZ-IO. E

(continued)

Procedure guideline 12.22 Inserting an intraosseous needle (*continued*)

Action	Rationale
28 Disconnect the 10 mL syringe from the EZ-connect.	To prepare for drug and/or fluid administration. E
29 Connect primed IV administration set or administer bolus drugs.	To deliver the prescribed medication or fluids. E
Post-procedure	
30 Remove gloves and discard waste, placing it in the correct containers, for example sharps into a designated container.	To ensure safe disposal and avoid injury to staff (DH 2005, C ; MHRA 2004, C ; EU 2010, C).
31 Document time and date of insertion, size, length of needle, number of attempts, location of device, and name of practitioner who inserted device.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C). To ensure staff are aware of insertion date as an IO device should not remain in longer than 24 hours (NMC 2010a, C).
32 Assess the site for potential complications/extravasation.	To minimize the risk of complications and to treat promptly. E

746

Procedure guideline 12.23 Removing an intraosseous needle**Essential equipment**

- Dressing pack
- Sterile gloves
- Syringe (10 mL)
- Dressing

Pre-procedure

Action	Rationale
1 Approach the patient in a confident manner and explain the procedure to the patient/family whilst gaining consent.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C ; NMC 2015, C). In a cardiac arrest, it may not be possible to gain consent. E
2 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, apply an apron and gloves and assemble and open the necessary equipment.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E). To prepare the equipment for use. E
3 Remove the extension set from the needle hub.	To facilitate the removal of the needle. E
4 Carefully remove the EZ-stabilizer dressing.	To allow the safe removal of the needle. E
5 Attach a 10 mL sterile syringe with Luer-Lok fitting.	This will act as a handle and cap the open port. E
6 Grasp the syringe and continuously rotate clockwise while gently pulling the catheter out whilst maintaining a 90° angle to the bone. DO NOT ROCK OR BEND DURING REMOVAL.	This will enable the catheter to be removed easily without damaging the bone. E
7 Dispose of the IO catheter into a sharps container.	To ensure safe disposal and avoid injury to staff (DH 2005, C ; HSE 2013, C ; MHRA 2004, C ; NHS Employers 2007, C).
8 Apply pressure to the site with sterile gauze until bleeding has stopped.	To ensure bleeding has stopped. E
9 Apply an adhesive dressing.	To protect the puncture site from infection. E

Post-procedure

10 Dispose of waste in the correct containers.	To ensure safe disposal (DH 2005, C).
11 Document time and date of removal.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Post-procedural considerations

The manufacturer's recommended maximum length of time for all IO needles to stay *in situ* is 24 hours. It is good practice to document the time and location of insertion in the patient's medical and nursing notes (Resuscitation Council 2010).

Complications

Complications associated with the use of the IO device are rare but care must be taken during the insertion and use of the device. Possible complications include:

- infection
- extravasation
- embolism
- compartment syndrome
- fracture of the selected limb
- skin necrosis (Resuscitation Council 2010).

Intravenous injections and infusions

Definition

The introduction of medication or solutions into the circulatory system via a peripheral or central vein (Chernecky et al. 2002).

Anatomy and physiology

See Chapter 14: Vascular access devices: insertion and management for anatomy and physiology related to the venous system.

Related theory

Intravenous therapy is now an integral part of the majority of nurses' professional practice (RCN 2010). The nurse's role has progressed considerably from being able to add drugs to infusion bags (DHSS 1976) to now assessing patients and inserting the appropriate vascular access device (VAD) prior to drug administration (Gabriel 2005).

Any nurse administering intravenous drugs must be competent in all aspects of intravenous therapy and act in accordance with *The Code* (NMC 2015), that is, to maintain knowledge and skills (Hyde 2008, RCN 2010). Training and assessment should comprise both theoretical and practical components and include legal and professional issues, fluid balance, pharmacology, drug administration, local and systemic complications, infection control issues, use of equipment and risk management (Hyde 2008, RCN 2010).

The nurse's responsibilities in relation to intravenous drug administration include the following.

- Knowing the therapeutic use of the drug or solution, its normal dosage, side-effects, precautions and contraindications.
- Preparing the drug aseptically and safely, checking the container and drug for faults, using the correct diluent and only preparing it immediately prior to administration.
- Identifying the patient and checking allergy status.
- Checking the prescription chart.
- Checking and maintaining patency of the VAD.
- Inspecting the site of the VAD and managing/reporting complications where appropriate.
- Controlling the flow rate of infusion and/or speed of injection.
- Monitoring the condition of the patient and reporting changes.
- Making clear and immediate records of all drugs administered (Finlay 2008, NMC 2010a, NMC 2010b, RCN 2010).

Evidence-based approaches

Methods of administering intravenous drugs

There are three methods of administering intravenous drugs: continuous infusion, intermittent infusion and direct intermittent injection.

Continuous infusion

Continuous infusion may be defined as the intravenous delivery of a medication or fluid at a constant rate over a prescribed time period, ranging from several hours to several days to achieve a controlled therapeutic response (Turner and Hankins 2010). The greater dilution also helps to reduce venous irritation (Weinstein and Plumer 2007, Whittington 2008).

A continuous infusion may be used when:

- the drugs to be administered must be highly diluted
- maintenance of steady blood levels of the drug is required (Turner and Hankins 2010).

Pre-prepared infusion fluids with additives such as those containing potassium chloride should be used whenever possible. This reduces the risk of extrinsic contamination, which can occur during the mixing of drugs (Weinstein and Plumer 2007). Only one addition should be made to each bottle or bag of fluid after the compatibility has been ascertained. More additions can increase the risk of incompatibility occurring, for example precipitation (Weinstein and Plumer 2007, Whittington 2008). The additive and fluid must be mixed well to prevent a layering effect which can occur with some drugs (Whittington 2008). The danger is that a bolus injection of the drug may be delivered. To safeguard against this, any additions should be made to the infusion fluid and the container inverted a number of times to ensure mixing of the drug, before the fluid is hung on the infusion stand (NPSA 2007d). The infusion container should be labelled clearly after the addition has been made. Constant monitoring of the infusion fluid mixture (Weinstein and Plumer 2007, Whittington 2008) for cloudiness or presence of particles should occur, as well as checking the patient's condition and intravenous site for patency, extravasation or infiltration (Downie et al. 2003).

Intermittent infusion

Intermittent infusion is the administration of a small-volume infusion, that is, 25–250 mL, over a period of between 15 minutes and 2 hours (Turner and Hankins 2010). This may be given as a specific dose at one time or at repeated intervals during 24 hours (Pickstone 1999).

An intermittent infusion may be used when:

- a peak plasma level is required therapeutically
- the pharmacology of the drug dictates this specific dilution
- the drug will not remain stable for the time required to administer a more dilute volume
- the patient is on a restricted intake of fluids (Whittington 2008).

Delivery of the drug by intermittent infusion can be piggy-backed (via a needle-free injection port), if the primary infusion is of a compatible fluid; this may utilize a system such as a 'Y' set or a burette set with a chamber capacity of 100 or 150 mL (Turner and Hankins 2010). This is when the drug can be added to the burette and infused while the primary infusion is switched off. A small-volume infusion may also be connected to a cannula specifically to keep the vein open and maintain patency.

All the points considered when preparing for a continuous infusion should be taken into account here, for example pre-prepared fluids, single additions of drugs, adequate mixing, labelling and monitoring.

Direct intermittent injection

Direct intermittent injection (also known as intravenous push or bolus) involves the injection of a drug from a syringe into the injection port of the administration set or directly into a VAD (Chernecky et al. 2002, Turner and Hankins 2010). Most are administered over a time span anywhere from 3 to 10 minutes depending upon the drug (Weinstein and Plumer 2007, Whittington 2008).

A direct injection may be used when:

- a maximum concentration of the drug is required to vital organs. This is a 'bolus' injection which is given rapidly over seconds, as in an emergency, for example adrenaline
- the drug cannot be further diluted for pharmacological or therapeutic reasons or does not require dilution. This is given as a controlled 'push' injection over a few minutes
- a peak blood level is required and cannot be achieved by small-volume infusion (Turner and Hankins 2010).

Rapid administration could result in toxic levels and an anaphylactic-type reaction. Manufacturer's recommendations of rates of administration (i.e. millilitres or milligrams per minute) should be adhered to. In the absence of such recommendations, administration should proceed slowly, over 5–10 minutes (Dougherty 2002).

Delivery of the drug by direct injection may be via the cannula through a resealable needle-less injection cap, extension set or via the injection site of an administration set.

- If a peripheral device is *in situ*, the bandage and dressing must be removed to inspect the insertion of the cannula, unless a transparent dressing is in place (Finlay 2008).
- Patency of the vein must be confirmed prior to administration and the vein's ability to accept an extra flow of fluid or irritant chemical must also be checked (Dougherty 2008a).

Administration into the injection site of a fast-running drip may be advised if the infusion in progress is compatible in order to dilute the drug further and reduce local chemical irritation (Dougherty 2002). Alternatively, a stop-start procedure may be employed if there is doubt about venous patency. This allows the nurse to constantly check the patency of the vein and detect early signs of extravasation. If the infusion fluid is incompatible with the drug, the administration set may be switched off and a compatible solution may be used as a flush (NPSA 2007d).

If a number of drugs are being administered, 0.9% sodium chloride must be used to flush in between each drug to prevent interactions. In addition, 0.9% sodium chloride should be used at the end of the administration to ensure that all the drug has been delivered. The device should then be flushed to ensure patency is maintained (see Chapter 14: Vascular access devices: insertion and management) (Dougherty 2008a).

The following principles are to be applied throughout preparation and administration.

Asepsis and reducing the risk of infection

Microbes on the hands of healthcare personnel contribute to healthcare-associated infection (Weinstein and Plumer 2007). Therefore aseptic technique must be adhered to throughout all intravenous procedures (see Chapter 14: Vascular access devices: insertion and management). The nurse must employ good hand-washing and drying techniques using a bactericidal soap or bactericidal alcohol handrub. If asepsis is not maintained, local infection, septic phlebitis or septicaemia may result (Hart 2008, Loveday et al. 2014, RCN 2010).

The insertion site should be inspected at least once a day for complications such as infiltration, phlebitis or any indication of infection, for example redness at the insertion site or pyrexia (RCN 2010). These problems may necessitate the removal of the device and/or further investigation (Finlay 2008).

It is desirable that a closed system of infusion is maintained wherever possible, with as few connections as is necessary for its purpose (Finlay 2008, Hart 2008). This reduces the risk of bacterial contamination. Any extra connections within the administration system increase the risk of infection. Three-way taps have been shown to encourage the growth of micro-organisms. They are difficult to clean due to their design, as micro-organisms can become lodged and are then able to multiply in the warm, moist

environment (Finlay 2008, Hart 2008). This reservoir of micro-organisms may then be released into the circulation.

The injection sites on administration sets or injection caps should be cleaned using a 2% chlorhexidine alcohol-based antiseptic, allowing time for it to dry (Loveday et al. 2014). Connections should be cleaned before changing administration sets and manipulations kept to a minimum. Administration sets should be changed according to use (intermittent/continuous therapy), type of device and type of solution, and the set must be labelled with the date and time of change (NPSA 2007d, RCN 2010).

To ensure safe delivery of intravenous fluids and medication:

- replace all tubing when the vascular device is replaced (Loveday et al. 2014)
- replace solution administration sets and stopcocks used for continuous infusions every 96 hours unless clinically indicated, for example, if drug stability data indicate otherwise (Loveday et al. 2014, RCN 2010). A Cochrane review of 13 randomized controlled trials found no evidence that changing intravenous administration sets more often than every 96 hours reduces the incidence of bloodstream infection (Loveday et al. 2014)
- replace solution administration sets used for lipid emulsions and parenteral nutrition at the end of the infusion or within 24 hours of initiating the infusion (Loveday et al. 2014, RCN 2010)
- replace blood administration sets at least every 12 hours and after every second unit of blood (Loveday et al. 2014, McClelland 2007, RCN 2010)
- all solution sets used for intermittent infusions, for example antibiotics, should be discarded immediately after use and not allowed to hang for reuse (RCN 2010)
- if administering more than one infusion via a multilumen extension set or multiple ports, be aware of the risk of back-tracking of medication and consider using sets with one-way, non-return or antireflux valves (MHRA 2010a).

Inspection of fluids, drugs, equipment and their packaging must be undertaken to detect any points where contamination may have occurred during manufacture and/or transport. This intrinsic contamination may be detected as cloudiness, discoloration or the presence of particles (BNF 2014, RCN 2010, Weinstein and Plumer 2007). Infusion bags should not be left hanging for longer than 24 hours. In the case of blood and blood products, this is reduced to 5 hours (McClelland 2007, RCN 2010).

Safety

All details of the prescription and all calculations must be checked carefully in accordance with hospital policy in order to ensure safe preparation and administration of the drug(s).

The nurse must also check the compatibility of the drug with the diluent or infusion fluid. The nurse should be aware of the types of incompatibilities and the factors which could influence them. These include pH, concentration, time, temperature, light and the brand of the drug. If insufficient information is available, a reference book (e.g. *British National Formulary*) or the product data sheet must be consulted (NPSA 2007d, Whittington 2008). If the nurse is unsure about any aspect of the preparation and/or administration of a drug, they should not proceed and should consult with a senior member of staff (NMC 2010a). Constant monitoring of both the mixture and the patient is important. The preferred method and rate of intravenous administration must be determined.

Drugs should never be added to the following: blood; blood products, that is plasma or platelet concentrate (see Chapter 7: Nutrition, fluid balance and blood transfusion); mannitol solutions; sodium bicarbonate solution; and so on. Only specially prepared additives should be used with fat emulsions or amino acid preparations (Downie et al. 2003).

Accurate labelling of additives and records of administration are essential (NPSA 2007d, RCN 2010).

Any protective clothing which is advised should be worn, and vinyl gloves should be used to reduce the risk of latex allergy (Hart 2008). Healthcare professionals who use gloves frequently or for long periods face a high risk of allergy from latex products. All healthcare facilities should develop policies and procedures that determine measures to protect staff and patients from latex exposure and outline a treatment plan for latex reactions (RCN 2010).

Preventing needlestick injuries should be key in any health and safety programme and organizations should introduce safety devices and needle-free systems wherever possible (EU Directive 2010). Basic rules of safety include not resheathing needles, disposal of needles immediately after use into a recognized sharps bin and convenient location of sharps bins in all areas where needles and sharps are used (Hart 2008, MHRA 2004, RCN 2010).

Comfort

Both the physical and psychological comfort of the patient must be considered. Comprehensive explanation of the practical aspects of the procedure together with information about the effects of treatment will contribute to reducing anxiety and will need to be tailored to each patient's individual needs.

Legal and professional issues

At least one patient will experience a potentially serious intravenous (IV) drug error every day in an 'average' hospital. IV drug errors have been estimated to be a third of all drug errors. 'Fifteen million infusions are performed in the NHS every year and 700 unsafe incidents are reported each year with 19% attributed to user error' (NPSA 2004, p.1). Between 2005 and 2010, the MHRA investigated 1085 reports involving infusion pumps (MHRA 2011). In 69% of incidents no cause was established. However, of the remaining incidents, 21% were attributed to user error (e.g. misloading of the administration set or syringe, setting the wrong rate, confusing pump type) and 11% to device-related issues (e.g. poor maintenance, cleaning) (MHRA 2011). Syringe pumps have given rise to the most significant problems in terms of patient mortality and morbidity (Fox 2000, MHRA 2010b, NPSA 2003).

The high frequency of human error has highlighted the need for more formalized, validated, competency-based training and assessment (MHRA 2010b, NPSA 2003, 2004, Pickstone 2000, Quinn 2000). Nurses must be familiar with the device they are using and not attempt to operate any device that they have not been fully trained to use (MHRA 2011, Murray and Glenister 2001, NPSA 2003). As a minimum, the training should cover the device, drugs and solutions, and the practical procedures related to setting up the device and problem solving (MHRA 2010b, MHRA 2011, MHRA 2014). Staff should also be made aware of the mechanisms for reporting faults with devices and procedures for adverse incident reporting within their trust and to the MHRA (MHRA 2006b, MHRA 2011).

A useful checklist (Box 12.19) has been produced by the Medical Devices Agency for staff to follow prior to using a medical device to ensure safe practice (MHRA 2010b, MHRA 2014).

The nurse must have knowledge of the solutions, their effects, rate of administration, factors that affect flow of infusion, as well as the complications which could occur when flow is not controlled (Weinstein and Plumer 2007). The nurse should have an understanding of which groups require accurate flow control in order to prevent complications (Box 12.20) and how to select the most appropriate device for accuracy of delivery to best meet the patient's flow control needs (according to age, condition, setting and prescribed therapy) (Weinstein and Plumer 2007).

The identification of risks is crucial, for example complex calculations, prescription errors (Dougherty 2002, Weinstein and Plumer 2007) and the risks associated with infusions, such as neonatal risk infusions, high-risk infusions, low-risk infusions and ambulatory infusions (MHRA 2010b, Quinn 2000). The early detection of errors and infusion-related complications, for example over- and underinfusion (Box 12.21), is imperative in order to

Box 12.19 Checklist: how safe is your practice?

- Have I been trained in the use of the infusion device?
- Was the training formalized and recorded or did I just pick it up as I went along?
- How was my competency in relation to the infusion device assessed?
- Have I read the user instructions on how to use the infusion device and am I familiar with any warning labels?
- When was the infusion device last serviced?
- Are there any signs of wear, damage or faults?
- Do I know how to set up and use the infusion device?
- Is the infusion device and any additional equipment in good working order?
- Do I know how the infusion device should perform and the monitoring that needs to be done to check its performance?
- Am I using the correct additional equipment, for example the appropriate disposable administration set for the infusion pump?
- Do I know how to recognize whether the infusion device has failed?
- Do I know what to do if the infusion device fails?
- Do I know how and to whom to report an infusion device-related adverse incident?
- Does checking the infusion device indicate it is functioning correctly and to the manufacturer's specification?
- What action should be taken if the infusion device is not functioning properly?
- Is there up-to-date documentation to record regular checking of the infusion device?
- What are the details (name and serial number) of the infusion device being used?
- What is the cleaning and/or decontamination procedure for the infusion device and what are my responsibilities in this process?
- Do I know how to report an adverse incident?
- Do I have access to MHRA device bulletins of relevance to my area of practice and do I read and take note of hazard and safety notices?

instigate the appropriate interventions in response to an error or to manage any complications, as serious errors or complications can result in patient death (Dougherty 2002, NPSA 2003, Quinn 2008). Overinfusion accounts for about half of the reported errors involving infusion pumps, with 80% due to user error rather than a fault with the device (MHRA 2014). The use of infusion devices, both mechanical and electronic, has increased the level of safety

Box 12.20 Groups at risk of complications associated with flow control

- Infants and young children
- The elderly
- Patients with compromised cardiovascular status
- Patients with impairment or failure of organs, for example kidneys
- Patients with major sepsis
- Patients suffering from shock, whatever the cause
- Post-operative or post-trauma patients
- Stressed patients, whose endocrine homeostatic controls may be affected
- Patients receiving multiple medications, whose clinical status may change rapidly

Box 12.21 Complications of inadequate flow control**Complications associated with overinfusion**

- Fluid overload with accompanying electrolyte imbalance.
- Metabolic disturbances during parenteral nutrition, mainly related to serum glucose levels.
- Toxic concentrations of medications, which may result in a shock-like syndrome ('speed shock').
- Air embolism, due to containers running dry before expected.
- An increase in venous complications, for example chemical phlebitis, caused by reduced dilution of irritant substances (Weinstein and Plumer 2007).

Complications associated with underinfusion

- Dehydration.
- Metabolic disturbances.
- A delayed response to medications or below therapeutic dose.
- Occlusion of a cannula/catheter due to slow flow or cessation of flow.

in intravenous therapy. However, it is recommended that a clearly defined structure for management of infusion systems must exist within a hospital (Department of Health, Social Services and Public Safety 2006, MHRA 2010b, MHRA 2011, NHS Litigation Authority 2013, NPSA 2004) (Box 12.22).

Strategies need to be developed for replacement of old, obsolete or inappropriate devices (Department of Health, Social Services and Public Safety 2006, Health Care Standards Unit 2007a, Health Care Standards Unit 2007b, MHRA 2010b, NHS Litigation Authority 2013, Quinn 2000), planned service maintenance programmes and acceptance testing (MHRA 2010b, MHRA 2011).

Healthcare professionals are personally accountable for their use of infusion devices and they must therefore ensure they have appropriate training before using the pump (MHRA 2008a, MHRA 2011, Quinn 2008). Records of training must also be maintained.

Improving infusion device safety

A high frequency of human error is reported in the use of infusion device systems, so competence-based training is advocated for users of these systems (MHRA 2010b, NPSA 2004). By rationalizing the range of infusion device types within organizations and the establishment of a centralized equipment library, the number of patient safety incidents will be reduced (MHRA 2010b, NPSA

2004). Smart infusion pumps reduce pump programming errors by the setting of pre-programmed upper and lower dose limits for specific drugs. The pump will alert the nurse when setting the infusion device if the pump has been set outside the pre-set dose limits (Keohane et al. 2005, MRHA 2011, Weinstein and Plumer 2007, Wilson and Sullivan 2004). Whatever infusion device is used, the need to monitor the patient and the device remains paramount for patient safety (Quinn 2008, RCN 2010).

Pre-procedural considerations**Equipment****Vascular access devices**

For vascular access devices see Chapter 14: Vascular access devices: insertion and management.

Administration sets

An administration set is used to administer fluids, blood or medications via an infusion bag into a VAD. The set comprises a number of components (see Figure 12.29, Figure 12.30, Figure 12.31). At the top is a spike which is inserted into the infusion container via an entry port. This is covered by a sterile plastic lid which is removed just prior to insertion into the container (Downie et al. 2003). The plastic tubing continues from the spike to a drip chamber which may contain a filter. This is filled by squeezing it when attached to the fluid and waiting for the chamber to fill halfway, thus allowing the practitioner to observe the drops. Along the tubing is a roller clamp which allows the tubing to be incrementally occluded by pinching the tubing as the clamp is tightened; this is used to adjust the rate of flow (Hadaway 2010). It is usually positioned on the upper third of the administration set but should be repositioned along the set at intervals as the tubing can develop a 'memory' and not regain its shape, making it difficult to regulate (Hadaway 2010). It is opened to allow the fluid along the tubing to remove the air and then closed until attached to the patient's VAD. Finally the Luer-Lok end is covered with a plastic cap to maintain sterility until ready to be attached (Downie et al. 2003).

There is a variety of sets. A solution set is used to administer crystalloid solutions (it can be used as a primary or secondary set and is also available as a Y-set to allow for dual administration of compatible solutions). Parenteral nutrition is also administered via solution sets. Solution sets may have needle-free injection ports which allow for the administration of bolus injections or connection of secondary infusions. Sets may also have back check valves which allow solutions to flow in one direction only and are used especially when a secondary set is used (Hadaway 2010).

Blood and blood products are administered via a blood administration set (Figure 12.32) which has a special filter. Platelets

Box 12.22 Criteria for selection of an infusion device

- Rationalization of devices
- Clinical requirement
- Education
- Compatibility with other equipment
- Disposables
- Product support
- Costs
- Service and maintenance
- Regulatory issues, for example compliance with European Community Directives

Figure 12.29 Fluid administration set.

Figure 12.30 Roller clamp.

can be administered via blood sets (check with manufacturer) or specialist platelet administration sets. Some medications such as taxanes must be administered via special taxane administration sets as they have a 0.22 micron filter.

Extension sets

Extension sets are used to add length (Hadaway 2010). The short extension sets tend to have a needle-free connector (Figure 12.33) and are attached directly to the VAD to provide a closed system and other equipment is then attached via the needle-free connector. The long (50–200 cm) extension sets are used to connect from syringe pumps to a VAD and usually have a back-check or antisiphon valve. They can be single, double or triple and may contain a slide or pinch clamp but do not regulate flow (Hadaway 2010).

Needleless connectors/injection caps

These are caps that are attached to the end of a VAD or extension set (see Figure 12.33) to provide a closed system and remove the need for needles when administering medications, thus removing the risk of needlestick injury. There are various types available categorized by (a) the internal mechanisms (split septum or mechanical valve) (Hadaway 2010) and (b) how they function – that is, the presence of fluid displacement inside the device. There

Figure 12.32 Blood administration set.

Figure 12.31 Labelled administration set.

Figure 12.33 Extension set with needle-free injection cap.

are three main types: negative (blood will be pulled back into the catheter lumen which occurs, for example, when an empty fluid container is left connected which can lead to occlusion), positive (these valves have a reservoir for holding a small amount of fluid; upon disconnection this fluid is pushed out to the catheter lumen to overcome the reflux of blood that has occurred) or neutral (prevents blood reflux upon connection and disconnection) (Hadaway 2010). Others are coated with antimicrobial or antibacterial solutions on external or internal parts to reduce the risk of infection (Hadaway 2010). These require regular changing in accordance with the manufacturer's instructions as well as cleaning before and after each use (MHRA 2007, MHRA 2008).

It has been suggested that needle-free systems can increase the risk of bloodstream infections (Danzig et al. 1995). However, most studies have found no difference in microbial contamination when comparing conventional and needle-free systems (Brown et al. 1997, Luebke et al. 1998, Mendelson et al. 1998). It appears that an increased risk is only likely where there is lack of compliance with cleaning protocols or changing of equipment (Loveday et al. 2014).

Other equipment

Other IV equipment includes stopcocks (used to direct flow), usually three- or four-way devices. These tend to be used in critical care but are discouraged in the general setting due to misuse and contamination issues. If used, they should be capped off (Hadaway 2010).

Infusion devices

An infusion device is designed to accurately deliver measured amounts of fluid or drug via a number of routes (intravenous, subcutaneous or epidural) over a period of time. The infusion device is set at an appropriate rate to achieve the desired therapeutic response and prevent complications (Dougherty 2002, MHRA 2010b, MHRA 2011).

Gravity infusion devices

Gravity infusion devices depend entirely on gravity to deliver the infusion. The system consists of an administration set containing a drip chamber and a roller clamp to control the flow, which is usually measured by counting drops (Pickstone 1999). The indications for use are:

- delivery of fluids without additives
- administration of drugs or fluids where adverse effects are not anticipated and which do not need to be infused with absolute precision
- where the patient's condition does not give cause for concern and no complication is predicted (Quinn 2008).

The flow rate is calculated using a formula that requires the following information: the volume to be infused; the number of hours the infusion is running over; and the drop rate of the administration set (which will differ depending on type of set). The number of drops per millilitre is dependent on the type of administration set used and the viscosity of the infusion fluid. Increased viscosity causes the size of the drop to increase. For example, crystalloid fluid administered via a solution set is delivered at the rate of 20 drops/mL; the rate of packed red cells given via a blood set will be calculated at 15 drops/mL (Quinn 2008).

The rate of administration of a continuous or intermittent infusion may be calculated from the following equation (Pickstone 1999):

$$\frac{\text{Volume to be infused}}{\text{Time in hours}} \times \frac{\text{Drop rate}}{60 \text{ minutes}} = \text{Drops per minute}$$

In this equation, 60 is a factor for the conversion of the number of hours to the number of minutes.

Factors influencing flow rates are as follows.

Type of fluid

The composition, viscosity and concentration of the fluid affect flow (Pickstone 1999, Quinn 2000, Springhouse 2005, Weinstein and Plumer 2007). Irritating solutions may result in venospasm and impede the flow rate, which may be resolved by the use of a warm pack over the cannula site and the limb (Springhouse 2005, Weinstein and Plumer 2007).

Height of the infusion container

Intravenous fluids run by gravity and so any changes in the height of the container will alter the flow rate. The container can be hung up to 1.5 m above the infusion site which will provide a hydrostatic pressure of 110 mmHg (MHRA 2010b, Springhouse 2005). One metre above the infusion site would create 70 mmHg of pressure, which is adequate to overcome venous pressure (normal range in an adult is 25–80 mmHg) (Pickstone 1999). If it is hung too high then it can create too great a pressure within the vein, leading to infiltration of the medication (MHRA 2006a). Therefore any alterations in the patient's position may alter the flow rate and necessitate a change in the speed of the infusion to maintain the appropriate rate of flow (Hadaway 2010, MHRA 2011, Weinstein and Plumer 2007). Positioning of the patient will affect flow and patients should be instructed to keep the arm lower than the infusion, if the infusion is reliant on gravity (Quinn 2008).

Administration set

The flow rate of the infusion may be affected in several ways.

- Roller clamps (see Figure 12.30) or screw clamps, used to adjust and maintain rates of flow on gravity infusions, vary considerably in their efficiency and accuracy which are often dependent on a number of variables such as patient movement and height of infusion container (Hadaway 2010). The roller clamp should be used as the primary means of occluding the tubing even if there is an anti-free flow device (MHRA 2010b).
- The inner diameter of the lumen and the length of tubing will also affect flow. Microbore sets have a narrow lumen, so flow is restricted to some degree. However, these sets may be used as a safeguard against 'runaway' or bolus infusions by either an integrated antisiphon valve or anti-free flow device (Hadaway 2010, Quinn 2000, Weinstein and Plumer 2007).
- Inclusion of other in-line devices, for example filters, may also affect the flow rate (Hadaway 2010, MHRA 2010b).

Vascular access device

The flow rate may be affected by any of the following.

- *The condition and size of the vein:* for example, phlebitis can reduce the lumen size and decrease flow (Quinn 2008, Weinstein and Plumer 2007).
- *The gauge of the cannula/catheter* (MHRA 2010b, Springhouse 2005, Weinstein and Plumer 2007).
- *The position of the device within the vein:* that is, whether it is up against the vein wall (Quinn 2008).
- *The site of the vascular access device:* for example, the flow may be affected by the change in position of a limb, such as a decrease in flow when a patient bends their arm if a cannula is sited over the elbow joint (Springhouse 2005).
- *Kinking, pinching or compression* of the cannula/catheter or tubing of the administration set may cause variation in the set rate (MHRA 2010b, Springhouse 2005).
- *Restricted venous circulation:* for example, a blood pressure cuff or the patient lying on the limb increases the risk of occlusion and may result in clot formation (Quinn 2008).

The patient

Patients occasionally adjust the control clamp or other parts of the delivery system, for example, change the height of the container, thereby making flow unreliable. Some pumps have tamper-proof features to minimize the risk of accidental manipulation of the

infusion device (Hadaway 2010) or unauthorized changing of infusion device controls (Amoore and Adamson 2003).

Advantages and disadvantages of gravity infusion devices

A gravity flow system is simple to set up. It is low cost and the infusion of air is less likely than with electronic devices (Pickstone 1999). However, the system does require frequent observation and adjustment due to:

- the tubing changing shape over time
- creep or distortion of tubing made of polyvinyl chloride (PVC)
- fluctuations of venous pressure which can affect the flow of the solution
- the roller clamp can be unreliable, leading to inconsistent flow rates.

There can also be variability of drop size and, if the roller clamp is inadvertently left open, free flow will occur. Infusion rates with viscous fluids can be reduced (particularly if administered via small cannulas) and there is a limitation on the type of infusion as it is not suitable for arterial infusions: this is because viscosity and arterial flow offer a high resistance to flow which cannot be overcome by gravity (Pickstone 1999, Quinn 2008). If more than one infusion is infusing and one is slower than the other or there is no flow in the second set then there is a risk of back-tracking which leads to underinfusion or bolus delivery of medicines. The MHRA recommends that in these systems, the sets should include antireflux valves (MHRA 2007).

Gravity drip rate controllers

A controller is a mechanical device that operates by gravity. These devices use standard solution sets and, although they look much like a pump, they have no pumping mechanism. The desired flow rate is set in drops per minute and controlled by battery- or mains-powered occlusion valves (MHRA 2010b).

Advantages and disadvantages of gravity drip rate controllers

Although they can maintain a drip rate within 1%, volumetric accuracy is not guaranteed and many of the disadvantages associated with gravity flow still remain. The main advantages are that they are relatively inexpensive and can usually use standard gravity sets. They also incorporate some audible and visual alarm systems (MHRA 2010b).

Infusion pumps

These devices use pressure to overcome resistance from many causes along the fluid pathway, for example length and bore of tubing or particulate matter in the tubing (Hadaway 2010). There are a number of general features required in infusion pumps.

Accuracy of delivery

In order to meet requirements for high-risk and neonatal infusions, pumps must be accurate to within $\pm 5\%$ of the set rate when measured over a 60-minute period although some may be as accurate as $\pm 2\%$ (Hadaway 2010, MHRA 2010b). They also have to satisfy short-term, minute-to-minute accuracy requirements, which demand smoothness and consistency of output (MHRA 2010b).

Occlusion response and pressure

Flow will occur if the pressure at the tip of an intravascular device is just fractionally above the pressure in the vein; the pressure does not need to be excessive. In an adult peripheral vein, pressure is approximately 25 mmHg while in a neonate it is 5 mmHg (Quinn 2000). Most pumps have a variable pressure setting which allows the user to use their own judgement about the pressure needed to deliver therapy safely. The normal pumping pressure is only slightly lower than the occlusion pressure (Hadaway 2010). Flow is dependent upon pressure divided by resistance. If long

extension sets of small internal bore are used, the resistance to flow will increase (Pickstone 1999, Quinn 2000).

If an administration set occludes, the resistance increases and the infusion will not flow into the vein. The longer the occlusion occurs, the greater the pressure and the pump will continue to pump until an occlusion alarm is activated. There are two types of occlusions: upstream, between the pump and the container, and downstream, between the pump and the patient. An upstream occlusion alarms when a vacuum is created in the upstream tubing or full reservoir, due to a collapsed or empty plastic fluid container or clamped/kinking tubing. A downstream occlusion is when the pressure required by the pump exceeds a certain pounds per square inch (psi) limit to overcome the pressure created by the occlusion. Downstream occlusion pressures range from 1.5 to 15 psi (Hadaway 2010).

Pumps alarm at 'occlusion alarm pressure' and many pumps allow the user to set the pressure within a range (MHRA 2010b). Therefore, the time it takes to alarm depends on the rate of flow: high rates alarm more quickly. When the alarm is activated, a certain amount of stored medication will be present and it is important that what could be a potentially large bolus is not released into the vein. The release of the stored bolus could lead to rupture of the vein or constitute overinfusion, which may be detrimental to the patient, particularly if it is a critical medication (Amoore and Adamson 2003, MHRA 2010b). With a syringe pump, to prevent a bolus being delivered to the patient, the clamp should not be opened as this will release the bolus: the first action is to remove the pressure by opening the syringe plunger clamp and then deal with the occlusion.

A pump's downstream occlusion alarm must not be relied upon to detect infiltration or extravasation (Huber and Augustine 2009, Marders 2012, MHRA 2011) and routine assessment of IV sites is still vital to prevent these complications. Single-unit variable pressure pump settings which allow an earlier alarm alert are used in neonatal and paediatric units (Quinn 2008).

Air in line

Air-in-line detectors are designed to detect only visible or microscopic 'champagne' bubbles. They should not create anxiety over small particles of air but alert the nurse to the integrity of the system (MHRA 2011). Most air bubbles detected are too small to have a harmful effect but the nurse should clarify the cause of any alarms (MHRA 2010b).

Antisiphonage

Uncontrolled flow from a syringe is called siphonage; this is a result of gravity or leakage of air into the syringe and administration set. Siphonage can occur whether or not the syringe is fixed into an infusion device (Quinn 2008). It has been reported that 'in practice, a 50 mL syringe attached to a length of administration set with an internal diameter of 3 mm has been shown to empty by siphonage in less than 1 minute' (Pickstone 1999, p.57).

To minimize the risk of siphonage, the following safe practice should be undertaken.

- The syringe (plunger and barrel) should be correctly located and secured (MHRA 2011).
- Intravenous administration extension sets should always be micro/narrow bore in diameter to increase the resistance to flow; wide-bore extension sets should be avoided.
- The syringe pump should always be positioned at the same level as the infusion site (MHRA 2011).
- Extension sets with an integral antisiphonage/antireflux valve should be used (MHRA 2007, MHRA 2010b, Quinn 2008).

Safety software

Smart pump technology incorporates safeguards such as a list of high alert medications, soft and hard dosage limits and a drug library that can be tailored to specific patient care areas (Agius 2012, Harding 2012, Hertz and Sousa 2009). A number of

studies have evaluated the effectiveness of using smart pumps to prevent medication errors, showing the success of these systems (Dennison 2007, Fields and Peterson 2005, Larson et al. 2005, Rothschild et al. 2005). It is now recommended that nurses use this technology when administering intravenous fluids and medications (Harding et al. 2011) but careful selection and training are vital for compliance and to ensure safety outcomes (Longshore et al. 2010).

Volumetric pumps

Volumetric pumps (Figure 12.34) pump fluid from an infusion bag or bottle via an administration set and work by calculating the volume delivered (Quinn 2008). This is achieved when the pump measures the volume displaced in a 'reservoir'. The reservoir is an integral component of the administration set (Hadaway 2010). The mechanism of action may be piston or peristaltic (Hadaway 2010). The indications for use are all large-volume infusions, both venous and arterial.

All are mains and battery powered, with the rate selected in millilitres per hour. The accuracy of flow is usually within 5% when measured over a period of time, which is more than adequate for most clinical applications (MHRA 2010b, Pickstone 1999).

Advantages and disadvantages of volumetric pumps

These pumps are able to overcome resistance to flow by increased delivery pressure and do not rely on gravity. This generally makes the performance of pumps predictable and capable of accurate delivery over a wider range of flow rates (MHRA 2010b).

The pumps also incorporate a wide range of features, including air-in-line detectors, variable pressure settings and comprehensive alarms such as end of infusion, keep vein open (KVO), where the pump switches to a low flow rate, for example 5 mL/h,

in order to continue flow to prevent occlusion of the device) and low battery. Many have a secondary infusion facility, which allows for intermittent therapy, for example antibiotics. The pump is programmed to switch to a secondary set and, when completed, it reverts back to the primary infusion at the previously set rate. The changing hospital environment has led to an increased demand on volumetric pumps, which in turn has resulted in the development of multichannel and dual-channel infusion pumps. These may consist of two devices with an attached housing or of several infusion channels within a single device (Hadaway 2010).

The disadvantages are that these are usually relatively expensive and often dedicated administration sets are required. The use of the wrong set could result in error even if the pump appears to work. Some are complicated to set up, which can also lead to errors (MHRA 2010b).

Syringe pumps

Syringe pumps (Figure 12.35) are low-volume, high-accuracy devices designed to infuse at low flow rates. The plunger of a syringe containing the substance to be infused is driven forward by the syringe pump at a controlled rate to deliver it to the patient (MHRA 2010b).

Syringe pumps are useful where small volumes of highly concentrated drugs need to be infused at low flow rates (Quinn 2008). The volume for infusion is limited to the size of the syringe used in the device, which is usually 60 mL, but most pumps will accept different sizes and brands of syringe.

These devices are calibrated for delivery in millilitres per hour (Weinstein and Plumer 2007).

Advantages and disadvantages of syringe pumps

Syringe pumps are mains and/or battery powered, are usually easy to operate, and tend to cost less than volumetric pumps. The alarm systems are becoming more comprehensive and include low battery, end of infusion and syringe clamp open alarms. Most of the problems associated with the older models, for example free flow, mechanical backlash (slackness which delays the start-up time of the infusion) and incorrect fitting of the syringe, have been eliminated in the newer models (MHRA 2010b, Quinn 2008). The risk of free flow is minimized by the use of an antisiphonage valve which may be integral to the administration set (Pickstone 1999). Despite the use of an anti-siphonage valve, the clamp of the administration set must still be used (MHRA 2010b). Where mechanical backlash is an issue and there is a prime or purge option, this should be used at the start of the infusion to take up the mechanical slack (Amoore et al. 2001).

Figure 12.34 Volumetric pump.

Figure 12.35 Syringe pump.

Specialist pumps

Patient-controlled analgesia pumps

Patient-controlled analgesia (PCA) devices are typically syringe pumps (although some are based on volumetric designs) (MHRA 2010b) (Figure 12.36). The syringe pump forces down on the syringe piston, collapsing the syringe at a pre-set rate, but the distinguishing feature is the ability of the pump to deliver doses on demand, which occurs when the patient pushes a button (Hadaway 2010). Whether or not the dose is delivered is determined by pre-set parameters in the pump. That is, if the maximum amount of drug over a given period of time has already been delivered, a further dose cannot be delivered.

Patient-controlled analgesia pumps are useful for patients who require pain control. They are used more in the acute setting but are also useful in ambulatory situations (Chumbley and Mountford 2010).

Infusion options of a PCA pump are usually categorized into three types.

- *Basal*: a 'baseline' rate can be accompanied by intermittent doses requested by patients. This aims to achieve pain relief with minimal medication, but not necessarily to achieve a pain-free state (Hadaway 2010).
- *Continuous*: designed for the patient who needs maximum pain relief without the option of demand dosing, for example epidural.
- *Demand*: drug delivered by intermittent infusion when a button is pushed and can be used alone or supplemented by the basal rate. Doses can be limited by a designated maximum amount (Hadaway 2010).

The PCA pump can dispense a bolus dose, with an initial bolus being called a loading dose. This may benefit patients as the one-time dose is significantly higher than a demand dose in order to achieve immediate pain relief (see Chapter 8: Patient comfort and end-of-life care).

Advantages and disadvantages of PCA pumps

These devices offer a 'lock-out' feature (when a key or a combination of numbers is necessary to gain access to pump controls), which is designed for patient safety. They have an extensive memory capability which can be accessed through the display via a printer or computer (MHRA 2010b). This facility is critical for the pump's effective use in pain management (Hadaway 2010), as it enables the clinician to determine when and how often demand is made by a patient and what total volume has been infused (Hadaway 2010). It has also been shown that they

Figure 12.36 PCA pump used generally in acute hospital settings.

increase patient satisfaction, patients require less sedation, their anxiety is reduced and so are their nursing needs and time in hospital (Ripamonti and Bruera 1997).

Anaesthesia pumps

These are syringe pumps designed for delivery of anaesthesia or sedation and must only ever be used for that purpose. They should be restricted to operating theatres or critical care units and should be clearly labelled. They are designed to allow rapid changes in flow rate and bolus to be made while the pump is infusing (Quinn 2008). Total intravenous anaesthesia (TIVA) and target-controlled infusion (TCI) pumps are now available, designed to control the induction, maintenance and reversal phases of anaesthesia (Absalom and Struys 2006).

Epidural pumps

Epidural pumps (Figure 12.37) provide analgesia (most commonly a combination of opioids and anaesthetic agents) via a fine catheter inserted directly into the epidural space. As a form of analgesia delivery, the efficacy of the epidural route has been well highlighted (Block et al. 2003, Werawatganon and Charuluxanun 2005, Wheatley et al. 2001). See also Chapter 8: Patient comfort and end-of-life care.

Ambulatory infusion devices

Ambulatory infusion devices were developed to allow patients more freedom and to enable the patient to continue with normal activities or to move unencumbered by a large infusion device (Hadaway 2010). Ambulatory devices range in size and weight and are used for small volumes of drugs and are mainly designed for patients to wear and use when ambulant. The solution containers are often more cumbersome than the actual pump itself. Due to their size, the number of alarms may be more limited. Considerations for selection of an ambulatory device include the following.

- Type of therapy
- Patient's ability to understand how to manage the infusion device

Figure 12.37 Epidural pump.

- Drug stability
- Frequency of doses
- Reservoir volumes required
- Control of flow/flow rates
- Type of access
- Cost-effectiveness
- Portability
- Convenience

Ambulatory pumps fall into two categories: mechanical and battery-operated infusion devices.

Mechanical infusion devices

These are simple and compact but may not necessarily be cost-effective as they are usually disposable. The mechanism for delivery is by balloon or simple spring, or they may be gas powered. They are usually very 'user friendly' as they require minimal input from the patient and no battery. They can also be purchased pre-filled (Quinn 2008). Flow rates are influenced by pressure gradient, viscosity and temperature, leading to inaccuracies (Ackermann et al. 2007, DH 2005, Skrybina and Dunn 2006).

Elastomeric balloon devices

These are made of a soft rubberized material capable of being inflated to a pre-determined volume and the drug is then administered over a very specific infusion time. The balloon is encapsulated inside a rigid transparent container which may be round or cylindrical. The rate of infusion is not controlled by the balloon but by the diameter of the restricting outlet located in the pre-attached tubing (Quinn 2008). It is designed to supply the patient's need for a single dose infusion of drugs, for example intermittent small-volume parenteral therapies such as delivery of antibiotics. Its small size causes little disruption to the patient's daily activities and it tends to be well tolerated (Broadhurst 2012, Hadaway 2010). Figure 12.38 shows an elastomeric device.

Spring mechanism

Spring coil piston syringes have a spring which powers the plunger of a syringe in the absence of manual pressure. The volume is restricted by the size of the syringe, which is usually pre-filled. The spring coil container tends to be a multidose, small-volume administration device and is a combination of a

spring coil in a collapsible flattened disc. Its shape can accommodate many therapies and volumes (Hadaway 2010).

Battery-operated infusion devices

Battery-operated pumps are small and light enough to be carried around by the patient without interfering with most everyday activities. They are operated using rechargeable or alkaline batteries but, owing to their size, the available battery capacity tends to be low. The length of time the battery lasts is often dependent on the rate at which the pump is set. Most give an output in the form of a small bolus delivered every few minutes. Most devices have an integral case or pouch which allows the pump and the reservoir/syringe to be worn with discretion by the patient. There are two types: ambulatory volumetric infusion pumps and syringe drivers.

Ambulatory volumetric infusion/syringe pumps

An ambulatory volumetric infusion/syringe pump is an infusion device which pumps in the same way as a large volumetric pump but by nature of its size, it is portable and useful in the ambulatory setting (hospital or home care) (MHRA 2011).

This pump is suitable for patients who have been prescribed continuous infusional treatment for a period of time, for example from 4 days to 6 months, and enables the patients, where appropriate, to receive treatment at home, because it is small and portable.

The advantages of the ambulatory pump are as follows.

- Able to deliver drugs continuously or intermittently.
- Infusion routes: central, peripheral venous, epidural, intra-arterial, intrathecal and subcutaneous.
- Delivery of drugs accurately over a set period of time.
- Improving potential outcomes of treatment by delivering treatment continuously.
- Heightening the patient's independence and control by allowing them to be at home and participate in their own care.
- Compact, light and easy to use.
- Has audible alarm systems.

The disadvantages are as follows.

- It may require the insertion of a central venous access device, which has associated complications and problems.
- It could malfunction at home, which could be distressing and dangerous for the patient.
- In spite of its ease of use, some patients may not be able to cope with it at home.
- Patients may have to adapt their lifestyle to cope with living with a pump continuously (MHRA 2011).

Syringe drivers

See 'Subcutaneous infusion equipment'.

Specific patient preparation

Selecting the appropriate infusion device for the patient

The nurse has a responsibility to determine when and how to use an infusion device to deliver hydration, drugs, transfusions and nutritional support, and how to select the appropriate device in order to manage the needs of the patient. The following factors should be considered when selecting an appropriate infusion delivery system (Quinn 2008).

- Risk to the patient of:
 - overinfusion
 - underinfusion
 - uneven flow
 - inadvertent bolus
 - high-pressure delivery
 - extravascular infusion.

Figure 12.38 Elastomeric device.

- Delivery parameters:
 - infusion rate and volume required
 - accuracy required (over a long or short period of time)
 - alarms required
 - ability to infuse into site chosen (venous, arterial, subcutaneous)
 - suitability of device for infusing drug (e.g. ability to infuse viscous drugs).
- Environmental features:
 - ease of operation
 - frequency of observation and adjustment
 - type of patient (neonate, child, critically ill)
 - mobility of patient.

Paediatric considerations

The MHRA classifies infusion devices into categories of infusion risk. Neonatal infusions are the highest risk category; high-risk infusions are typically the infusion of fluids in children where accuracy of the flow rate is essential (MHRA 2014). Infusion therapy

within the paediatric setting requires very specific skills (Frey and Pettit 2010). Competency in calculation of paediatric dosages, maintaining a stringent fluid balance, use of paediatric-specific devices and management of complications are paramount.

The MHRA has made recommendations on the safety and performance of infusion devices in order to enable users to make the appropriate choice of equipment to suit most applications (MHRA 2010b). The classification system is divided into three major categories according to the potential risks involved. These are shown in Table 12.12. A pump suited to the most risky category of therapy (A) can be safely used for the other categories (B and C). A pump suited to category B can be used for B and C, whereas a pump with the lowest specification (C) is suited only to category C therapies (MHRA 2010b) (Figure 12.39). Hospitals are required to label each infusion pump with its category and it is necessary to know the category of the proposed therapy and match it with a pump of the same or better category. A locally produced list of drugs/fluids by their categories will need to be provided to all device users (MHRA 2010b).

Procedure guideline 12.24 Medication: continuous infusion of intravenous drugs

This procedure may be carried out by the infusion of drugs from a bag, bottle or burette.

Essential equipment

- Clinically clean tray containing the prepared drug
- Patient's prescription chart
- Recording chart or book as required by law or hospital policy
- Non-sterile gloves
- Protective clothing as required by hospital policy for the administration of specific drugs
- Container of appropriate intravenous infusion fluid
- 2% chlorhexidine swab
- Drug additive label

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, E ; NMC 2013, C ; NMC 2015, C).
2 Inspect the infusion in progress.	To check it is the correct infusion being administered at the correct rate and that the contents are due to be delivered on time in order for the next prepared infusion bag to be connected. To check whether the patient is experiencing any discomfort at the site of insertion, which might indicate the peripheral device needs to be resited (NPSA 2007d, C).
3 Before administering any prescribed drug, check that it is due and has not already been given.	To protect the patient from harm (NPSA 2007d, C).
4 Before administering any prescribed drug, look at the patient's prescription chart and check the following. <ol style="list-style-type: none"> The correct patient Drug Dose Date and time of administration Route and method of administration Diluent as appropriate Validity of prescription Signature of prescriber The prescription is legible If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.	To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, C ; NMC 2010a, C). To protect the patient from harm (DH 2003b, C ; NMC 2010a, C). To prevent any errors occurring. E

(continued)

Procedure guideline 12.24 Medication: continuous infusion of intravenous drugs (continued)

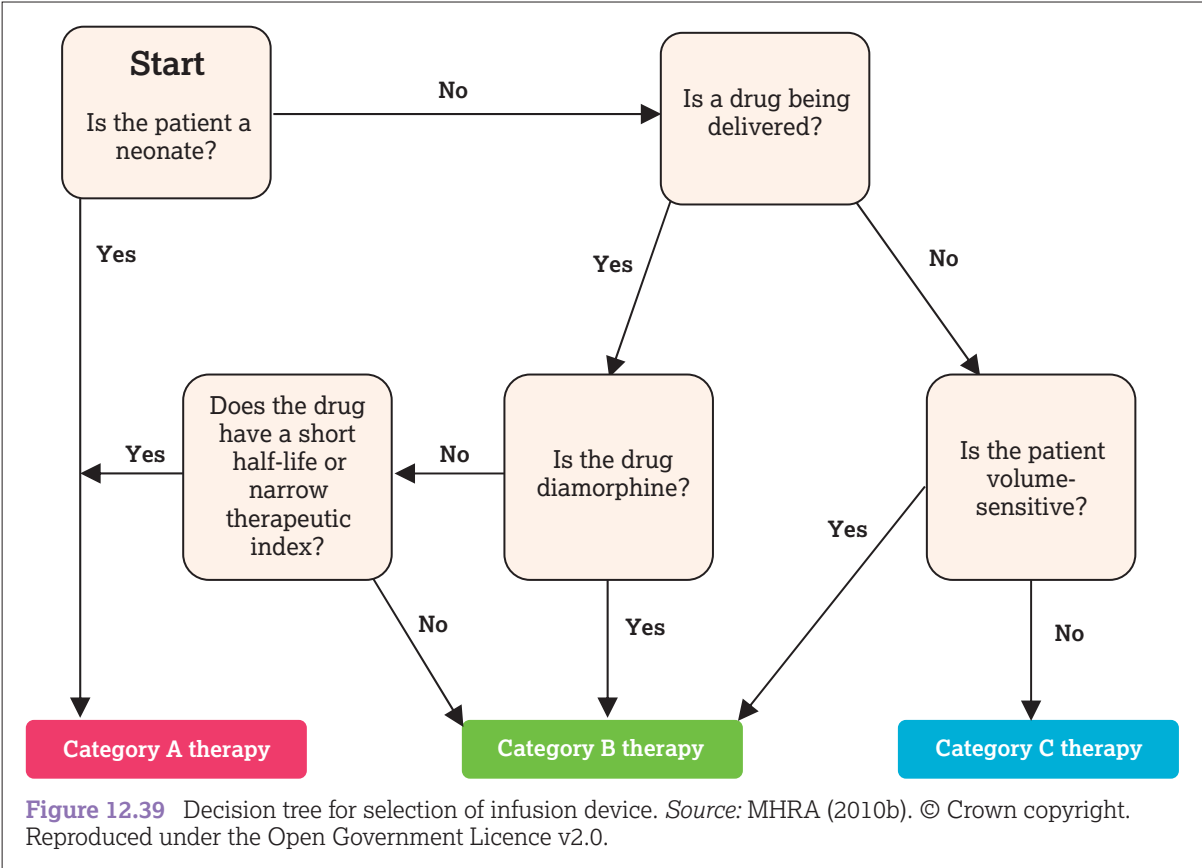

Action	Rationale
5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble the necessary equipment.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
6 Prepare the drug for injection as described in Procedure guidelines 12.12, 12.13, 12.14 and 12.15.	To ensure the drug is prepared (NPSA 2007d, C).
7 Check the name, strength and volume of intravenous fluid against the prescription chart.	To ensure that the correct type and quantity of fluid are administered (NMC 2010a, C ; NPSA 2007d, C).
8 Check the expiry date of the fluid.	To prevent an ineffective or toxic compound being administered to the patient (NPSA 2007d, C).
9 Check that the packaging is intact and inspect the container and contents in a good light for cracks, punctures and air bubbles.	To check that no contamination of the infusion container has occurred (NPSA 2007d, C).
10 Inspect the fluid for discoloration, haziness and crystalline or particulate matter.	To prevent any toxic or foreign matter being infused into the patient (NPSA 2007d, C).
11 Check the identity and amount of drug to be added. Consider: (a) compatibility of fluid and additive (b) stability of mixture over the prescribed duration of the infusion (c) any special directions for dilution, for example pH, optimum concentration (d) sensitivity to external factors such as light (e) any anticipated allergic reaction. If any doubts exist about the listed points, consult the pharmacist or appropriate reference works.	To minimize any risk of error. To ensure safe and effective administration of the drug. To enable anticipation of toxicities and the nursing implications of these (NPSA 2007d, C).
12 Any additions must be made immediately before use.	To prevent any possible microbial growth or degradation (NPSA 2007d, C).
13 Wash hands thoroughly using bactericidal soap and water or bactericidal alcohol handrub.	To minimize the risk of cross-infection (DH 2007, C ; Fraise and Bradley 2009, E).
14 Place infusion bag on flat surface.	To prevent puncturing the side of the infusion bag when making additions (NPSA 2007d, C).
15 Remove any seal present.	To expose the injection site on the container. E
Procedure	
16 Clean the site with the swab and allow it to dry.	To reduce the risk of contamination (NPSA 2007d, C).
17 Inject the drug using a new sterile needle into the bag, bottle or burette. A 23 or 25 G needle should be used. If the addition is made into a burette at the bedside: (a) avoid contamination of the needle and inlet port (b) check that the correct quantity of fluid is in the chamber (c) switch the infusion off briefly (d) add the drug.	To minimize the risk of contamination. To enable resealing of the latex or rubber injection site (NPSA 2007d, C).
	To minimize the risk of contamination (NPSA 2007d, C).
	To ensure the correct dilution (NPSA 2007d, C).
	To ensure a bolus injection is not given (NPSA 2007d, C).
18 Invert the container a number of times, especially if adding to a flexible infusion bag.	To ensure adequate mixing of the drug (NPSA 2007d, C).
19 Check again for haziness, discoloration and particles. This can occur even if the mixture is theoretically compatible, thus making vigilance essential.	To detect any incompatibility or degradation (NPSA 2007d, C).
20 Complete the drug additive label and fix it on the bag, bottle or burette.	To identify which drug has been added, when and by whom (NPSA 2007d, C).
21 Place the container in a clean receptacle. Wash hands and proceed to the patient.	To minimize the risk of contamination (DH 2007, C).
22 Check the identity of the patient against the prescription chart and infusion bag.	To minimize the risk of error and ensure the correct infusion is administered to the correct patient (NPSA 2007d, C).
23 Check that the contents of the previous container have been fully delivered.	To ensure that the preceding prescription has been administered (NPSA 2007d, C).

24	Switch off the infusion. Apply gloves. Place the new infusion bag on a flat surface and then disconnect empty infusion bag.	To ensure that the administration set spike will not puncture the side wall of the infusion bag (Finlay 2008, E ; NPSA 2007d, C).
25	Push the spike in fully without touching it and hang the new infusion bag on the infusion stand. Insert tubing into an infusion pump where appropriate.	To reduce the risk of contamination (DH 2007, C). To ensure accuracy of delivery (Quinn 2008, E).
26	For gravity infusion, restart the infusion and adjust the rate of flow as prescribed. If via an infusion pump, start the pump and set rate.	To ensure that the infusion will be delivered at the correct rate over the correct period of time (NPSA 2007d, C).
27	If the addition is made into a burette, the infusion can be restarted immediately following mixing and recording and the infusion rate adjusted accordingly.	To ensure that the infusion will be delivered correctly (NPSA 2007d, C).
28	Ask the patient whether any abnormal sensations are experienced.	To ascertain whether there are any problems that may require nursing care and refer to medical staff where appropriate. E .
Post-procedure		
29	Discard waste, making sure that it is placed in the correct containers, for example sharps into a designated receptacle.	To ensure safe disposal and avoid injury to staff. To prevent reuse of equipment (DH 2005, C ; EU 2010, C ; MHRA 2004, C).
30	Complete the patient's recording chart and other hospital and/or legally required documents.	To maintain accurate records. To provide a point of reference in the event of any queries. To prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Table 12.12 Therapy categories and performance parameters

Therapy category	Therapy description	Patient group	Critical performance parameters
A	Drugs with narrow therapeutic margin	Any	Good long-term accuracy
			Good short-term accuracy
	Drugs with short half-life	Any	Rapid alarm after occlusion
	Any infusion given to neonates	Neonates	Small occlusion bolus
			Able to detect very small air embolus (volumetric pumps only)
			Small flow rate increments
			Good bolus accuracy
B			Rapid start-up time (syringe pumps only)
	Drugs other than those with a short half-life	Any except neonates	Good long-term accuracy
	Parenteral nutrition	Volume sensitive except neonates	Alarm after occlusion
	Fluid maintenance		Small occlusion bolus
	Transfusions		Able to detect small air embolus (volumetric pumps only)
C			Small flow rate increments
	Diamorphine	Any except neonates	Bolus accuracy
	Parenteral nutrition	Any except volume sensitive or neonates	Long-term accuracy
	Fluid maintenance		Alarm after occlusion
	Transfusions		Small occlusion bolus
			Able to detect air embolus (volumetric pumps only)
			Incremental flow rates

6 Prime the intravenous administration set with infusion fluid mixture and hang it on the infusion stand.	To ensure removal of air from set and check that tubing is patent. To prepare for administration (NPSA 2007d, C).
7 Draw up 10 mL of compatible flush solution for injection using an aseptic technique.	To ensure sufficient flushing solution is available. E
8 Draw up solution (as advised by hospital policy) to be used for maintaining patency, for example 0.9% sodium chloride.	To prepare for administration. E
9 Place the syringes in a clinically clean tray on the bottom shelf of the dressing trolley.	To ensure top shelf is used for sterile dressing pack in order to minimize the risk of contamination. E
10 Collect the other equipment and place it on the bottom shelf of the dressing trolley.	To ensure all equipment is available to commence procedure. E
11 Place a sterile dressing pack on top of the trolley.	To minimize risk of contamination. E
12 Check that all necessary equipment is present.	To prevent delays and interruption of the procedure. E
13 Wash hands thoroughly using bactericidal soap and water or bactericidal alcohol handrub before leaving the clinical room.	To minimize the risk of cross-infection (DH 2007, C ; Fraiese and Bradley 2009, E).
14 Proceed to the patient. Check patient's identity against prescription chart and prepared drugs.	To minimize the risk of error and ensure the correct drug is given to the correct patient (NMC 2010a, C ; NPSA 2007d, C).
Procedure	
15 Open the sterile dressing pack.	To minimize the risk of cross-infection (DH 2007, C ; Fraiese and Bradley 2009, E).
16 Open the 2% chlorhexidine swab packet and empty it onto the pack.	To ensure the correct cleaning swab is available (DH 2007, E).
17 Wash hands with bactericidal soap and water or with a bactericidal alcohol handrub.	To minimize the risk of cross-infection. (DH 2007, C ; Fraiese and Bradley 2009, E).
18 If peripheral device is <i>in situ</i> remove the patient's bandage and dressing, where appropriate.	To observe the insertion site (Dougherty 2008a, E).
19 Inspect the insertion site of the device.	To detect any signs of inflammation, infiltration, and so on. If present, take appropriate action (DH 2003c, C).
20 Wash and dry hands.	To minimize the risk of contamination (DH 2007, C).
21 Put on gloves.	To protect against contamination with hazardous substances, for example cytotoxic drugs (NPSA 2007d, C).
22 Place a sterile towel under the patient's arm.	To create a sterile area on which to work. E
23 Clean the needle-free cap with 2% chlorhexidine swab.	To minimize the risk of contamination and maintain a closed system (Loveday et al. 2014, C).
24 Gently inject 10 mL of 0.9% sodium chloride for injection.	To confirm the patency of the device. E

(continued)

Procedure guideline 12.25 Medication: intermittent infusion of intravenous drugs (continued)

Action	Rationale
25 Check that no resistance is met, no pain or discomfort is felt by the patient, no swelling is evident, no leakage occurs around the device and there is a good backflow of blood on aspiration.	To ensure the device is patent (Dougherty 2008a, E).
26 Connect the infusion to the device.	To commence treatment. E
27 Open the roller clamp and/or insert the tubing into an infusion pump and start pump.	To check the infusion is flowing freely. E
28 Check the insertion site and ask the patient if they are comfortable.	To confirm that the vein can accommodate the extra fluid flow and that the patient experiences no pain. E
29 Adjust the flow rate as prescribed.	To ensure that the correct speed of administration is established (NPSA 2007d, C).
30 Tape the administration set in a way that places no strain on the device, which could in turn damage the vein.	To reduce the risk of mechanical phlebitis or infiltration (Dougherty 2008a, E).
31 If a peripheral device is <i>in situ</i> , cover it with a sterile topical swab and tape it in place.	To maintain asepsis (Dougherty 2008a, E).
32 Remove gloves.	To ensure disposal. E
33 If the infusion is to be completed within 30 minutes, bandaging is unnecessary and the patient may be instructed to keep the arm resting on the sterile towel. Otherwise reapply bandage.	To reduce the risk of dislodging the device. E
34 The equipment must be cleared away and new equipment only prepared when required at the end of the infusion.	To ensure that the equipment used is sterile prior to use. E
35 Monitor flow rate and device site frequently.	To ensure the flow rate is correct and the patient is comfortable, and to check for signs of infiltration (NPSA 2007d, C).
36 When the infusion is complete, wash hands using bactericidal soap and water or bactericidal alcohol handrub, and recheck that all the equipment required is present.	To maintain asepsis and ensure that the procedure runs smoothly (DH 2007 C ; Finlay 2008, E).
37 Stop the infusion when all the fluid has been delivered.	To ensure that all the prescribed mixture has been delivered and prevent air infusing into the patient (NPSA 2007d, C).
38 Put on non-sterile gloves.	To protect against contamination with hazardous substances. E
39 Disconnect the infusion set and flush the device with 10 mL of 0.9% sodium chloride or other compatible solution for injection. (A 'minibag' may be used to flush the drug through the tubing but the cost implications of this as well as the risk to patients on restricted intake should be considered before this is adopted routinely.)	To flush any remaining irritating solution away from the cannula. E
40 Attach a new sterile injection cap if necessary.	To maintain a closed system (Hart 2008a, E).
41 Flushing must follow.	To maintain the patency of the device (Dougherty 2008a, E).
42 Clean the injection site of the cap with 2% chlorhexidine swab.	To minimize the risk of contamination (Hart 2008, E).
43 Administer flushing solution using the push-pause technique and ending with positive pressure.	To maintain the patency of the device and if needle was used, to enable reseal of the injection site (Dougherty 2008a, E).
44 If a peripheral device is <i>in situ</i> , cover the insertion site and cannula with a new sterile low-linting swab. Tape it in place. Apply a bandage.	To minimize the risk of contamination of the insertion site. To reduce the risk of dislodging the cannula. E
45 Remove gloves.	To ensure disposal. E
46 Assist the patient into a comfortable position.	To ensure the patient is comfortable. E
Post-procedure	
47 Discard waste, placing it in the correct containers, for example sharps into a designated container.	To ensure safe disposal and avoid injury to staff (DH 2005, C ; EU 2010, C ; MHRA 2004, C ; NHS Employers 2007, C).
48 Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Procedure guideline 12.26 Medication: injection (bolus or push) of intravenous drugs

Essential equipment

- Clinically clean tray containing the prepared drug(s) to be administered
- Patient's prescription chart
- Protective clothing as required by hospital policy for administering drugs
- Clean dressing trolley
- Sterile needles and syringes
- 0.9% sodium chloride, 20 mL for injection, or compatible solution
- Flushing solution, in accordance with hospital policy
- 2% chlorhexidine swab
- Sterile dressing pack
- Hypoallergenic tape
- Sharps container

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Before administering any prescribed drug, check that it is due and has not been given already.
- 3 Before administering any prescribed drug, look at the patient's prescription chart and check the following.
 - (a) The correct patient
 - (b) Drug
 - (c) Dose
 - (d) Date and time of administration
 - (e) Route and method of administration
 - (f) Diluent as appropriate
 - (g) Validity of prescription
 - (h) Signature of prescriber
 - (i) The prescription is legible
 If any of these pieces of information are missing, are unclear or illegible then the nurse should not proceed with administration and should consult with the prescriber.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (Griffith and Jordan 2003, **E**; NMC 2013, **C**; NMC 2015, **C**).
- To protect the patient from harm (NMC 2010a, **C**).
- To ensure that the correct patient is given the correct drug in the prescribed dose using the appropriate diluent and by the correct route (DH 2003b, **C**; NMC 2010a, **C**). To protect the patient from harm (DH 2003b, **C**; NMC 2010a, **C**).
- To protect the patient from harm.
- To comply with NMC (2010a) *Standards for Medicines Management*.
- To prevent any errors occurring. **E**

Procedure

- 4 Select the required medication and check the expiry date.

Treatment with medication that is outside the expiry date is dangerous. Drugs deteriorate with storage. The expiry date indicates when a particular drug is no longer pharmacologically efficacious (NPSA 2007d, **C**).
- 5 Wash hands with bactericidal soap and water or bactericidal alcohol handrub, and assemble necessary equipment.

To minimize the risk of infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).
- 6 Prepare the drug for injection as described in Procedure guidelines 12.12, 12.13, 12.14 and 12.15.

To prepare the drug correctly. **E**
- 7 Prepare a 20 mL syringe of 0.9% sodium chloride (or compatible solution) for injection, as described, using aseptic technique.

To use for flushing between each drug (NPSA 2007d, **C**).
- 8 Draw up the flushing solution, as indicated by local hospital policy.

To prepare for administration. **E**
- 9 Place syringes in a clinically clean receptacle on the bottom shelf of the dressing trolley, along with the receptacle containing any drug(s) to be administered.

To ensure top shelf is used for sterile dressing pack in order to minimize the risk of contamination. **E**
- 10 Collect the other equipment and place it on the bottom of the trolley.

To ensure all equipment is available to commence procedure. **E**
- 11 Place a sterile dressing pack on top of the trolley.

To minimize the risk of contamination. **E**
- 12 Check that all necessary equipment is present.

To prevent delays and interruption of the procedure. **E**
- 13 Wash hands thoroughly.

To minimize the risk of infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).

(continued)

Procedure guideline 12.26 Medication: injection (bolus or push) of intravenous drugs (continued)

Action	Rationale
14 Proceed to the patient and check their identity and the prepared drug against the prescription chart.	To minimize the risk of error and ensure the drug is given to the correct patient (NPSA 2007d, C).
15 Open the sterile dressing pack and 2% chlorhexidine swab and empty onto pack.	To gain access to equipment and to ensure there is a cleaning swab available (DH 2007, C).
16 Wash hands with bactericidal soap and water or with bactericidal alcohol handrub.	To reduce the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
17 If a peripheral device is <i>in situ</i> , remove the bandage and dressing (if appropriate).	To observe the insertion site. E
18 Inspect the insertion site of the device.	To detect any signs of inflammation, infiltration, and so on. If present, take appropriate action (see Problem-solving table 12.3) (DH 2003c, C).
19 Observe the infusion, if in progress.	To confirm that it is infusing as desired (NPSA 2007d, C).
20 Check whether the infusion fluid and the drugs are compatible. If not, change the infusion fluid to 0.9% sodium chloride to flush between the drugs if necessary.	To prevent drug interaction. Some manufacturers may recommend that the drug is given into the injection site of a rapidly running infusion (NPSA 2007d, C). A compatible fluid must be used to remove the medication and prevent precipitation or drug incompatibility if medications mix in the tubing (Whittington 2008, E).
21 Wash hands or clean them with an alcohol handrub.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
22 Place a sterile towel under the patient's arm.	To create a sterile field. E
23 Apply gloves and the injection site with a 2% chlorhexidine swab and allow to dry.	To reduce the number of pathogens introduced by the needle at the time of the insertion. To ensure complete disinfection has occurred (Loveday et al. 2014, C).
24 Switch off the infusion.	To prevent excessive pressure within the vein. To prevent contact with an incompatible infusion fluid. To allow the nurse to concentrate on the site of insertion and injection (NPSA 2007d, C).
25 If a peripheral device is <i>in situ</i> , gently inject 0.9% sodium chloride. This may not be necessary if the patient has a 0.9% sodium chloride infusion in progress.	To confirm patency of the vein. To prevent contact with an incompatible infusion solution (NPSA 2007d, C).
26 Open the roller clamp of the administration set fully. Inject the drug at a speed sufficient to slow but not stop the infusion and inject the drug smoothly in the direction of flow at the specified rate.	To prevent backflow of drug up the tubing. To prevent excessive pressure within the vein. To prevent speed shock (NPSA 2007d, C).
27 Ensure needles and syringes are disposed of immediately into appropriate sharps container (or are returned to tray). Do not leave any sharps on opened sterile pack.	To reduce the risk of needlestick injury and to prevent contamination of pack (RCN 2010, C).
28 Observe the insertion site of the device throughout.	To detect any complications at an early stage, for example extravasation or local allergic reaction (Dougherty 2008b, E).
29 Blood return and/or 'flashback' must be checked frequently throughout the injection (that is, every 3–5 mL) but other signs and symptoms must be taken into consideration.	To confirm that the device is correctly placed and that the vein remains patent (Weinstein and Plumer 2007, E). Flashback alone is not an indicator that the vein is patent (Dougherty 2008a, E).
30 Consult the patient during the injection about any discomfort, and so on.	To detect any complications at an early stage, and ensure patient comfort (Dougherty 2008a, E).
31 If more than one drug is to be administered, flush with 0.9% sodium chloride between administrations by restarting the infusion or changing syringes.	To prevent drug interactions (NPSA 2007d, C).
32 At the end of the injection, flush with 0.9% sodium chloride by restarting the infusion or attaching a syringe containing 0.9% sodium chloride.	To flush any remaining irritant solution away from the device site (NPSA 2007d, C).

33	After the final flush of 0.9% sodium chloride, adjust the infusion rate as prescribed or open the fluid path of the tap/stopcock or administer the flushing solution using pulsatile flush and ending with positive pressure.	To continue delivery of therapy. To maintain the patency of the cannula (Finlay 2008, E).
34	If a peripheral device is <i>in situ</i> , cover the insertion site with new sterile low-linting swab and tape it in place.	To minimize the risk of contamination of the insertion site. E
35	Apply a bandage.	To reduce the risk of dislodging the cannula. E
36	Assist the patient into a comfortable position.	To ensure the patient is comfortable. E
Post-procedure		
37	Dispose of used syringes with the needle, unsheathed, directly into a sharps container during procedure or place back on to plastic tray and then dispose of in a sharps container as soon as possible. <i>Do not</i> disconnect needle from syringe prior to disposal. Other waste should be placed into the appropriate plastic bags.	To avoid needlestick injury (EU 2010, C ; MHRA 2004, C ; NHS Employers 2007, C).
38	Record the administration on appropriate charts.	To maintain accurate records, provide a point of reference in the event of any queries and prevent any duplication of treatment (NMC 2010a, C ; NMC 2010b, C).

Problem-solving table 12.3 Prevention and resolution (Procedure guidelines 12.24, 12.25 and 12.26)

Problem	Cause	Prevention	Action
Infusion slows or stops (part 1).	Change in position of the following.		
	(a) Patient.	Check the height of the fluid container if the patient is active and receiving an infusion using gravity flow.	Adjust the height of the container accordingly. The infusion should not hang higher than 1 m above the patient as the increased height will result in increased pressure and possible rupture of the vessel/device (Quinn 2008).
	(b) Limb.	Prevent by avoiding inserting peripheral devices at joints of limbs. Instruct the patient on the amount of movement permitted. Continued movement could result in mechanical phlebitis (Lamb and Dougherty 2008).	Move the arm or hand until infusion starts again. Secure the device, then bandage or splint the limb again carefully in the desired position. Take care not to cause damage to the limb.
	(c) Administration set.	Tape the administration set so that it cannot become kinked or occluded.	Check for kinks and/or compression if the patient is active or restless and correct accordingly.
	(d) Cannula.	Secure the cannula firmly to prevent movement. It may come into contact with the vein wall or a valve. Infusions sited in small veins are prone to this problem.	Remove the bandage and dressing and manoeuvre the peripheral device gently, without pulling it out of the vein, until the infusion starts again. Secure adequately.
Infusion slows or stops (part 2).	Technical problems.		
	(a) Negative pressure prevents flow of fluid.	Ensure that the container is vented using an air inlet.	Vent if necessary, using venting needle.
	(b) Empty container.	Check fluid levels regularly.	Replace the fluid container before it runs dry.
	(c) Venous spasm due to chemical irritation or cold fluids/drugs.	Dilute drugs as recommended. Remove solutions from the refrigerator a short time before use.	Apply a warm compress to soothe and dilate the vein, increase the blood flow and dilute the infusion mixture.

(continued)

Problem-solving table 12.3 Prevention and resolution (Procedure guidelines 12.24, 12.25 and 12.26) (continued)

Problem	Cause	Prevention	Action
	(d) Injury to the vein.	Detect any injury early as it is likely to progress and cause more serious conditions.	Stop the infusion and resite the cannula.
	(e) Occlusion of the device due to fibrin formation.	Maintain a continuous, regular fluid flow or ensure that patency is maintained by flushing. Instruct the patient to keep arm below the level of the heart if ambulant and attached to a gravity flow infusion.	<p><i>If peripheral device:</i> remove extension set/injection cap and attempt to flush the cannula gently using a 10 mL syringe of 0.9% sodium chloride. If resistance is met, stop and resite the peripheral device (see Chapter 14: Vascular access devices: insertion and management).</p> <p><i>If CVAD:</i> remove injection cap and attempt to flush the cannula gently using a 10 mL syringe of 0.9% sodium chloride. If resistance is met, attempt to instil fibrinolytic agent such as urokinase (see Chapter 14: Vascular access devices: insertion and management).</p>
	(f) The cannula has become displaced either completely or partially; that is, fluid or drug has leaked into the surrounding tissues (infiltration). If the drugs were vesicant in nature this would then be defined as extravasation.	Secure the cannula and tape the administration set to prevent pulling and dislodgement. Instruct the patient on the amount of movement permitted with the limb that has the device <i>in situ</i> (Fabian 2000).	<p>Confirm that infiltration of drugs has/has not occurred by:</p> <ul style="list-style-type: none"> (i) inspecting the site for leakage, swelling, and so on (ii) testing the temperature of the skin: it will be cooler if infiltration has occurred (iii) comparing the size of the limb with the opposite limb. <p>Once infiltration has been confirmed, stop the infusion and request a resiting of the device. If the infusion is allowed to progress, discomfort and tissue damage will result. Apply cold or warm compresses to provide symptomatic relief, whichever provides the most comfort for the patient. Reassure the patient by explaining what is happening. Document in care plan and monitor site (Lamb and Dougherty 2008).</p> <p>If extravasation occurs, follow hospital policy and procedure.</p>
Infusion pump alarming.			
(a) Air detected.	Air bubbles in administration set.	Ensure all air is removed from all equipment prior to use.	Remove all air from the administration set and restart the infusion.
(b) Tube misload.	Administration set has been incorrectly loaded.	Ensure set is loaded correctly.	Check that the set is loaded correctly and reload if necessary.
(c) Upstream occlusion.	Closed clamp, obstruction or kink in the administration set is preventing fluid flow.	Ensure the container/fluid bag has been adequately pierced by the administration spike.	Inspect the administration set and restart the infusion.
		Ensure that the tubing is taped to prevent kinking.	If tubing is kinked, reposition, tape and restart infusion.
		Ensure the regulating (roller) clamp is open.	Check the administration set and open the clamp; restart the infusion.
(d) Downstream occlusion.	Phlebitis/infiltration or extravasation.	Observe site regularly for signs of swelling, pain and erythema.	Remove peripheral device, provide symptomatic relief where appropriate. Initiate extravasation procedure. Resite as appropriate.
	Closed distal clamp.	Ensure clamps are open.	Locate distal occlusion, restart infusion.
(e) KVO alert (keep vein open).	The volume infused is complete and the device is infusing at the KVO rate.	Programme in a new volume as appropriate.	Do not turn the device off. Allow KVO mode to run to maintain patency of device. Prepare new infusion or discontinue as appropriate.

Problem	Cause	Prevention	Action
Infusion devices malfunctioning (electrical/mechanical).	Not charging at mains.	Ensure that the device is kept plugged in where appropriate.	Change device and remove device from use until fully charged. Send to clinical engineering to check plug.
	Low battery.	Check lead is pushed in adequately.	
	Batteries keep requiring replacement.	Do not use small rechargeable batteries in ambulatory devices.	
	Technical fault.	Ensure all infusion devices are serviced regularly.	Remove infusion device from use and contact clinical engineering department or relevant personnel.
Unstable infusion device.	Device soiled inside mechanism.	Maintain equipment and keep clean and free from contamination.	Remove administration set, wipe pump, reload. Do not use alcohol-based solutions on internal mechanisms.
	Mounted on old, poorly maintained stands.	Ensure that stands are maintained and kept clean. Replace old stands.	Remove device from stand. Remove stand and send to clinical engineering for repair.
	Mounted on incorrect stands.	Ensure the correct stands are used.	Check the stand and change to appropriate stand.
	Equipment not balanced on stand.	Ensure that all equipment is balanced around the stand.	Remove devices and attach to two stands if necessary. Balance equipment.

Post-procedural considerations

Ongoing care

Monitoring of the infusion while in progress includes monitoring of the patient's condition and response to therapy, the VAD site, the rate and volume infused. It may also include the battery life and occlusion pressure. The frequency of monitoring is often based on the type of therapy and patient condition, for example checking the rate of infusion and the infusion site 15 minutes after setting up infusion, then at 1 hour and then 4 hourly (or more frequently depending on medication). This information must be documented on the patient's fluid balance chart or in their notes. The type and make of pump along with the serial number should also be documented (useful if any errors occur) (MHRA 2008a).

Complications

For phlebitis, thrombosis, septicaemia and embolism, see Chapter 14: Vascular access devices: insertion and management.

Infiltration and extravasation

Infiltration

Definition

Infiltration tends to refer to the leakage of non-vesicant solutions/medications into the surrounding tissues (INS 2011) and generally does not cause tissue necrosis but can result in long-term injury due to local inflammatory reactions or by compression of the surrounding tissues (if a large volume infiltrates) which is known as compartment syndrome (Doellman et al. 2009, RCN 2010, Schulmeister 2009).

Extravasation

Definition

Extravasation literally means 'leaking into the tissues' but it has been linked with vesicants to describe a process that requires immediate action if local tissue damage is to be prevented (INS

2011, Polovich et al. 2014, Schulmeister 2009). A vesicant is any solution or medication that causes the formation of blisters with subsequent tissue necrosis and may be DNA or non-DNA binding (INS 2011, Polovich et al. 2014).

Related theory

It is important to recognize and distinguish extravasation from an infiltration or flare reaction.

Flare reaction is a local inflammatory reaction to an agent manifested by red tracking along the vein or red blotches but without pain (although the area may feel itchy) (Polovich et al. 2014). It occurs in 3–6% of patients (How and Brown 1998). It is caused by a venous inflammatory response to histamine release, is characterized by redness and blotchiness and may result in the formation of small wheals, having a similar appearance to a nettle rash. It usually subsides in 30–60 minutes, with 86% resolving within 45 minutes (How and Brown 1998). Slowing infusion rates may be helpful but it responds well within a few minutes to the application of a topical steroid (Schulmeister 2009, Weinstein and Plumer 2007).

Tissue damage following extravasation of vesicant drugs occurs for a number of reasons.

- Whether the drugs bind to DNA or not.
 - DNA-binding vesicants (e.g. doxorubicin, epirubicin) bind to nucleic acids in the DNA of healthy cells, resulting in cell death. There is then cellular uptake of extracellular substances and this sets up a continuing cycle of tissue damage as the DNA-binding vesicant is retained and recirculated in the tissue, sometimes for a prolonged period of time (Goolsby and Lombardo 2006, Polovich et al. 2014, Schulmeister 2009).
 - Non-DNA binding vesicants (e.g. paclitaxel, vinca alkaloids) have an indirect rather than a direct effect on the cells. They are eventually metabolized in the tissue and then neutralized (more easily than DNA-binding vesicants) (Polovich et al. 2014).
- The concentration and amount of vesicant drug in the tissue.
- The location of the extravasation, for example hand, arm.
- Patient factors, for example older age, co-morbidities (Polovich et al. 2014, Schulmeister 2009).

Box 12.23 Considerations for the prevention of extravasation

- Monitoring the site
- Location of the device
- Patients at risk
- Sequence of drugs
- Types of devices
- Method of administration
- Skill of practitioner
- Informing the patient

Evidence-based approaches

Extravasation is a well-recognized complication of IV chemotherapy administration, but in general is a condition that is often underdiagnosed, undertreated and under-reported (Stanley 2002). The incidence of extravasation is estimated to be between 0.5% and 6.0% of all cytotoxic drug administrations (Goolsby and Lombardo 2006, Kassner 2000, Khan and Holmes 2002, Lawson 2003, Masoorli 2003), with some estimates for peripheral extravasation between 23% and 25% (Roth 2003). CVADs have decreased the incidence of extravasation but it can still occur and the incidence is estimated to be up to 6% with ports (Masoorli 2003). However, whilst the incidence is lower, the severity of the injuries is far greater as detection tends to occur later (Kassner 2000, Polovich et al. 2014, Stanley 2002). Even when practitioners have many years of experience, extravasation of vesicant agents can occur and is an extremely stressful event, but is not in itself an act of negligence (Weinstein and Plumer 2007). Early detection and treatment are crucial if the consequences of an untreated or poorly managed extravasation are to be avoided (Box 12.23, Figure 12.40). These may include:

- blistering (typically occurs 1–2 weeks post extravasation)
- peeling and sloughing of the skin (about 2 weeks post extravasation)
- tissue necrosis (2–3 weeks post extravasation) with resulting pain
- damage to tendons, nerves and joints
- functional and sensory impairment of affected area such as limb disfigurement
- loss of limb or breast (Polovich et al. 2014).

These can all result in possible hospitalization and plastic surgery, delay in the treatment of disease and psychological distress for the patient.

Figure 12.40 Extravasation.

Table 12.13 Examples of vesicant cytotoxic and non-cytotoxic drugs in common use

Group A drugs	Group B drugs
Vinca alkaloids:	Amsacrine
Vinblastine	Carmustine (concentrated solution)
Vindesine	Dacarbazine (concentrated solution)
Vinorelbine	Dactinomycin
Vincristine	Daunorubicin
Vinflunine	Doxorubicin
Paclitaxel	Epirubicin
Calcium chloride	Idarubicin
Calcium gluconate	Amrubicin
Phenytoin	Actinomycin D
Hypertonic solutions, for example sodium chloride >0.9%	Mitomycin C
Sodium bicarbonate (>5%)	Mechlorethamine
Glucose 50%	Streptozocin
	Aciclovir
	Amphotericin
	Cefotaxime
	Diazepam
	Ganciclovir
	Mannitol
	Potassium chloride (>40 mmol/L)
	Potassium phosphate
	Thiopental

Before administration of any vesicant drugs, the nurse should know which agents are capable of producing tissue necrosis; damage is usually caused by the ability to bind to DNA, pH, osmolarity or vasoconstrictive nature of the drugs (Table 12.13). Drugs should not be reconstituted to give solutions which are higher in concentration than is recommended by the manufacturer, and the method of administration should be checked, for example infusion or injection. If in any doubt, the drug data sheet should be consulted or the pharmacy department should be consulted if the information is insufficient, regarding action to take if a vesicant drug extravasates. Consideration should be given to the management of mixed vesicant drug extravasation in terms of which drug to treat with which antidote. For example, if drug A and drug B were in the same infusion and they required different antidotes, but drug A would cause more damage than drug B, the correct action would be to use the antidote for drug A (How and Brown 1998).

Possible causes of extravasation are shown in Table 12.14.

Methods for preventing infiltration/extravasation

The nurse's focus should be on safe intravenous technique and implementing strategies to minimize risk (Weinstein and Plumer 2007). This includes the following strategies.

Patients at risk

Patients who are at increased risk of extravasation (Box 12.24) should be observed more closely and cared for with extra caution.

Table 12.14 Possible causes of extravasation

Peripheral devices	Central venous access devices
Vein wall puncture or trauma	Perforation of the vein
Dislodgement of the cannula from the vein	Catheter leakage, rupture or fracture
Administration of a vesicant in a vein below a recent venepuncture or cannulation site (<24 hours)	Separation of the catheter from the portal body of an implanted port
	Incomplete insertion of needle into an implanted port
	Needle dislodgement from an implanted port
	Fibrin sheath – leading to backflow of drug along the catheter from the insertion site

Source: Adapted from Mayo (1998), Polovich et al. (2014), Schulmeister (1998).

Types of devices

The use of steel needles is associated with a greater risk of extravasation and should be discouraged and a plastic cannula should be used instead (Sauerland et al. 2006, Schrijvers 2003, Polovich et al. 2014). Vesicants should be given via a newly established cannula wherever possible (Dougherty 2010, Goolsby and Lombardo 2006) and consideration should be given to changing the cannula site after 24 hours. However, if the fluid runs freely, there is good blood return and there are no signs of erythema, pain or swelling at the site, there is no reason to inflict a second cannulation on the patient (Weinstein and Plumer 2007). Consideration should be given to a CVAD if peripheral access is difficult and a decision-making tool can assist with this.

Location of the device

The most appropriate site for the location of a peripheral cannula is considered to be the forearm (Schrijvers 2003, Weinstein and Plumer 2007). However, a large straight vein over the dorsum of the hand is preferable to a smaller vein in the forearm (Weinstein and Plumer 2007). Siting over joints should be avoided as tissue damage in this area may limit joint movement in the future. It is also recommended that the antecubital fossa should never be used for the administration of vesicants because of the risk of

damage to local structures such as nerves and tendons (Gabriel 2008, Weinstein and Plumer 2007). Avoid venepuncture sites in limbs with impaired circulation, sclerosis, thrombosis or scar formation. Also avoid cannulation below a recent venepuncture site (Goolsby and Lombardo 2006).

Sequence of drugs

Vesicants should be given first (Table 12.15) (Goolsby and Lombardo 2006, Kassner 2000, Wilkes and Barton Burke 2011). Reasons for this include the following.

- Vascular integrity decreases over time.
- Vein is most stable and least irritated at start of treatment.
- Initial assessment of vein patency is most accurate.
- Patient's awareness of changes more acute (Weinstein and Plumer 2007).

Methods of administration

Many vesicants must be given as a slow bolus injection, often via the side arm of a fast-running intravenous infusion of a compatible solution, for example doxorubicin or epirubicin via an infusion of 0.9% sodium chloride. If repeated infusions are to be given then a CVAD may be more appropriate (Stanley 2002, Weinstein and Plumer 2007).

Monitoring the site and early recognition of extravasation

Confirm venous patency by flushing with 0.9% sodium chloride solution with at least 5–10 mL prior to administration of vesicants and monitor frequently thereafter (Goolsby and Lombardo 2006, Weinstein and Plumer 2007). Checking blood return after every 2–5 mL is recommended but cannot be relied upon as the key sign when giving a bolus injection; monitor the site every 5–10 minutes for any swelling (Weinstein and Plumer 2007).

It is important that the nurse does not rely in infusion pumps to alarm downstream occlusion and alert her/him to an infiltration or extravasation (Huber and Augustine 2009, Marders 2012) (see Table 12.16 and Box 12.25).

Legal and professional issues

Competencies

Nurses are now being named in malpractice allegations, and infiltration and extravasation injuries are an area for concern (Dougherty 2003, Masoorli 2003, Roth 2003, Weinstein and Plumer 2007). Therefore it is vital that nurses have the correct level of knowledge and skills in order to perform the following:

- correct choice of device and location
- the ability to use the most appropriate vasodilation techniques

Table 12.15 Drug sequencing – rationale for administering vesicant drugs first or last

Vesicants first	Vesicants last
Vascular integrity decreases over time	Vesicants are irritating and increase vein fragility
Vein is most stable and least irritated at start of treatment	Venous spasm may occur and mask signs of extravasation
Initial assessment of vein patency is most accurate	
Patient's awareness of changes more acute	

Source: Adapted from Stanley (2002), Weinstein and Plumer (2007).

Box 12.24 Patients at risk of extravasation

- Infants and young children.
- Elderly patients.
- Those who are unable to communicate, for example sedated, unconscious, confused, language issues.
- Those with chronic diseases, for example cancer, peripheral vascular disease, superior vena cava (SVC) syndrome, lymphoedema.
- Those on medications: anticoagulants, steroids.
- Those who have undergone repeated intravenous cannulation/venepuncture.
- Those with fragile veins or who are thrombocytopenic.

Source: Adapted from Polovich et al. (2014), Sauerland et al. (2006), Wilkes and Barton Burke (2011).

Table 12.16 Nursing assessment of extravasation

Assessment parameter	Flare reaction	Venous irritation	Immediate manifestations, i.e. during drug administration	Delayed manifestations, i.e. from 24 hours after extravasation
Pain	None	Aching, throbbing sensation along vein and in the limb	Severe stinging or burning pain (not always present). This can last from minutes to hours and will eventually subside. Occurs during drug administration at the device site and surrounding areas	Can continue following extravasation or start within 48 hours. Pain may intensify over time
Redness	Immediate blotches or tracking along the vein. This will subside within 30–45 minutes with or without treatment (usually steroid cream)	Vein may become red or darkened	Not always present immediately; more likely to see blanching of the skin. As area becomes inflamed, redness will appear around the device site	Later occurrence
Swelling	Unlikely	Unlikely	May occur immediately but may not always be easy to identify immediately	Usually within 48 hours
Blood return	Usually present	Usually present but may require application of heat to improve blood return	Inability to obtain blood return (peripheral or central) but blood return may be present throughout	
Ulceration	Unlikely	Unlikely	Unlikely	Can occur within 48–96 hours but may take 3–4 weeks to develop
Others	Urticaria	None	Change in quality of the infusion or pressure on the syringe	Local tingling and sensory deficits

- early recognition of infiltration/extravasation and ability to take prompt action (Dougherty 2008b, Goolsby and Lombardo 2006, Sauerland *et al.* 2006, Schrijvers 2003).

Successful cannulation at the first attempt is ideal, as vesicants have been known to seep into tissues at a vein entry site of a previous cannulation (Gault and Challands 1997). This also includes accessing a port as it is vital that the correct needle is selected and that the device is secured adequately (Camp-Sorrell 2005).

Consent

Patients should be informed of the potential problems of administering vesicants and the possible consequences of extravasation (Polovich *et al.* 2014, Sauerland *et al.* 2006, Stanley 2002, Weinstein and Plumer 2007). Adequate information given to patients will ensure early recognition and co-operation as patients are the first to notice pain. The patient should be urged to report immediately any change in sensation such as burning or stinging (Goolsby and Lombardo 2006).

Box 12.25 Signs and symptoms of extravasation

- The patient complains of burning, stinging pain or any other acute change at the injection site, although this is not always present (Polovich *et al.* 2014, Wilkes and Barton Burke 2011). This should be distinguished from a feeling of cold, which may occur with some drugs, or venous spasm which can be caused by irritation usually accompanied by pain described as an achiness or tightness (Wilkes and Barton Burke 2011). Any change of sensation warrants further investigation (Goolsby and Lombardo 2006).
- Swelling is a common symptom (Polovich *et al.* 2014). Induration or leakage may also occur at the injection site. Swelling may not always be immediately obvious if the patient has the cannula sited in an area of deep subcutaneous fat, in a deep vein or if the leak is via the posterior vein wall (Dougherty 2010).
- Blanching of the skin occurs (Comerford *et al.* 2002). Erythema can occur around the injection site but this is not usually present immediately (Wilkes and Barton Burke 2011). It is important that this is distinguished from a flare reaction (Polovich *et al.* 2014).
- Blood return is one of the most misleading of all signs particularly related to peripheral devices. In peripheral devices, if blood return is sluggish or absent, this may indicate lack of patency or incorrect position of the device. However, if no other signs are apparent, this should not be regarded as an indication of a non-patent vein, as a vein may not bleed back for a number of reasons and extravasation may occur even in the event of good blood return as the device may still be in the vein but the leak may be in the posterior vein wall (Wilkes and Barton Burke 2011). Any change in blood flow should be investigated (Weinstein and Plumer 2007, Wilkes and Barton Burke 2011). In CVADs there should always be blood return and if this is absent, steps should be followed to verify correct tip and needle position or resolve a fibrin sheath (see Chapter 14; see Figure 14.4).
- A resistance is felt on the plunger of the syringe if drugs are given by bolus (Stanley 2002).
- There is absence of free flow when administration is by infusion, once other reasons have been excluded, for example position (Polovich *et al.* 2014, Stanley 2002).
- Leaking around the IV cannula or implanted port needle (Polovich *et al.* 2014).

Note: one or more of the above may be present. If extravasation is suspected or confirmed, the injection or infusion must be stopped immediately and action must be taken (INS 2011, Polovich *et al.* 2014, Weinstein and Plumer 2007).

Pre-procedural considerations

Equipment

Extravasation kits

The use of extravasation kits has been recommended in order to provide immediate management (Khan and Holmes 2002). Kits should be assembled according to the particular needs of individual institutions. They should be kept in all areas where staff are regularly administering vesicant drugs, so that staff have immediate access to equipment (Gabriel 2008). The kit should be simple, to avoid confusion, but comprehensive enough to meet all reasonable needs (Stanley 2002) (see Procedure guideline 12.27: Extravasation management: peripheral cannula). Instructions should be clear and easy to follow, and the use of a flowchart enables staff to follow the management procedure in easy steps (Figure 12.41).

Assessment and recording tools

Decision-making tools have been developed both nationally and locally to address issues related to selecting the correct vascular access device (Jackson et al. 2013) as well as grading infiltration (INS 2011). See Figure 12.42 for an example.

Pharmacological support

A number of 'antidotes' are available but, again, there is a lack of scientific evidence to demonstrate their value and so the role of antidotes is still not clear (Polovich et al. 2014). There appear to be two main methods: (i) localize and neutralize (using hyaluronidase) (CP Pharmaceuticals 1999); and (ii) spread and dilute (using an antidote) (Stanley 2002). Administration of injectable antidotes if not via the cannula is by the pincushion technique; that is, instilling small volumes around and over the areas affected using a small-gauge (25) needle towards the centre of a clock face. The procedure causes considerable discomfort to patients and if large areas are to be tackled, analgesia should be considered (Stanley 2002).

Hyaluronidase

This is an enzyme which breaks down hyaluronic acid, a normal component of tissue 'cement', and helps to reduce or prevent tissue damage by allowing rapid (within 10 minutes) diffusion of the extravasated fluid and restoration of tissue permeability within 24–48 hours (Doellman et al. 2009, Few 1987). The usual dose is 1500 international units (Bertelli 1995). It should be injected within 1 hour of extravasation, ideally through the intravenous device delivering the enzyme to the same tissue (Perez Fidalgo et al. 2012, Weinstein and Plumer 2007).

NB: Hyaluronidase increases the absorption of local anaesthetic. Therefore, if local anaesthetic has been applied to the area, for example Ametop gel prior to cannulation, within 6 hours of extravasation, then the patient should be monitored for signs and symptoms of systemic anaesthesia such as increased pulse rate and decreased respirations and the doctor informed immediately (BNF 2014).

Corticosteroids

These have long been advocated as a treatment for anthracycline extravasation in reducing inflammatory components, although inflammation is not a prominent feature of tissue necrosis (Camp-Sorrell 1998) and they appear to have little benefit. Data now discourage the use of locally injected steroids, as there is little evidence to support their use (Bertelli 1995, Gault and Challands 1997, Perez Fidalgo et al. 2012, Wickham et al. 2006). However, given as a cream, they can help to reduce local trauma and irritation (Stanley 2002).

Dimethylsulphoxide (DMSO)

This is a topically applied solvent that may improve systematic absorption of vesicants. It acts as a potent free radical scavenger

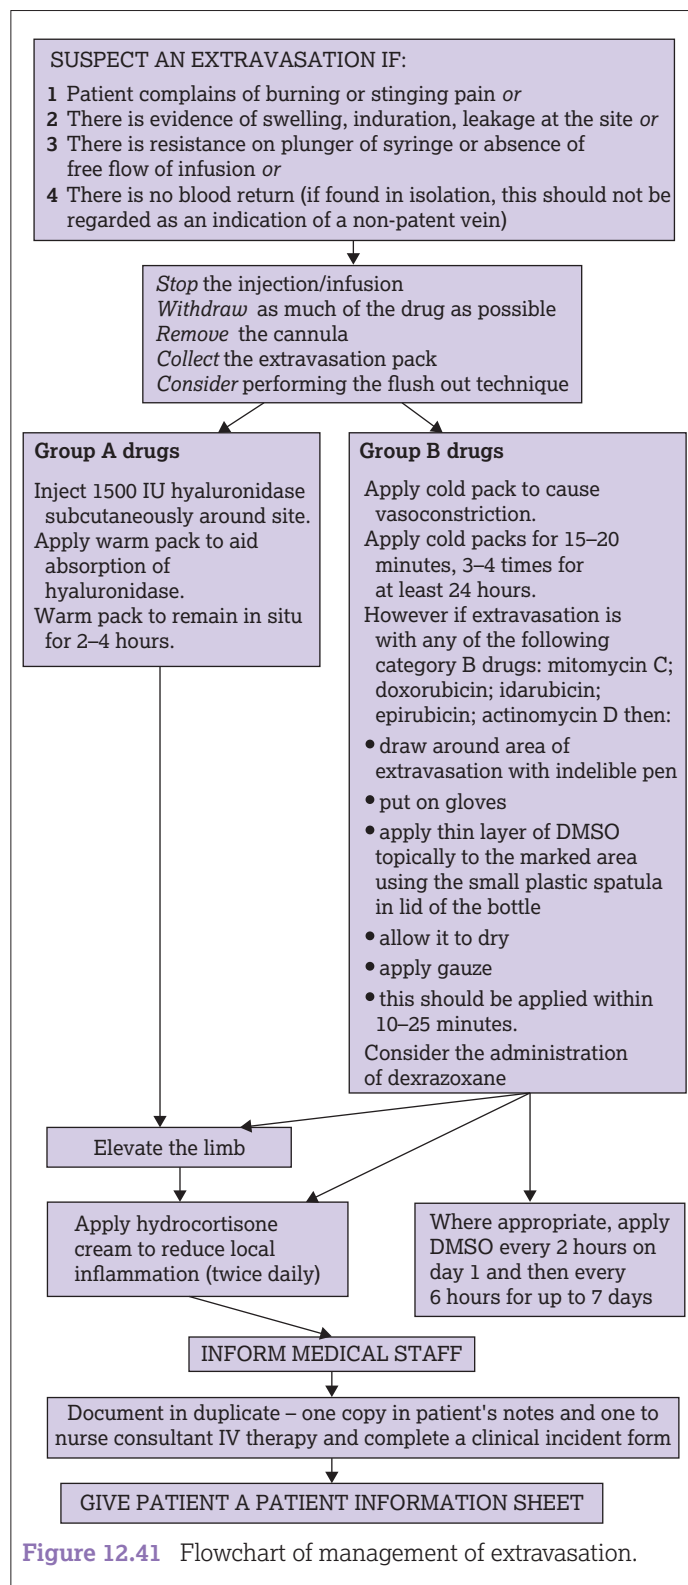

Figure 12.41 Flowchart of management of extravasation.

that rapidly penetrates tissues and prevents DNA damage (Bertelli 1995, Doellman et al. 2009). Reports on the clinical use of topical DMSO show it is effective and well tolerated in extravasation (Bertelli 1995). However, this is based on a high-dose (99%) solution although it is not always available (Perez Fidalgo et al. 2012). Side-effects from DMSO include itching, erythema, mild burning and a characteristic breath odour (Bertelli 1995).

Any drug to be delivered by a continuous ambulatory drug delivery system or TPN must be administered via central venous access.

Patient Identification label	Regimen		Date
	Planned length of treatment		
Vein assessment	Yes	No	<i>Does the patient have accessible peripheral veins of sufficient quality suitable to provide the required level of venous access?</i> <i>Does your team have the necessary skill level to establish peripheral venous access for the patient at every visit?</i>
Absence of larger palpable veins			
Extensive oedema / adipose tissue over forearms			
Inadequate venous fill of target veins			
Significant vein wall rigidity			
Significant cellulitis of forearm and/or upper arms			
Vein availability	Yes	No	<i>Will the patient have accessible peripheral veins available for the proposed term of treatment? (accounting for vein rotation and deterioration)</i>
Axillary lymph node clearance			
Upper limb/axilla/SVC venous thrombosis			
Extensive skin lesions - forearms			
Previous CVA			
Thrombo-phlebitis present			
VAD insertion & patency factors	Yes	No	<i>Is there an increased risk of cannula dislodgement, haematoma formation or thrombo-phlebitis for the patient with peripheral venous access?</i> <i>Is there an increased risk of infection for this patient? e.g. long-term steroid therapy</i>
Fragile skin quality			
Decreased platelets < 50 x 10 ⁹ /L			
Anticoagulant therapy i.e warfarin, aspirin, LMW heparin			
Anxiety / Needle phobia			
Factors affecting long-term venous access patency			<i>Will the patient be receiving therapy where intensive fluid management will be required? (such as concentrated electrolytes)</i> <i>Is there an increased risk of vein deterioration and thrombo-phlebitis in the patient?</i> <i>Would a skin tunnelled catheter or implanted port offer a lower risk of site infection for the patient?</i>
Vesicant and/or irritant therapy for > 6 cycles			
Anticipated intensive IV therapy, i.e. blood products, electrolyte support, fluid support, multiple antimicrobial therapy			
Expected periods of sustained neutropenia (<0.5 x 10 ⁹ /L for > 7 days)			
Co-morbidities that may affect peripheral venous access	Yes	No	<i>The effects of co-morbidities individual to the patient must be accounted when undertaking a venous access assessment.</i> <i>Would the patient be able to cope with the presence of a CVAD and notify the team appropriately to report adverse events?</i>
Diabetes			
Peripheral vascular disease			
Raynaud's phenomenon			
Hypotension

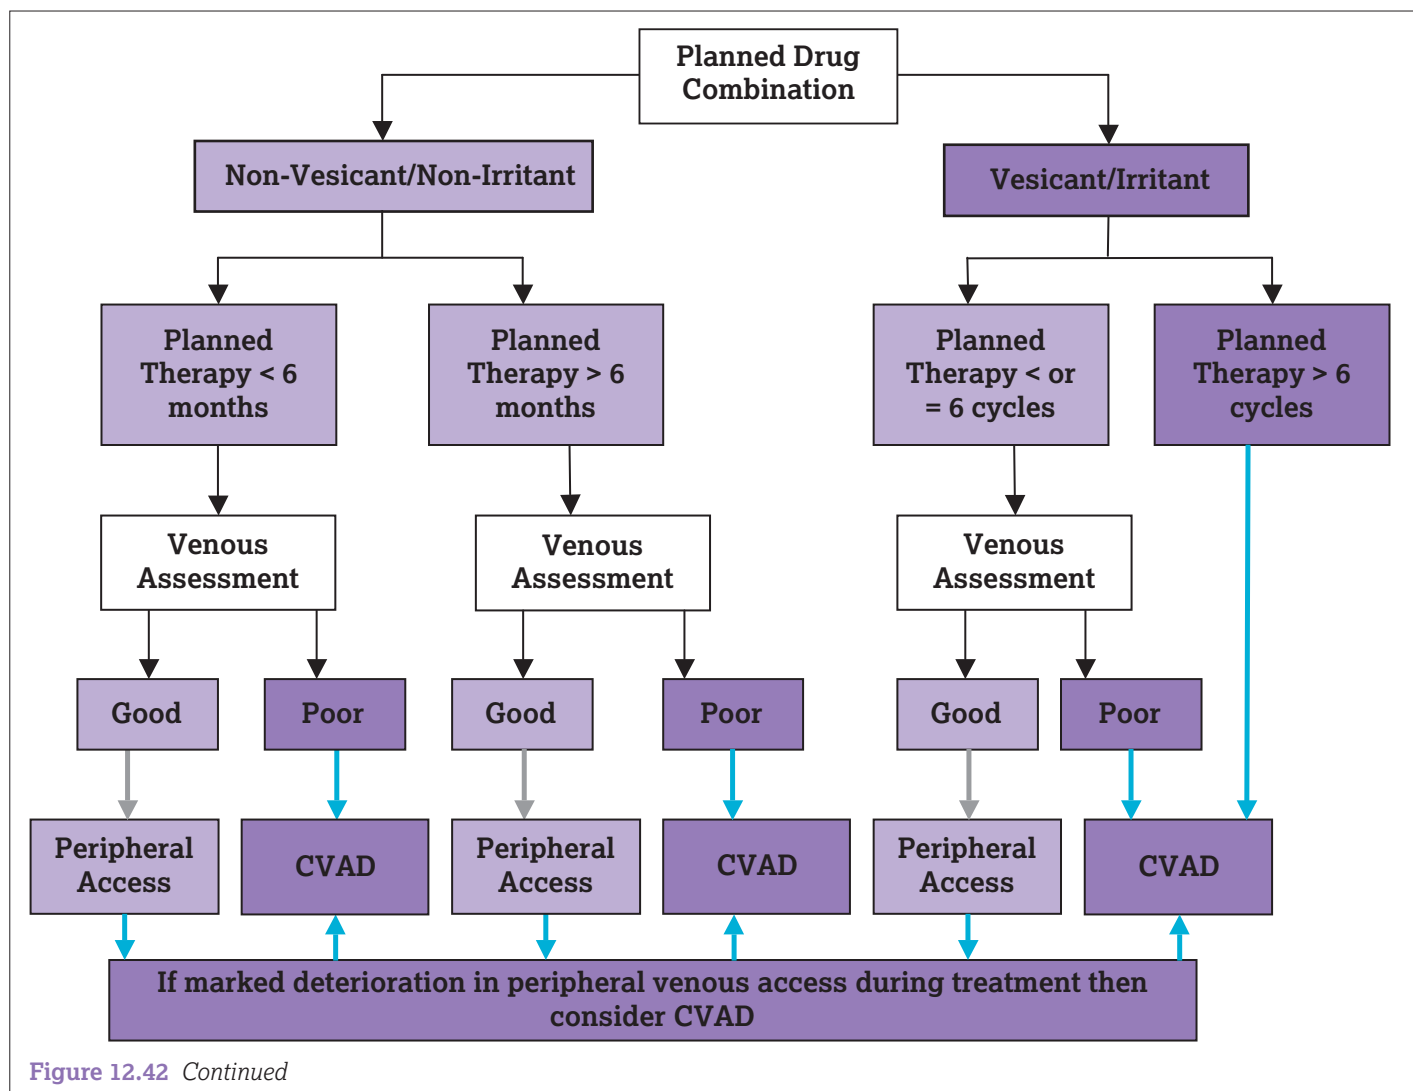

Figure 12.42 Continued

Dexrazoxane (Savene)

A topoisomerase II catalytic inhibitor, used clinically to minimize the cardiotoxicity of doxorubicin, was first tested in animals (Langer et al. 2006) and then a small number of patients for its use in extravasation (Doroshov 2012). It is given IV as soon as possible after the extravasation and it appears to reduce the wound size and duration of tissue damage with anthracyclines. The triple dosage appears to be more effective than a single dose (El-Saghir et al. 2004, Langer et al. 2000). In two multicentre studies, it was shown that the administration of Savene reduced the need for surgical interventions, and late sequelae such as pain, fibrosis, atrophy and sensory disturbance were judged as mild (Mouridsen et al. 2007, Doroshov 2012).

A consensus group (Jackson 2006) developed recommendations for the use of dexrazoxane and these have been further adapted by the European Oncology Nursing Society (2007) which recommended that for anthracycline extravasations resulting from peripheral administration, the site expert or team should be consulted in order to determine whether the use of dexrazoxane is indicated. Absolute indications are if the peripherally extravasated volume exceeds 3–5 mL and in the event of a central venous access device extravasation (Langer 2008). It is now included in many treatment algorithms for anthracycline extravasations (Gonzalez 2013, Perez Fidalgo et al. 2012).

Granulocyte macrophage-colony stimulating factor

Finally, granulocyte macrophage-colony stimulating factor (GM-CSF) is a growth factor and is effective in accelerating wound healing and inducing formation of granulation tissue (El-Saghir et al. 2004, Ulutin et al. 2000).

Non-pharmacological support

Stopping infusion/injection and aspirating the drug

It appears that most authors agree that aspirating as much of the drug as possible, as soon as extravasation is suspected, is beneficial (Polovich et al. 2014, Rudolph and Larson 1987, Weinstein and Plumer 2007) and can help lower the concentration of drug in the area (Goolsby and Lombardo 2006). However, withdrawal is only possible immediately during bolus injections, because if the drug was being delivered via an infusion, this would need to be stopped and a syringe attached in an attempt to aspirate. Aspiration may be successful if extravasation presents as a raised blister, but may be unsuccessful if tissue is soft and soggy (CP Pharmaceuticals 1999, Stanley 2002). It may help to reduce the size of the lesion. In practice, it may achieve little and often distresses the patient (Gault and Challands 1997). The likelihood of withdrawing blood, as suggested by Ignoffo and Friedman (1980), is small and the practitioner may waste valuable time attempting

this which could lead to delay in the rest of the management procedure.

Removing the device

Some clinicians advocate that the peripheral vascular access device be left *in situ* in order to instil the antidote via the device into the affected tissues (Kassner 2000, Stanley 2002, Weinstein and Plumer 2007). However, others recommend that the peripheral device should be removed to prevent any injected solution increasing the size of the affected area (CP Pharmaceuticals 1999, Rudolph and Larson 1987). There appears to be no research evidence to support either practice.

Application of hot or cold packs

Cooling appears to be a better choice, with the exception of the vinca alkaloids and some non-cytotoxic drugs, than warming (Bertelli 1995, CP Pharmaceuticals 1999). Cold causes vasoconstriction, localizing the extravasation and perhaps allowing time for local vascular and lymphatic systems to contain the drug. It should be applied for 15–20 minutes, 3–4 times a day for up to 3 days (CP Pharmaceuticals 1999, Gault and Challands 1997, Polovich et al. 2014). Heat promotes healing after the first 24 hours by increasing the blood supply (Polovich et al. 2014, Weinstein and Plumer 2007). It also decreases local drug concentration, increasing the blood flow which results in enhanced resolution of pain and reabsorption of any localized swelling.

Elevation of limb

This is recommended as it minimizes swelling (Rudolph and Larson 1987). This can be achieved by use of a Bradford sling but this is usually recommended when the extravasation has occurred in the hand. Gentle movement should be encouraged to prevent adhesion of damaged areas to underlying tissue (Gabriel 2008).

Surgical techniques

It is now recognized that a plastic surgery consultation should form part of the management procedure in order to remove the tissue containing the drug. Surgical intervention is recommended, especially if the lesion is greater than 2 cm, there is significant residual pain 1–2 weeks after extravasation, or there is minimal healing 2–3 weeks after injury despite local therapeutic measures (Goolsby and Lombardo 2006, Perez Fidalgo et al. 2012). A liposuction cannula can be used to aspirate extravasated material and subcutaneous fat or a flush-out technique can remove extravasated drug without resorting to excision and skin grafting.

Flush-out technique

If there is little subcutaneous fat, then the saline flush-out technique is recommended, particularly if it is done within the first 24 hours (Dionyssiou et al. 2011, Gault 1993). It has been suggested as a less traumatic and cheaper procedure than surgery. Only appropriately trained doctors or nurses may perform the flush-out technique for superficial peripheral extravasations where there is no visible skin damage or extensive swelling (Dougherty and Oakley 2011). A number of small stab incisions are made and large volumes of 0.9% sodium chloride are administered which flush out the extravasated drug (Dougherty and Oakley 2011, Gault and Challands 1997); this is more successful if performed within 24 hours of extravasation (Dionyssiou et al. 2011) (see Procedure guideline 12.28: Extravasation: performing flush-out following an extravasation).

Management of infiltration

Treatment is often dependent upon the severity of the infiltration. There should be ongoing observation and assessment of the infiltrated site. The presence and severity of the infiltration should be documented. Infiltration statistics should include frequency, severity and type of infusate. The infiltration rate should be calculated according to a standard formula (INS 2011, RCN 2010).

Procedure guideline 12.27 Extravasation management: peripheral cannula

This procedure was drawn up with the assistance of pharmacist and medical colleagues. It relates specifically to the management of extravasation of a drug from a peripheral cannula.

Essential equipment

- Gel packs × 2: one to be kept in the fridge and one available for heating (an electric heating blanket can be used whilst pack is heating)
- 2 mL syringe × 1
- 25 G needle × 1
- 23 G needle × 1
- Alcohol swabs
- Documentation forms
- Copy of extravasation management procedure
- Patient information leaflet
- Prescription chart

Medicinal products

- Hyaluronidase 1500 international units/2 mL sterile water
- Hydrocortisone cream 1% 15 g tube × 1
- Savene (dexrazoxane) (optional)
- DMSO topical solution (99%)

Pre-procedure

Action

- 1 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.

Rationale

To minimize the risk of infection (DH 2007, **C**; Fraise and Bradley 2009, **E**).

Procedure

- 2 Stop injection or infusion *immediately*, leaving the cannula in place.

To minimize local injury. To allow aspiration of the drug to be attempted (Polovich et al. 2014, **C**; RCN 2010, **C**).

3 Aspirate any residual drug from the device and suspected extravasation site.	To minimize local injury by removing as much drug as possible but only attempt if appropriate. Subsequent damage is related to the volume of the extravasation, in addition to other factors (Polovich et al. 2014, C ; RCN 2010, C).
4 Remove the cannula.	To prevent the device from being used for antidote administration (Rudolph and Larson 1987, E).
5 Consider contacting the extravasation team and whether the flush-out technique would be appropriate (see Figure 12.41).	Flush-out is most effective if undertaken as soon as extravasation is suspected (Gault 1993, E).
6 Collect the extravasation pack and take it to the patient.	It contains all the equipment necessary for managing extravasation (Dougherty 2010, E ; Stanley 2002, E).
7 <i>Either:</i> For Group A drugs: <ul style="list-style-type: none"> • Draw up hyaluronidase 1500 IU in 1 mL water for injection and inject volumes of 0.1–0.2 mL subcutaneously at points of the compass around the circumference of the area of extravasation. • Apply warm pack. <i>Or:</i> For Group B drugs (except those listed below): <ul style="list-style-type: none"> • Apply cold pack or ice instantly. <i>Or:</i> If extravasation is with any of the following category B drugs: mitomycin C, doxorubicin, idarubicin, epirubicin, actinomycin D, then: <ul style="list-style-type: none"> • Draw around area of extravasation with indelible pen. • Put on gloves. • Apply thin layer of DMSO topically to the marked area using the small plastic spatula in lid of the bottle. Allow it to dry. • Apply gauze. • This should be applied within 10–25 minutes. <i>Or:</i> If extravasation of doxorubicin, epirubicin, idarubicin or daunorubicin occurs (i.e. 5 mL or more peripherally or any volume from a central venous access device) then stop cold pack, do not apply DMSO and contact member of extravasation team to advise on use of dexrazoxane.	<p>This is the recommended agent for group A drugs. The warm pack speeds up absorption of the drug by the tissues (Bertelli 1995, E).</p> <p>To localize the area of extravasation, slow cell metabolism and decrease the area of tissue destruction. To reduce local pain (Polovich et al. 2014, C).</p> <p>This is the recommended agent for these anthracyclines and helps to reduce local tissue damage (Bertelli 1995, C).</p> <p>Cooling and DMSO interfere with the efficacy of dexrazoxane and it should be administered as soon as possible after extravasation (El Saghir et al. 2004, E; Langer et al. 2000, E).</p>
8 Where possible, elevate the extremity and/or encourage movement.	To minimize swelling and to prevent adhesion of damaged area to underlying tissue, which could result in restriction of movement (Rudolph and Larson 1987, E).
Post-procedure	
9 Inform a member of the medical staff at the earliest opportunity and administer any other prescribed antidotes, for example dexrazoxane.	To enable actions differing from agreed policy to be taken if considered in the best interests of the patient. To notify the doctor of the need to prescribe any other drugs. E
10 Apply hydrocortisone cream 1% twice daily, and instruct the patient how to do this. Continue as long as erythema persists.	To reduce local inflammation and promote patient comfort (Stanley 2002, E).
11 Where appropriate, apply DMSO every 2 hours on day 1 and then every 6 hours for up to 7 days (patients will need to have this prescribed as a 'to take out' [TTO] and continue treatment at home where necessary).	To help reduce local tissue damage (Bertelli 1995, E).
12 Heat packs (group A drugs) should be reapplied after initial management for 2–4 hours. Cold packs (group B drugs) should be applied for 15–20 minutes, 3–4 times a day for up to 3 days.	To localize the steroid effect in the area of extravasation. To reduce local pain and promote patient comfort (Bertelli 1995, E).

(continued)

Procedure guideline 12.27 Extravasation management: peripheral cannula (continued)

Action	Rationale
13 Provide analgesia as required.	To promote patient comfort. To encourage movement of the limb as advised. E
14 Dispose of waste in appropriate containers.	To ensure safe disposal and avoid laceration or injury to other staff (DH 2005, C ; EU 2010, C).
15 Document the following details, in duplicate, on the form provided. (a) Patient's name/number (b) Ward/unit (c) Date, time (d) Signs and symptoms (e) Cannulation site (on diagram) (f) Drug sequence (g) Drug administration technique, that is, 'bolus' or infusion (h) Approximate amount of the drug extravasated (i) Diameter, length and width of extravasation area (j) Appearance of the area (k) Step-by-step management with date and time of each step performed and medical officer notification (l) Patient's complaints, comments, statements (m) Indication that the patient information sheet has been given to patient (n) Follow-up section (o) Whether photograph was taken (p) If required, when patient referred to plastic surgeon (q) Signature of the nurse	To provide an immediate full record of all details of the incident, which may be referred to if necessary. To provide a baseline for future observation and monitoring of patient's condition. To comply with NMC guidelines (NMC 2010b, C ; RCN 2010, C ; Schulmeister 2009, E ; Weinstein and Plumer 2007, E).
16 Explain to the patient that the site may remain sore for several days.	To reduce anxiety and ensure continued co-operation. P, E
17 As part of the follow-up, all patients should receive written information explaining what has occurred, what management has been carried out, what they need to look for at the site and when to report any changes. For example, increased discomfort, peeling or blistering of the skin should be reported immediately.	To detect any changes as early as possible, and allow for a review of future management. This may include referral to a plastic surgeon (Gault and Challands 1997, E ; Polovich et al. 2014, C ; RCN 2010, C).
18 Observe the area regularly for erythema, induration, blistering or necrosis. <i>Inpatients</i> : monitor daily. Where appropriate, take photograph.	To detect any changes at the earliest possible moment (RCN 2010, C).
19 If blistering or tissue breakdown occurs, begin dressing techniques and seek advice regarding wound management.	To minimize the risk of a superimposed infection and increase healing (Naylor 2005, E).
20 Depending on size of lesion, degree of pain, type of drug, refer to plastic surgeon.	To prevent further pain or other complications as chemically induced ulcers rarely heal spontaneously (Dougherty 2010, E ; Polovich et al. 2014, C).

Procedure guideline 12.28 Extravasation: performing flush-out following an extravasation

This procedure would begin once the immediate management of extravasation had been performed; that is, stop infusion/injection, aspirate any drug if possible, apply appropriate pack and elevate limb.

Essential equipment

- Eye protection
- Disposable gown
- 20 mL Luer-Lok syringe × 1
- 10 mL Luer-Lok syringe × 1
- 5 mL Luer-Lok syringe × 1
- 25 G needle × 1
- 23 G needle × 3
- Disposable scalpel (size 11)
- Bandage
- Sterile pack (containing gauze, drapes/towels and gallipot)
- Sterile gloves
- Cleaning solution (2% chlorhexidine Chloraprep 3 mL)
- Blunt needle/18 G or 20 G cannula × 4
- Three-way tap with extension set
- Blank labels for syringes
- Solution administration set
- Sterile marker pen
- Plastic-backed towel (e.g. incontinence pad)
- Transparent dressing (large)
- Sterile scissors
- Extra gauze swabs

Medicinal products

- Lidocaine 1% 10 mL (kept at room temperature)
- Hyaluronidase 1500 international units and 2 mL water for injection
- Mepitel dressing
- 500 mL 0.9% sodium chloride infusion bag
- Bactericidal alcohol handrub
- Bactericidal soap

Pre-procedure

Action	Rationale
1 Explain the procedure and reason for performing it to the patient and gain written consent using pre-prepared consent form.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Ascertain what emergency treatment has been carried out, for example was hyaluronidase administered?	To ensure that only required treatment is carried out; for example, if hyaluronidase has been given, no further dose would be administered as this could result in a sensitivity reaction. E
3 Assemble all the equipment necessary for the procedure.	To ensure that time is not wasted and the procedure goes smoothly without any unnecessary interruptions. E
4 Check all packaging before opening and preparing the equipment to be used.	To maintain asepsis throughout and check that no equipment is damaged or out of date (Fraise and Bradley 2009, E).
5 Carefully wash hands using bactericidal soap and water or bactericidal alcohol handrub before commencement and dry.	To minimize the risk of infection (DH 2007, C).
6 Place the patient's arm on the plastic-backed towel.	To prevent leakage of the flushed-out solution and possible contamination of the area with cytotoxic drugs. E
7 Apply disposable gown and eye protection.	To prevent possible contamination of practitioner with cytotoxic drugs. E
8 Open a pack, empty all equipment onto the pack and place a sterile dressing towel under the patient's arm.	To create a sterile working area. E
9 Wash hands using bactericidal soap and water.	To minimize the risk of infection (DH 2007, C ; Fraise and Bradley 2009, E).
10 Apply sterile gloves.	To minimize the risk of infection (DH, 2007, C ; Fraise and Bradley 2009, E) and prevent contamination of the nurse.
11 Clean skin with 2% chlorhexidine and allow the area to dry.	To maintain asepsis and remove skin flora (DH, 2007, C ; Fraise and Bradley 2009, E).

Procedure

12 Draw up 1% lidocaine in 10 mL syringe.	To prepare for infiltration of area. E
13 Mix hyaluronidase with sterile water in a separate 5 mL syringe	To ensure drug is reconstituted correctly (BNF 2014, C).
14 Mark the area of extravasation with a sterile marker where incisions will be made.	To ensure the correct area is treated. E
15 Using a 25 G needle, make a small bleb by inserting the needle intradermally and administering 0.1–2 mL of lidocaine slowly towards the four points of the compass. Allow it to take effect.	To reduce any discomfort to the patient. E
16 Then, using a 23 G needle, infiltrate the marked area with lidocaine subdermally towards the four points of the compass. Check with patient what kind of sensation they can feel, for example sharp or dull, before proceeding.	To ensure administration of anaesthetic to area and to ensure anaesthetic has taken effect. E
17 Attach a 23 G needle to the syringe of hyaluronidase and infiltrate the anaesthetized area at the four points of the compass.	This will facilitate the flush-out by loosening the tissues. E
18 Cut an opening in a transparent dressing that matches the size of the infiltrated area and apply to the patient's skin.	To protect the skin from the flushed-out vesicant drugs. E
19 Attach the administration set, three-way tap and extension set to the bag of 0.9% sodium chloride and withdraw 20 mL via the tap.	To prepare the syringe and to enable continued access without having to open the system. E

(continued)

Procedure guideline 12.28 Extravasation: performing flush-out following an extravasation (continued)

Action	Rationale
20 Make at least four incisions at the four points of the compass using a size 11 scalpel by inserting the blade straight down to a depth of no more than 0.5 cm and one small incision to use for insertion of the cannula.	To prepare the area for flushing. The number of incisions will depend on the size of the area to be treated. To reduce risk of damage to tendons or other anatomical structures (Gault 1993, E).
21 Gently press on the area.	This alone may allow the fluid to escape (Gault 1993, E).
22 Insert the cannula through one of the incisions and push along tissues within the marked area.	To free up tissues from skin and to aid advancement of cannula and flush (Gault 1993, E).
23 Remove the stylet and attach the extension set to the cannula.	To facilitate the flushing. E
24 Flush the 0.9% sodium chloride through – it will exit out of the other incision holes. Pat with a sterile gauze swab, massaging and milking the area at the same time. The area will become puffy and swollen – this is normal.	To commence the flushing procedure. To assist with removal of saline (Gault 1993, E).
25 Draw up more 0.9% sodium chloride and repeat procedure using a minimum of 100 mL (up to 500 mL) of 0.9% sodium chloride.	To facilitate the flushing of the drug from the area (Gault 1993, E).
26 If saline does not flow out of one incision, it may be necessary to remove the cannula from the original incision and insert a new cannula into another one.	To ensure all areas are flushed. E
Post-procedure	
27 Remove the transparent dressing and clean and dry the area although it will continue to leak.	To aid patient comfort. E
28 Apply a Mepitel dressing and a loose bandage (do not wrap tightly).	To reduce the risk of infection and to prevent compression of the skin. E
29 Elevate the limb so that the hand is level with the head whenever the patient is at rest.	To aid reduction of oedema. E
30 Discard waste in appropriate containers.	To ensure safe disposal in the correct containers and avoid laceration or injury of other staff (DH 2005, C ; EU 2010, C).
31 Document in the patient's medical and nursing notes and on the flush-out technique form.	To ensure adequate records and enable continued care of the patient (NMC 2010b, C).
32 Discuss with medical colleagues the prescribing of oral antibiotics (flucloxacillin is recommended for reducing skin pathogens) and if necessary analgesia.	If the patient is neutropenic they may be more at risk of infection. To minimize pain and discomfort. E
33 Refer to a plastic surgeon if there are any problems during procedure or if there are any skin problems.	To ensure rapid access for further management. E
34 Monitor and review within first 24 hours. Have photograph taken if possible.	To observe and document for any skin changes or infection and provide immediate treatment. E
35 Dressing will need to be changed every 48 hours and should remain <i>in situ</i> for up to a week. The skin incisions will heal within 1–2 weeks.	To prevent risk of infection. E
36 Ensure the patient knows when and how to make contact if they have any problems once at home. Organize for the patient to return for dressing changes at the hospital or with the community nurses. Inform the patient to contact the hospital if: <ul style="list-style-type: none"> • the swelling does not reduce • they have pain • there is any tingling or numbness in the fingers or arm. 	To ensure patient receives immediate treatment should there be any problems post procedure. E

Post-procedural considerations**Ongoing care**

Patient follow-up will be dependent upon the patient's needs and the degree of damage. Assessment should include inspection and management of the area of extravasation, skin integrity, presence

of pain, other symptoms such as mobility and sensation of the limb (see Table 12.17). If damage has occurred, it will be affected by the site, amount of drug, concentration of the agent and if it binds to DNA or not (Polovich et al. 2014). Blistering may occur within 24 hours (for example, with vinorelbine) or ulceration may occur over a period of days to weeks (for example, with epirubicin)

Table 12.17 Grading scale for monitoring extravasation

Grade	1	2	3	4	5
Skin colour	Normal	Pink	Red	Blanched area surrounded by red	Blackened
Skin integrity	Unbroken	Blistered	Superficial skin loss	Tissue loss and exposed subcutaneous tissue	Tissue loss and exposed bone/muscle with necrosis/crater
Skin temperature	Normal	Warm	Hot		
Oedema	Absent	Non-pitting	Pitting		
Mobility	Full	Slightly limited	Very limited	Immobile	
Pain	Grade using a scale of 0–10 where 0 = no pain and 10 = worst pain				
Temperature	Normal	Elevated (indicate actual temperature)			

and extravasation wounds may be complicated by tissue ischaemia related to endothelial damage (Naylor 2005). The type of injury will dictate the type of dressing. Assessment of the wound should include position and size of the wound, amount and type of tissue present, amount and type of exudate, and extent and spread of erythema (Naylor 2005). If the flush-out technique has been undertaken then the incisions should be dressed using a dressing that allows the fluid to continue to leak from the site, for example Mepitel. It is also important to recognize the impact on the patient's psychological and situational dynamics that may diminish their quality of life (Gonzalez 2013).

Documentation

An extravasation must be reported and fully documented as it is an accident and the patient may require follow-up care (NMC 2010b, RCN 2010). The ONS lists the key elements of vesicant extravasation documentation (Polovich et al. 2014) (Box 12.26). Statistics on the incidence, degree, causes and corrective action should be monitored and analysed (Gonzalez 2013, INS 2011, Perez Fidalgo et al. 2012). Finally, records may be required in the case of litigation, which is now on the increase (Doellman et al. 2009, Dougherty 2003, Masoorli 2003).

Education of patient and relevant others

Patients should always be informed when an extravasation has occurred and be given an explanation of what has happened and

what management has been carried out (McCaffrey Boyle and Engelking 1995). An information sheet should be given to patients with instructions of what symptoms to look out for and when to contact the hospital during the follow-up period (Gabriel 2008).

Complications

If the extravasation is not managed correctly then an injury will result. In certain circumstances, in spite of managing an extravasation, an injury can still result and must be dealt with on an individual basis. Following the flush-out technique, it may be necessary to administer prophylactic antibiotics to prevent local infection (although this is rare).

Allergic reaction

This is a complication associated with any medication administration but because it happens more rapidly when IV medication is administered, it is often considered as more of an issue.

An allergic reaction is a response to a medication or solution to which the patient is sensitive and may be immediate or delayed (Lamb and Dougherty 2008, Perucca 2010). Clinical features may start with chills and fever, with or without urticaria, erythema and itching. The patient could then go on to experience shortness of breath with or without wheezing, then angioneurotic oedema and in severe cases anaphylactic shock (Lamb and Dougherty 2008). Prevention is by assessment and recording of patient allergies (drug, food and products) and application of allergy identification wristbands (NPSA 2008a, Perucca 2010). In the event of an allergic reaction, the infusion should be stopped immediately, the tubing and container changed and the vein kept patent. The doctor should be notified and any interventions undertaken (Lamb and Dougherty 2008).

Circulatory overload (isotonic fluid expansion)

A critical and common complication of intravenous therapy is circulatory overload, which is *isotonic fluid expansion*. It is caused by infusion of fluids of the same tonicity as plasma into the vascular circulation, for example sodium chloride 0.9%. As isotonic solutions do not affect osmolarity, water does not flow from the extracellular to the intracellular compartment. The result is that the extracellular compartment expands in proportion to the fluid infused (Weinstein and Plumer 2007). Because of the electrolyte concentration, no extra water is available to enable the kidneys selectively to excrete and restore the balance. It can also occur due to:

- infusing excessive amounts of sodium chloride solutions
- large-volume infusions running over multiple days
- rapid fluid infusion into patients with compromised cardiac, liver or renal status (Lamb and Dougherty 2008, Macklin and Chernenky 2004).

Box 12.26 Key elements of vesicant extravasation documentation

- Date and time the extravasation occurred
- Type and size of vascular access device
- Length and gauge of needle (ports only)
- Location of device
- Details of how patency was established before and during administration (description and quality of blood return)
- Number and location of all cannulation attempts
- Vesicant administration method, for example bolus, infusion
- Estimated amount of extravasated drug
- Symptoms reported by the patient
- Description of device site, for example swelling, redness and so on
- Assessment of limb (where applicable) for range of movement
- Immediate nursing interventions
- Follow-up interventions
- Patient information

Prevention includes thorough assessment of the patient before commencing IV therapy, close monitoring of patient, maintaining infusion rates as prescribed and use of infusion devices where required (Lamb and Dougherty 2008). If circulatory overload is detected early, sit the patient upright (Macklin and Chernecky 2004). Treatment consists of withholding all fluids until excess water and electrolytes have been eliminated by the body and/or administration of diuretics to promote rapid diuresis (Weinstein and Plumer 2007). However, careful monitoring should continue to prevent isotonic contraction occurring (where there is loss of fluid and electrolytes isotonic to the extracellular fluid such as blood and large volumes of fluid from diarrhoea and vomiting; Weinstein and Plumer 2007). If fluid administration is allowed to continue unchecked, it can result in left-sided heart failure, circulatory collapse and cardiac arrest (Dougherty 2002).

Dehydration

Dehydration may be categorized as either hypertonic or hypotonic contraction and may be caused by underinfusion. Hypertonic contraction occurs when water is lost without corresponding loss of salts (Weinstein and Plumer 2007) and occurs in patients unable to take sufficient fluids (elderly, unconscious or incontinent patients) or who have excessive insensible water loss via skin and lungs or as a result of certain drugs in excess. Hypotonic

contraction occurs when fluids containing more salt than water are lost and this results in a decrease in osmolarity of the extracellular compartment (Weinstein and Plumer 2007).

It is important that the nurse recognizes the symptoms of over-infusion or underinfusion and certain factors should be considered when monitoring patients (Weinstein and Plumer 2007) (Table 12.18).

Speed shock

Speed shock is a systemic reaction that occurs when a substance foreign to the body is rapidly introduced into the circulation (Perucca 2010, Weinstein and Plumer 2007). This complication can manifest following administration of intravenous bolus injections or when large volumes of fluid are given too rapidly (Perucca 2010). This should not be confused with pulmonary oedema, which relates to the volume of fluid infused into the patient. Rapid, uncontrolled administration of drugs will result in toxic concentrations reaching vital organs (Lamb and Dougherty 2008). Toxicity may be manifested by an exaggeration of the usual pharmacological actions of the drug or by signs and symptoms specific for that drug or class of drugs. The most extreme toxic response which can occur if a drug is given at a dose or rate exceeding that recommended is termed the lethal response.

Table 12.18 Monitoring overinfusion and underinfusion

Type of fluid/ electrolyte imbalance	Patients at risk	Signs and symptoms	Treatment
Circulatory overload (isotonic fluid expansion)	Early post-operative or post-trauma patients, older people, those with impaired renal and cardiac function and children	Weight gain A relative increase in fluid intake compared to output A high bounding pulse pressure, indicating a high cardiac output Raised central venous pressure measurements Peripheral hand vein emptying time longer than normal (peripheral veins will usually empty in 3–5 seconds when the hand is elevated and will fill in the same length of time when the hand is lowered to a dependent position) Peripheral oedema Hoarseness Dyspnoea, cyanosis and coughing due to pulmonary oedema and neck vein engorgement	If detected early: withholding all fluids until excess water and electrolytes have been eliminated by the body and/or administration of diuretics to promote rapid diuresis
Dehydration (hypertonic contraction or hypotonic contraction)	<i>Hypertonic:</i> elderly, unconscious or incontinent patients <i>Hypotonic:</i> infants are at greatest risk, especially if they have diarrhoea. Loss of salt from various sources: excess diuresis, fistula drainage, burns, vomiting or sweating	<i>Hyper/hypotonic contraction:</i> weight loss <i>Hypercontraction:</i> thirst (although this may be absent in the elderly) Irritability and restlessness and possible confusion Diminished skin turgor Dry mouth and furred tongue <i>Hypocontraction:</i> negative fluid balance Weak, thready, rapid pulse rate Increased 'hand filling time' Increased skin turgor	Replacement of fluids and electrolytes

Signs of speed shock may include:

- flushed face
- headache and dizziness
- congestion of the chest
- tachycardia and fall in blood pressure
- syncope
- shock
- cardiovascular collapse (Perucca 2010, Weinstein and Plumer 2007).

Prevention of speed shock involves the nurse having knowledge of the drug and the recommended rate of administration. When commencing an infusion using gravity flow, check that the solution is flowing freely before adjusting the rate and monitored regularly (Perucca 2010). Movement of the patient or the device within the vessel can cause the infusion to flow more or less freely after a few minutes of setting the rate (Weinstein and Plumer 2007). For high-risk medications an electronic flow control device is recommended (RCN 2010). Although most pumps have an anti-free flow mechanism, always close the roller clamp prior to removing the set from the pump (MHRA 2006a, Pickstone 1999).

If speed shock occurs, the infusion must be slowed down or discontinued. Medical staff should be notified immediately and the patient's condition treated as clinically indicated (Perucca 2010).

Chapter 13

Perioperative care

Procedure guidelines

- 13.1** Step-by-step guide to measuring and applying antiembolic stockings 802
- 13.2** Pre-operative care: checking that the patient is fully prepared for surgery 811
- 13.3** Caring for the patient in the anaesthetic room 816
- 13.4** Operating theatre procedure: maintaining the safety of a patient while undergoing surgery 824
- 13.5** Handover in post-anaesthetic care unit: scrub nurse/ODP to recovery practitioner 827
- 13.6** Safe management of the patient in the PACU 829
- 13.7** Drainage systems: changing the dressing around the drain site for both open and closed drains 838
- 13.8** Closed drainage systems: changing a vacuum bottle 839
- 13.9** Wound drain removal: closed drainage system 841
- 13.10** Wound drain shortening for open drainage systems 843
- 13.11** Wound drain shortening for closed drainage systems 845

Overview

Care of the patient undergoing any surgical procedure begins pre-operatively. The patient is pre-assessed and any appropriate investigations are undertaken to ensure they are physically able to undergo the surgery and be mentally prepared for the process. The care continues in the immediate pre-operative phase to ensure the patient is prepared adequately for the surgical procedure and to mitigate associated risks. Intraoperative care usually comprises three phases: induction of anaesthesia, surgery and recovery of the patient within the post-anaesthetic care unit (PACU). As care within surgery is delivered by a multidisciplinary team, a thorough handover of the patient is essential at every stage. The care continues beyond the intraoperative phase when the patient receives post-operative care both before and after discharge from hospital. The amount and complexity of post-operative care required will vary significantly according to the nature of the surgery (minor, major, laparoscopic, robotic, etc.) and the physical, mental and social status of the patient.

This chapter relates to the care provided to the patient in all three stages of surgery:

- 790 • pre-operative care
- intraoperative care
- post-operative care.

Pre-operative care

Definition

Pre-operative care is the physical and psychosocial care provided to the patient to help them prepare to safely undergo surgery. Psychosocial preparation includes assessing and managing stress, patient education and informed consent, whilst physical preparation is concerned with the prevention of peri- and post-operative complications (Liddle 2012, Scott et al. 2007).

Related theory

Optimal pre-operative care is underpinned by thorough assessment and planning. The assessment aims to reduce cancellations on the day of surgery, rationalize the amount of investigations and tests required pre-operatively (so ensuring there are no unnecessary costs) and reduce patient anxiety whilst improving post-operative outcomes for patients (Pritchard 2012). This is ensured by properly managing and optimizing any co-morbidities pre-operatively that may affect the perioperative care of the patient. Because general anaesthesia is considered a risk to the patient, it is necessary to 'consider the patient's health and quality of life and to question whether the proposed benefits of surgery outweigh the attendant risks' (Avidan 2003).

Traditionally, patients were admitted to hospital 1–2 days pre-operatively to allow for the appropriate assessment, tests and investigations to be completed prior to their surgery. Once they were admitted, it was frequently found that patients were presenting with complicated, newly identified or inappropriately managed co-morbidities so surgery was often delayed or cancelled. It was also found that a large number of cancelled operations occurred because patients did not arrive for their scheduled operation fasted. Some did not arrive because the date provided was inconvenient (due to childcare or work-related concerns) or the surgery was no longer wanted or needed. Pre-operative assessment clinics were established to address these issues. It has been found that providing patients with a time and place to explore their concerns and gain the information they need has increased the attendance of patients and therefore made more effective use of operating theatre time and other associated resources (NHS Modernization Agency 2005).

Pre-operative assessment (POA) and planning carried out prior to treatment is an essential part of the planned surgical care pathway (NHSIP 2008). POA and planning should take into

account the physiological, psychological and social needs of the patient undergoing surgery with the aim of optimizing patient safety at all times and minimizing intra-/post-operative complications. Depending on the complexity of the surgery, POA can be undertaken during face-to-face or telephone clinics, which are increasingly nurse led.

Evidence-based approaches

Principles of care

Pre-operative assessment should include a comprehensive history taking, physical examination and the ordering of appropriate investigations.

Pre-operative history taking includes the following.

Medical history

Medical history should start with the history of the presenting illness. For the pre-operative assessment, this starts with the reason why the patient is having the planned procedure. It is important to include how the patient first presented with the symptoms of the condition, and any treatments provided. Details of treatments such as previous chemotherapy or radiotherapy are important to obtain within the health history. A full history of current and previous medical problems should be taken. This would include any history of disorders such as diabetes mellitus, hypertension, asthma, epilepsy, strokes or cardiac symptoms such as chest pains or shortness of breath. It is valuable to obtain information such as dates of diagnosis, severity, ongoing treatments and any history of hospitalizations for the disorders. By obtaining a reliable and clear record of the patient's medical history, the foundations for creating a plan of care are laid. 'This ensures the patient's surgical journey is effective, reducing the risk of suboptimal management and increasing safety with the least possible distress for the patient and their significant others' (Walsgrove 2011).

Family history

Asking the patient about common familial illnesses, such as hypertension, coronary artery disease, stroke, diabetes and hypercholesterolaemia, will alert the anaesthetist to any potential medical problems.

Body system review

It is essential to assess each of the following body systems in more detail as this contributes to the information about the patient's overall health status.

Cardiovascular system

- Cardiac function.
- History of cardiovascular disease such as ischaemia, anaemias and clotting disorders.
- Blood pressure.
- Patient's risk of thrombosis, excessive bleeding. If the patient has a history of thrombosis or is undergoing surgery where this presents a significant risk, they may require anticoagulation pre-operatively.

Respiratory system

- History of respiratory disease such as asthma, chronic obstructive airway disease.
- Respiratory infections.

Gastrointestinal system

- Digestive history.
- Nutritional and BMI status.
- Hepatic functioning.
- Renal function including urination patterns.

Central nervous system

- History of neurological disease such as epilepsy, transient ischaemic attacks.
- Pain profile.

Endocrine system

- Thyroid function.
- Blood glucose levels measured with HbA1c test.
- History of any other endocrine disorder.

Musculoskeletal system

- This should include a review of the range of movement and any musculoskeletal disease that may either give the patient pain or restrict their movement.

Surgical and anaesthetic history

Assessors must gather history of previous surgery. History of previous major surgeries or recent anaesthetics gives the assessor a good idea of the fitness of the patient for the planned surgery. It is also important to find out about previous anaesthetic problems such as post-operative nausea and vomiting, as well as a history of malignant hyperthermia. Identifying these factors is important in assessing the potential risk in performing the designated procedure on the patient. The American Society of Anesthesiologists (ASA) developed a scale with which to classify patients on the basis of their existing co-morbidities (Table 13.1). The scale is a well-established scoring tool that is useful for calculating patient risk of anaesthetic complications in relation to existing conditions (Walsgrove 2011).

The anaesthetic assessment also includes any cardiovascular, hepatic or pulmonary impairment, bleeding disorders, significant history of reflux or a hiatus hernia, breathing difficulties such as sleep apnoea, paroxysmal nocturnal dyspnoea or orthopnoea.

Medications and allergies

A full list of the patient's current medications, including over-the-counter medications as well as vitamin and herbal supplements, is essential. Many medications interact with anaesthetic agents

or will negatively affect the patient in the intra- or post-operative period. These include anticoagulants, diabetic medications, calcium channel antagonists, beta-blockers and some antidepressants. If a patient is taking steroids or opiates, these require careful titration intra- or post-operatively. Specific medications may need to be discontinued days or weeks prior to surgery (Figure 13.1).

The patient's allergy status should be determined and specific details of reactions recorded. Medication 'intolerance' should also be documented to avoid severe side-effects such as nausea and vomiting. History of previous anaphylactic reactions should be thoroughly documented to avoid potential incidents. Patients who are allergic to latex will need to be first on the theatre list, and theatre staff will need to be alerted to avoid complications (see Latex sensitivity and allergy).

Social history

Social history encompasses social situations such as home life and occupation. Within the social history, the assessor develops a general idea about the social practices of the patient that may affect their fitness for surgery but also influence their recovery.

It is important to know about the patient's past and current occupational picture. The patient's occupation will give the assessor a picture of not only the patient's home and financial situation, but also potential occupational disorders such as respiratory or musculoskeletal problems.

Understanding the patient's support systems such as family or wider community is important. This will allow the assessor to pick up on potential 'road blocks' for a timely discharge. If the patient is found to have little or no available support in the community, the assessor has the opportunity to initiate any discharge planning or Social Services referrals prior to admission. This allows the patient to avoid any potential delays in their discharge.

It is also necessary to explore smoking, drug and alcohol use. Long-term abuse of alcohol, tobacco products or drugs can lead to organ damage, related medical complications, and therefore a higher incidence of perioperative morbidity and mortality. Intra- and post-operative events such as delirium tremens (acute episode of delirium) are considered medical emergencies.

Alcohol

It is imperative to communicate to the patient the importance of honesty with regard to alcohol or drug intake. Many patients will often admit to usage, but may deny they have excessive intake or a problem. It is important to assess the amount consumed on a daily or weekly basis. The recommended maximum intake for males is 21 units per week, and for females 14 units per week.

Smoking

It is important to assess smoking behaviour. The length of time an individual has smoked, the number smoked a week, the pattern of their smoking, i.e. times of day, smoking with specific activities such as waking up, going to sleep or managing stress. Pre-operative smoking cessation is important and help with this should be offered during the assessment. The extent of smoking-related effects is dependent upon the amount, and the length of time, of smoking. Smokers have hyper-reactive airways that lead them to become more susceptible to incidents of laryngospasm or bronchospasm. They have an increased chance of developing post-operative lung infections due to a compromised ability to clear secretions. Smoking also affects the liver, which may mean that the patient will require higher dosages of medications. Post-operative healing is also affected by smoking as nicotine is a vasoconstrictor. NICE (2013) recommends the implementation of a smoking cessation service for people having elective surgery where:

- patients who smoke are identified
- patients receive appropriate information, referral and intervention
- patients have a seamless pathway between secondary and primary care.

Table 13.1 Modified ASA Physical Status Classification System

Class	Physical status	Example
I	A healthy patient	A fit patient with an inguinal hernia
II	A patient with mild systemic disease	Essential hypertension, mild diabetes without end organ damage
III	A patient with severe systemic disease that is a constant threat to life	Angina, moderate-to-severe chronic obstructive pulmonary disease (COPD)
IV	A patient with an incapacitating disease that is a constant threat to life	Advanced COPD, cardiac failure
V	A moribund patient who is not expected to live 24 hours with or without surgery	Ruptured aortic aneurysm, massive pulmonary embolism
E	Emergency case

The Royal Marsden Foundation NHS Trust

Peri-operative Guidelines for Drug Therapy

- Medication to Omit
 Medication to Omit unless specifically asked to give by Doctor (see comments below)
 Medication to continue can be given up to 2 hours before surgery, with a sip of water

Gastro-intestinal System	H ₂ antagonists, e.g. ranitidine	
	Proton pump inhibitors, e.g. lansoprazole	
Cardiovascular System	Alpha antagonists, e.g. doxazosin	
	Anti-arrythmics, e.g. digoxin, amiodarone	
	Beta-blockers, e.g. atenolol	Avoid stopping suddenly. Continue iv if prolonged NBM
	Calcium antagonists, e.g. amlodipine	
	Loop & thiazide diuretics, e.g. furosemide, bendroflumethiazide	
	Nitrates, e.g. isosorbide mononitrate	
	ACE inhibitors, e.g. lisinopril	Consult Anaesthetist. May cause hypotension on induction of anaesthesia
	Angiotensin receptor II antagonists, e.g. losartan	Consult Anaesthetist. May cause hypotension on induction of anaesthesia
	Aspirin	If to be withheld, stop 7-10 days pre-op
	Clopidogrel	Stop 7 days pre-op unless Cardiologist states continue
	Dipyridamole	If procedure high risk, omit on day of surgery
	Low molecular weight heparin, e.g. tinzaparin, enoxaparin	Omit 12 hrs pre-op
	Potassium sparing diuretics, e.g. spironolactone, amiloride	Omit on day of surgery. May contribute to hyperkalaemia post-op
	Warfarin	Stop 3 days pre-op. If appropriate admit 3 days pre-op and start a heparin infusion until 4 hrs before surgery. Aim for APPT ratio < 1.5
Respiratory System	Aminophylline / Theophylline	
	Inhalers, e.g. salbutamol, beclomethasone	
Central Nervous System	Anti-epileptics, e.g. phenytoin	
	Antipsychotics, e.g. haloperidol, risperidone	
	Benzodiazepines, e.g. diazepam	
	Opioid analgesics, e.g. morphine, methadone, codeine	Consult Anaesthetist to plan post-op analgesia
	Paracetamol	
	Parkinson's treatment, e.g. co-careldopa, co-beneldopa	
	Selective serotonin re-uptake inhibitors (SSRIs), e.g. paroxetine, fluoxetine	
	Anti-dementia drugs, e.g. donepezil, rivastigmine, galantamine (acetylcholinesterase inhibitors)	May prolong neuromuscular blockade and exaggerate muscle relaxation with succinylcholine-type muscle relaxants. Alert Anaesthetist to the potential for prolonged neuromuscular blockade. Omit rivastigmine and galantamine 24-48 hours prior to surgery. It is recommended to stop donepezil 2-3 weeks prior to surgery; however these patients may not return to their baseline mental function, therefore may be unethical to stop
	Lithium	Check levels pre-op. Continue for minor surgery. Discuss with Anaesthetist plan for major surgery. Restart ASAP post-op
	Non-steroidal anti-inflammatory (NSAIDs), e.g. diclofenac, COX II inhibitors	Increased risk of bleeding. Can stop 1-3 days pre-op depending on half-life. Stop piroxicam 7 days pre-op
	Tricyclic antidepressants, e.g. amitriptyline	Increased risk of arrhythmias. Consult Anaesthetist
	Clozapine	Stop 12 hrs pre-op. Restart ASAP. Contact pharmacy for advice
	Monoamine-oxidase inhibitors (non-reversible), e.g. phenelzine	Stop 14 days pre-op (discuss with Psychiatrist). If not withdrawn inform Anaesthetist
	Reversible MAOIs, e.g. moclobemide	Omit on day of surgery
Infections	Antibiotics	
	Anti-virals, e.g. HIV antiretroviral drugs, aciclovir	

Figure 13.1 Guide to preoperative medication. *Source:* Reproduced with permission from Dr David Chisholm, Anaesthetist, The Royal Marsden Hospital NHS Foundation Trust, 2010.

Endocrine System	Corticosteroids, e.g. prednisolone (Current or stopped within last 3 months)	May need additional hydrocortisone bolus intra/post operation: Minor surgery: 25mg hydrocortisone at induction (or usual oral dose) Moderate surgery: 25mg hydrocortisone at induction (or usual oral dose) then 25mg hydrocortisone TDS for 24 hours and then restart usual steroid dose Major surgery: 25mg hydrocortisone at induction (or usual oral dose) then 50mg TDS hydrocortisone for 48-72 hours and then restart usual steroid dose
	Desmopressin (DDAVP)	
	Hormone antagonists, e.g. tamoxifen, anastrozole	Thromboprophylaxis and TEDS
	Hormone replacement therapy (HRT)	Thromboprophylaxis and TEDS
	Levothyroxine	
	Progesterone only oral contraceptives	Thromboprophylaxis and TEDS
	Combined oral contraceptives (i.e. containing oestrogen)	Omit 4 weeks prior to major surgery, institute thromboprophylaxis and TEDS. Advise on alternative family planning
	Glibenclamide, glipizide, gliclazide, tolbutamide & glitazones (e.g. pioglitazone)	Refer to Anaesthetist. Omit all oral hypoglycaemics on morning of surgery
	Insulin	Continue until morning of surgery. Omit morning dose & breakfast. Minor surgery: Re-start s/c insulin post-op with first meal. Major surgery: Omit breakfast and S/C insulin and start intravenous sliding scale insulin
	Metformin	Refer to Anaesthetist. Omit 48-72 hrs pre-op in patients with renal impairment
Malignant Disease & Immunosuppression	Drugs to prevent adverse effects, e.g. allopurinol	Seek advice from Oncologist/Haematologists
	DMARDS, e.g. methotrexate for Rheumatoid Arthritis	Continue unless at risk of renal complications. Discuss with specialist
	Immunosuppressants, e.g. azathioprine, ciclosporin	Seek advice from Oncologist/Haematologists
	Cytotoxics, e.g. alkylating agents, antimetabolites	Seek advice from Oncologist/Haematologists
Complementary Alternative Medicines	Echinacea (activates cell-mediated immunity allergic reactions, poor wound healing, increased risk of infection, reduced action of immunosuppressive medicines).	Discontinue as far in advance as possible before surgery
	Ephedra (causes dose-dependent increases in blood pressure and heart rate. Risk of MI and stroke from tachycardia and hypertension. Long-term use depletes endogenous catecholamines & may cause intraoperative haemodynamic instability. Interacts with MAOIs).	Discontinue 24 hrs before surgery
	Garlic (inhibits platelet aggregation (may be irreversible) so may increase risk of bleeding, especially when combined with other platelet inhibitors).	Discontinue at least 7 days before surgery
	Ginkgo (inhibits platelet activating factor so may increase risk of bleeding, especially when combined with other platelet inhibitors).	Discontinue at least 36 hrs before surgery
	Ginseng (lowers blood glucose & inhibits platelet aggregation so can lead to hypoglycaemia risk of bleeding. Platelet inhibition may be irreversible and increased).	Discontinue at least 7 days before surgery
	Kava (sedates and reduces anxiety so could increase sedative effect of anaesthetics. Has potential for tolerance).	Sedates & reduces anxiety Discontinue at least 24 hrs before surgery
	St John's Wort (inhibits neurotransmitter serotonin, norepinephrine and dopamine reuptake by neurons. Induces cytochrome P450 therefore concentrations of alfentanil, midazolam, and lidocaine may be reduced. Also reduces concentrations of digoxin, warfarin and ciclosporin).	Discontinue at least 5 days before surgery
	Valerian (sedates via modulation of GABA transmission and receptor function so increases the sedative effect of anaesthetics, especially those via GABA receptor e.g. midazolam. Long-term use could increase amount of anaesthetic required).	Reduce dose gradually over several weeks before surgery: risk of benzodiazepine-like withdrawal. If a patient is dependent on valerian, can be taken up until day of surgery. Benzodiazepines can be used to treat withdrawal in the post-operative period
Nutrition & Blood	Drugs for nutrition, e.g. iron, folic acid, calcium, magnesium	Continue unless specifically asked not to
This information applies to all types of surgery (minor or major). Please contact local pharmacy for administration advice if the patient requires a prolonged NBM period.		

Figure 13.1 Continued

Physical examination

Within the POA, baseline vital signs and a physical examination are essential and should be completed by a trained assessor. The physical examination should include specific attention to the respiratory and cardiac systems, as they are 'most obviously affected by anaesthetics and which themselves exert an influence on the course of anaesthesia and the post-operative period' (Cashman 2001, p.9). Examination of further organ systems, such as abdominal or neurological systems, should also be completed if indicated by the patient's history. For example, patients with known alcohol or drug abuse should be further examined for hepatic and neurological impairments.

Within the pre-operative assessment, it is vital to perform an airway assessment. This includes:

- range of motion of the neck and jaw
- mouth opening, including ability to protrude lower incisors in front of the upper incisors
- dentition – condition of teeth
- history of temporomandibular joint dysfunction and other airway abnormalities.

If there are any problems with the airway, the anaesthetist needs to be informed so that appropriate equipment can be ordered for

the day of surgery. Alert the anaesthetist if the patient has previously experienced a difficult intubation; has disease, surgical or radiotherapy scarring of the head, neck or mediastinum; difficult or noisy breathing; morbid obesity; poor mouth opening; rigid or deformed neck; receding chin or an overbite (Ong and Pearce 2011). Further explanation on physical assessment can be found in Chapter 2: Assessment and discharge.

Pre-operative investigations

Another aspect of the pre-operative assessment is the ordering and interpreting of pre-operative investigations. Investigations are often ordered to establish baseline values, support or refute differential diagnoses, and support or monitor the management of existing disease processes. The results of the physical examination and history taking direct the practitioner to the types of pre-operative investigations necessary. Investigations are often ordered based on routine rather than on patient health indicators or for aiding in perioperative management. *Pre-operative Tests: The Use of Routine Pre-operative Tests for Elective Surgery* (NICE 2003) is an evidence-based guide for the ordering and use of routine pre-operative testing in elective surgeries. The investigations are based on ASA status (see Table 13.1), the age of the patient and their co-morbidities. Table 13.2 lists various laboratory tests.

794

Table 13.2 Pre-operative laboratory tests

Test	Rationale
Haematology	
Full blood count (FBC), including haemoglobin, haematocrit	Patients with a history of: <ul style="list-style-type: none"> • smoking • malignancy • respiratory disease • cardiac disease may be at increased risk for anaemia and polycythaemia
White blood cell count	Patients with a history of: <ul style="list-style-type: none"> • recent chemotherapy and/or radiotherapy • malignancy • recent infection may have either raised or lowered white blood cell count
Platelet count	Platelet count should be checked on patients with a history of: <ul style="list-style-type: none"> • bleeding tendencies • renal or hepatic disease • recent treatment with chemotherapy
Coagulation screening, including prothrombin and activated partial thromboplastin time	This is not recommended unless the patient: <ul style="list-style-type: none"> • is taking anticoagulants • has a history of bleeding disorders • has a history of post-surgical bleeding • has a bleeding history (such as liver disease or malignancy) (Chee et al. 2008)
Group and save or cross-match	Having the blood tested prior to the date of surgery gives the blood bank more time to find the appropriate blood required for the specific patient. Patients with unusual blood typing or rare antibodies may need to have special blood obtained from a national blood bank, and having the sample collected in advance will decrease the chance of errors and of the patient having their surgery postponed
Serum biochemistry	
Glycosylated haemoglobin (HbA1c) level	Patients presenting with a history of: <ul style="list-style-type: none"> • steroid use • obesity • cardiovascular disease • symptoms suggestive of diabetes. The HbA1c is a more accurate measurement of the patient's long-term glucose control and compliance

Test	Rationale
Baseline serum creatinine and blood urea nitrogen level	<p>Patients with a history of:</p> <ul style="list-style-type: none"> • renal dysfunction • diabetes • cardiovascular disease • obesity • medications such as steroids or diuretics
Liver function tests, such as albumin	<p>Patients presenting with:</p> <ul style="list-style-type: none"> • liver disease • malignancy • alcohol abuse • malnutrition • jaundice. <p>The liver and kidneys aid the metabolism and elimination of many anaesthetics and medications. Therefore it is vital to ensure these are checked pre-operatively to ensure adequate organ function</p>
Electrolyte levels	<p>Electrolyte levels should be checked pre-operatively in patients with a history of:</p> <ul style="list-style-type: none"> • renal dysfunction • diabetes • malignancy • malnutrition • vomiting or diarrhoea • medications such as diuretics or chemotherapy. <p>These patients may require pre-operative prescribing of supplements such as potassium to optimize electrolyte levels prior to surgery. Electrolyte imbalances such as hypokalaemia or hyponatraemia can be potentially life-threatening in the perioperative period</p>
Other tests	
Thyroid function testing	<p>Patients with a history of hypo- or hyperthyroidism. Patients with untreated or severe thyroid disease are at increased risk of developing 'thyroid storm' (dangerously raised heart rate, blood pressure and temperature) relating to the stress of surgery or illness (Weinberg et al. 1983)</p>
Urinalysis	<p>Patients presenting with symptoms of a urinary tract infection or those presenting for procedures of the urinary tract, e.g. cystoscopy</p>
Pregnancy testing	<p>Pregnancy testing should be completed based on findings of the medical history, date of last menstrual cycle. This should ideally be done on the day of admission unless the patient suspects she might be pregnant during pre-assessment</p>

Electrocardiograms

A standard 12-lead electrocardiogram is frequently performed if indicated by the age of the patient, risk factors, co-morbidities and findings of the physical examination. The patient's ASA grading and the surgical grading of the planned surgery may also indicate an ECG. The proportion of patients with an abnormal ECG increases with age and the presence of co-morbidities. An ECG can also be completed to establish a baseline prior to surgery for post-operative comparison.

Imaging: chest X-ray (CXR)

A CXR can give the practitioner valuable information to support or refute potential diagnoses or further assess the severity of a specific disease. Patients presenting with history of cardiovascular or respiratory symptoms or disease processes should have a CXR completed pre-operatively. If the patient has had a CXR within the last 6 months, it does not need to be repeated unless new problems have arisen or the existing problems have worsened.

Cardiopulmonary exercise testing

Older and Smith (1988) introduced the concept of cardiopulmonary exercise testing (CPET) (Figure 13.2). CPET is a dynamic, non-invasive test, involving the use of an exercise bicycle (cycle ergometer) where the work rate is gradually and imperceptibly increased in a stepped or ramped manner until the patient is unable to continue. This enables examination of the ability of the patient's cardiorespiratory system to adapt to a 'stress' situation

of increased oxygen demand, in effect mimicking the conditions of surgery.

Cardiopulmonary exercise testing relies upon accurate breath-by-breath measurements of pulmonary gas exchange through a mouthpiece measuring respiratory gas exchange. In addition, electrocardiography, blood pressure, pulse oximetry and heart rate are monitored during exercise (American Thoracic Society and American College of Chest Physicians 2003, Wasserman 2012). From the CPET, two key indicators are derived: the body's maximum oxygen uptake (VO_{2max}) and the point at which anaerobic metabolism exceeds aerobic metabolism (anaerobic threshold, AT). Together these broadly indicate the ability of the cardiovascular system to deliver oxygen to the peripheral tissues and the ability of the tissues to utilize that oxygen. In addition, the AT has been shown to be a useful predictor of post-operative cardiac complications in abdominal surgery (Older et al. 1999).

Exercise testing is commonly used to reproduce common symptoms such as impaired exercise capacity, fatigue and exertional breathlessness. This enables accurate physiological measurements to be obtained, assisting with the overall assessment of suitability for surgery, and can predict post-operative mortality and morbidity (Cooper and Storer 2001). This assessment will reveal to both the healthcare professional and the patient what needs to be considered if optimum results are to be achieved from surgery.

Cardiopulmonary exercise testing is often referred to as 'the gold standard for measuring exercise tolerance'. It enables clinicians to triage patients to the appropriate level of care after surgery, allowing the efficient use of intensive care facilities

Figure 13.2 Cardiopulmonary exercise testing (CPET).

(MacGregor et al. 2009). It also assists surgeons in assessing treatment options more easily (Older et al. 1993). The patient is then in a better position to evaluate their own risk/benefit ratio for surgery and thus make a more informed decision on consent for an operation (American Thoracic Society and American College of Chest Physicians 2003, Lee et al. 2006).

Further referrals

During the patient's pre-operative assessment, it is often deemed necessary to refer for further expert assessment or advice. This is helpful in providing valuable information regarding the patient's condition and creating an appropriate plan of action for the patient in the perioperative or post-operative period. Patients are seen by a specialist to further assess whether they are in the optimum condition for the desired surgery and/or if their health can be 'optimized' prior to surgery to improve their post-operative outcomes.

Anticipated patient outcomes

Ensure patient safety at all times and minimize intra- and post-operative complications. According to the *National Good Practice Guidance on Pre-operative Assessment for Inpatient Surgery* (NHS Modernization Agency 2003), pre-operative assessment clinics were created with several objectives in mind.

- Provide the opportunity to further explain and discuss any information provided by the surgeon to the patient. This process should aid in minimizing any patient fears or anxieties, through ensuring that the patient understands the upcoming surgery, as well as what the recovery following the surgery will

entail. This gives the patient time to prepare psychologically, reducing stress and thereby enhancing recovery.

- Assist in the assessment of the patient's fitness for the surgery, as well as anaesthesia and post-operative recovery. This will provide information for a comprehensive assessment of the risks and benefits of the required surgery and anaesthesia, allowing the patient to make an informed decision. This is achieved through a comprehensive medical history, physical examination and the ordering of appropriate investigations (NICE 2003).
- Identify any co-morbidities that may require intervention prior to admission and surgery likely to affect the intra- and post-operative care of the patient. This should allow enough time to take appropriate action before admission to make changes to the patient's treatment regimen, such as discontinuation of anti-coagulants or implementation of antihypertensive medications.
- Assist in ensuring that the patient is in optimum health prior to surgery, through further referrals to secondary care specialists as necessary, for example cardiologists.
- Perform necessary investigations prior to surgery and ensure that the results of these investigations are actioned (for example, haematological investigations).
- Identify the need for and arrange supply of any specialist equipment and special requirements for the post-operative period (for example, critical care beds, bariatric equipment).
- Provide information to the patient about any specific pre-operative preparation that may be required (for example, fasting, bowel preparation). This may also include involving members of the multidisciplinary team such as clinical nurse specialists, physiotherapists or dieticians.
- Give the patient a point of contact for further questions or concerns, or if they want to postpone or cancel the surgery.
- Provide information to the patient on what they should anticipate in the post-operative period. This may include leaflets and videos to help the patient understand the planned procedure. This would also include discussion with the anaesthetist about pain control, intubation and potential critical care admission.
- Provide any assistance with health promotion activities such as smoking cessation, weight loss and alcohol use that will help to improve the outcome in the perioperative and post-operative periods. This may include further referrals to primary care services such as stop smoking services or dietetic advice.
- Identify any cultural, religious or communication needs for the patient.
- Individual admission and discharge planning, ensuring that the patient and carer(s) know what to expect, facilitating earlier discharge and enabling follow-up care to be undertaken in the primary care setting.
- Provide the appropriate pre-operative documentation for the multidisciplinary team. See Chapter 2: Assessment and discharge for further insight into POA processes (Liddle 2012, NICE 2003, Oakley and Bratchell 2010).

Thorough POA results in good clinical outcomes and enhanced patient experience as evidenced by the success of the Enhanced Recovery Partnership Programme, which has transformed elective surgical care pathways across the NHS since 2009 (DH 2011) (Box 13.1). It also minimizes length of hospital stay through:

- reduced cancellations due to patient ill health or DNAs (did not attend)
- increased number of same-day surgery admissions
- earlier discharge.

Legal and professional issues

The POA should only be performed by assessors trained and deemed competent in the process. Assessors can include not only doctors or anaesthetists but also nurses or operating department

Box 13.1 Enhanced Recovery Partnership Programme

Enhanced Recovery, also known as fast track, rapid or accelerated surgery, is transforming elective surgical care pathways across the NHS and improving both patient experience and clinical outcomes (including reduced length of stay) (NHSIP 2008). Since 2009, Enhanced Recovery pathways have been established and become standard practice in the vast majority of NHS hospitals in England (DH 2011).

The underlying principle of the Enhanced Recovery Programme involves ensuring patients are in the optimal condition for surgery, have the best possible care during their operation and experience optimal post-operative rehabilitation (DH 2009a). Shared decision making is integral to the Enhanced Recovery pathway, incorporating elements of patient self-care through to highly specialist care (DH 2011). Shared decision making involves the patient as an active participant in their care, first clarifying the range of clinically acceptable treatment options for the patient and then working in partnership with the patient in determining the best treatment, management and support for them, which best meets their individual needs, values and preferences at the time (DH 2011).

The Enhanced Recovery Programme includes the following.

- 1 Pre-operative assessment, planning and preparation before admission – optimize health (including encouraging patients to exercise and eat well) and pre-existing medical conditions (e.g. diabetes); discharge planning and information giving.
- 2 Reducing the physical stress of the operation – using minimally invasive surgical techniques (e.g. laparoscopic); individualized goal-directed fluid therapy; use of quick-offset anaesthetic agents, allowing quick recovery; prevent hypothermia; effective opiate-sparing analgesia, to facilitate early mobilization, e.g. nerve blocks; minimize the risk of post-operative nausea and vomiting; minimize the use of drains and nasogastric tubes.
- 3 Post-operative rehabilitation – early nutrition; early mobilization; early removal of catheters; post-operative education and support, e.g. stoma care; follow-up advice and support.

Box 13.2 Role of the assessor in the POA clinic

- Work to guidelines and competencies agreed by anaesthetists, surgeons and other allied health professionals to ensure a consistent approach.
- Take a targeted history and conduct a relevant physical examination of the patient, including airway assessment.
- Refer patients who fall outside the agreed criteria to the anaesthetist, who may then make further referrals.
- Arrange and perform investigations in accordance with NICE guidelines.
- Ensure that the results of tests are evaluated and refer abnormal investigation results to the available anaesthetist, surgeon and/or primary care, according to local guidelines.
- Refer a patient back to primary care or another healthcare professional to optimize the patient's medical condition, according to local guidelines.
- Take responsibility for following up referrals to ensure the patient remains in the pre-operative system.
- Liaise actively with the anaesthetic department.
- Arrange and co-ordinate any assessment and/or investigations needed near time of surgery. Take responsibility for all communication with the patient throughout their pre-operative journey.
- Commence necessary planning for the perioperative stay and ensure a timely discharge.
- Identify factors that may influence the dates of surgery offered, for example school holidays.
- Collate all information prior to surgery and ensure that the multidisciplinary documentation is available for anaesthetists to see at least 48 hours prior to admission.
- Communicate approximate length of operation, any special requirements and essential resources to the waiting list office, bed management, operating theatre department and/or theatre scheduler.
- Contact all patients failing to attend pre-operative assessment to identify the reason. Act on the reason, following local protocols for the management of DNAs (did not attend) in pre-operative assessment.

practitioners (ODPs). The role of the assessor is broad (Box 13.2), but they should be competent in the following procedures:

- take a comprehensive health history
- perform a physical examination
- order appropriate investigations.

The Association of Anaesthetists of Great Britain and Ireland (AAGBI 2010) states that trained staff 'play an essential role when, by working to agreed protocols, they screen patients for fitness for anaesthesia and surgery' although they are not qualified to make the final decision about a patient's fitness for surgery, but play an important role in 'identifying problem patients'. Non-complicated patients often do not require further assessment by an anaesthetist until the day of admission. Patients considered complicated by the trained assessor are further reviewed by an anaesthetist. This is supported by Kenny (2011) who found that approximately 20% of patients assessed by pre-assessment nurses were referred to the anaesthetic clinic. Of these, 10% were due to the discovery of poorly controlled, undiagnosed or complex health problems and 10% due to the nature of surgery required.

While the POA can be performed by non-anaesthetic personnel such as nurses, it is vital that the anaesthetist in charge of the patient's case is aware of the patient's co-morbidities. Competency assessment is also carried out in pre-assessment in the

form of a competency portfolio as advocated by Walsgrove (2011), which was designed in correlation with the NHS Modernization Agency's (2003) guidance for pre-operative assessment. This covers administrative function, physical assessment (medical and nursing history), psychological and social assessment, decision making, interventions (referral, pre-operative counselling, ordering and performing tests and investigations). To ensure quality, regular audits on the pre-assessment documentation should be carried out. Any incidents stemming from a pre-assessment, for example if a patient is cancelled on the day, must be reported immediately and investigated, so ensuring that the unit is continually improving its practice.

Patient information and education

Related theory

Patients undergoing surgery have information and supportive care needs before and after their surgery. Providing information to patients is considered a crucial issue and the central focus in patient educational activities. Patients require information that is meaningful for them as individuals. It is necessary to educate patients on the nature of the outcomes and the benefits and risks of procedures so they can be involved in the decision-making process and enabled to give fully informed consent. Accurate, reliable and complete information plays a pivotal role in helping patients make informed decisions.

Evidence-based approaches

Principles of care

The way in which information is delivered and understood will help determine whether a patient's actual post-operative experiences are congruent with expected ones; therefore it is essential that information is provided at the right time and in a variety of formats. Information materials must contain scientifically reliable information and be presented in a form that is acceptable and useful to patients, i.e. suitable for the patient's educational level. Patient education has been found to be extremely beneficial, reducing anxiety levels and promoting patient well-being (Bondy et al. 1999, Klopfenstein et al. 2000, Liddle 2012, Walker 2002).

Pre-operatively, pain and anaesthesia are amongst patients' greatest worries and need to be discussed so that anxiety can be reduced (Mitchell 2005), which may ultimately result in patients requiring less analgesia. Patients should also be provided with information about the equipment and intravenous access extension sets that they will be attached to post-operatively so that they know what to expect as this can be distressing to both the patient and their family/friends when they return from theatre. Patients should also be provided with information on the recovery period, including when they will be expected to mobilize, when they can eat and drink and the length of time they can expect to be in hospital.

There are currently three main forms of patient education: face to face; paper based and internet/web based (Table 13.3).

Patient education has been found to be extremely beneficial, reducing anxiety levels and promoting patient well-being (Jlala et al. 2010, Klopfenstein et al. 2000, Walker 2002). However, it is important that any form of patient education is tailored to individual patients to ensure that the needs of those patients requiring additional follow-up information, practical or psychosocial support are met. These can be identified through face-to-face education programmes or web-based consultations.

Any verbal information should be supported by paper or web-based written information, from reliable, evidence-based sources, which are tailored to the patient's educational level. Written patient information in particular can help patients to gain a greater understanding of surgery and what is expected of them and can:

- ensure patients arrive on time and are properly prepared for surgery, e.g. pre-operative fasting

- increase patient confidence, improving their overall experience
- refamiliarize patients with what they have already been told
- enhance patient and carer involvement in their treatment and condition (NHSIP 2008).

Legal and professional issues

Competencies

One of the principal responsibilities of a nurse is to educate patients (Anderson and Klemm 2008); however, time and work-related constraints can interfere with the provision of patient education. Timing is crucial and can influence a patient's ability to retain information. Furthermore, it is essential to consider the educational level of the patient, to ensure that any patient education/information is appropriate and meaningful. Effective patient education also requires evaluation to ensure the patient has understood and retained the information they have been given.

Consent

Definition

NHS Choices (2012) defines consent as: 'the principle that a person must give their permission before they receive any type of medical treatment'.

Evidence-based approaches

There are different types of consent in healthcare: written, verbal (explicit) and non-verbal (implied or implicit) (DH 2009b). The Department of Health (DH 2009b) and professional bodies including the Nursing and Midwifery Council (NMC) and General Medical Council (GMC) have produced comprehensive guidance about consent (GMC 2008, NMC 2013). The DH guidance (DH 2009b) includes information about what consent is, the different types of consent, when consent should be obtained, by whom and in what circumstances.

Principles of care

Unless it is an emergency, the gaining of consent should be treated as a process rather than a one-off event (DH 2009b). For major operations, it should be considered good practice to gain a person's consent to the proposed procedure well in advance, ideally prior to pre-assessment when there is time to respond

Table 13.3 Forms of patient education

Patient education	Definition	Advantages	Disadvantages
Face to face	Includes any education delivered verbally by a healthcare provider to a single patient or group of patients. This remains the most common form of patient education	Can be tailored to individual patient needs	Time consuming Consistency problems Relies on patient's ability to absorb, understand and retain the verbal information
Paper based	Includes any written information – patient information leaflets	Develop comprehensive educational materials that are consistently presented Patients can refer back to material	Unable to tailor to individual patient needs
Web based	Includes any verbal and written patient information. Web-based seminars, patient groups, programmes of care; interactive websites; podcasts; video/YouTube	Wide-ranging and current information A variety of teaching formats; patient empowerment – patient control vs healthcare professional control Support 24 hours a day Develop comprehensive educational materials that are consistently presented Patients can refer back to material Accessed all over world	Potential for inaccurate information Lack of access Poor quality of online resources Security and privacy issues

to the person's questions and provide adequate information so that the person has time to develop an understanding to allow an informed decision to be made (Hughes 2011).

Whilst the validity of consent does not depend on the form in which it is given (DH 2009b), it is good practice to use forms for written consent where an intervention such as surgery is to be undertaken. Most hospitals' local consent policies will require written consent to be obtained in these circumstances and this practice is supported by the Department of Health (DH 2009b). However, written consent merely serves as evidence of consent and a signature on a form alone will not make the consent valid. For example, if a person's signature to confirm their consent is gained immediately before the surgical procedure is due to start, at a time when they may be feeling particularly vulnerable, this would raise concerns about its validity (DH 2009b). Furthermore, patients should not in any situation be given routine pre-operative medication before being asked for their consent to proceed with the treatment (NMC 2013).

Legal and professional issues

It is accepted that when a patient gives valid consent, this is valid indefinitely unless withdrawn by the patient; therefore no specific time limit is designated from signature to procedure (Hughes 2011). However, it is good practice to confirm the patient's wishes if significant time has elapsed since the initial process. The patient is entitled to withdraw consent at any time (Hughes 2011).

For consent to be valid, it must encompass several factors.

- *Consent must be given willingly:* this is without pressure or undue influence to either undertake or not undertake treatment.
- *Consent must be informed:* the person must have an understanding of the procedure and the purpose behind it, and has been given relevant information about the benefits and risks of the procedure as well as potential alternatives. This information needs to be explained or presented in a way that is meaningful and easy to understand by the person in a variety of formats (both verbal and written) to enable them to make an informed decision.
- *The person must have the capacity to consent to the procedure in question:* that is, the ability to understand and retain the information provided, especially around the consequences of having or not having the procedure (NMC 2013). An assessment of a person's capacity must be based on their ability to make a specific decision at the time it needs to be made, and not their ability to make a decision in general (DH 2009b). Under the Mental Capacity Act 2005 (DCA 2007), which became fully effective in England and Wales in 2007, a person must be presumed to have capacity unless it is established that they lack capacity. If there is any doubt, then the healthcare professional should assess the capacity of the patient to take the decision in general (see Chapter 4: Communication).

Competencies

All healthcare professionals should be aware of the different types of consent and the importance of ensuring that the person understands what is going to happen to them and what is involved. Healthcare professionals should also be familiar with their local hospital consent policy and be aware of and understand what to do if people refuse care or treatment or when consent is not valid or is no longer valid.

Current guidance states that the person obtaining consent must either be capable of performing the procedure themselves or have received specialist training in advising patients about the procedure (DH 2009b, Oakley and Bratchell 2010). The person obtaining the patient's consent for surgery should ideally be the surgeon performing the procedure. The anaesthetist should also discuss the risks related to the chosen method of anaesthesia and obtain consent from the patient (Hughes 2011).

Physical pre-operative preparation

Definition

Physical pre-operative preparation is concerned with reducing harm and complications in the peri- and post-operative period (NPSA 2007, Scott et al. 2007).

Related theory

Peri- and post-operative physical complications include wrong site surgery, infection (e.g. chest infection and wound infection), deep vein thrombosis, pain and allergies/anaphylaxis (Scott et al. 2007).

Legal and professional issues

The National Patient Safety Agency (NPSA 2008a) received over 128,000 reports of patient safety incidents from surgical specialties from October 2006 to September 2007. The nature of these incidents varied widely from wrong site surgery to misplaced patient notes. Not all of these incidents were serious but some have led to patient harm or in some instances death. In 2008, this resulted in the World Health Organization (WHO) developing a Surgical Safety Checklist, which is a structured communication aid to enhance safety intraoperatively (www.who.int/patientsafety/safesurgery/ss_checklist/en/) (see 'Intraoperative' section and Box 13.11 for detailed information about the WHO surgical safety checklist). This checklist is currently mandated in many countries including the UK (NPSA 2008b).

Whilst the WHO Surgical Safety Checklist (2008) is used during the intraoperative period, several measures can be undertaken pre-operatively to help prevent peri- and post-operative complications from arising (Box 13.3).

Namebands

Namebands (otherwise known as identity bands or wristbands) are fundamental in the identification of patients. Patient misidentification contributes to errors and is a cause of patient safety incidents with potentially grave consequences. In 2007, the NPSA reported that incorrect namebands were the cause of more than 2900 incidents involving patients being mismatched to their planned care. In the most recent guidance by the NPSA (2007) and Information Standards Board for Health and Social Care (ISB 2009), it is suggested that standardizing the design of patient wristbands, the information on them and the processes used to produce and check them will improve patient safety. Since 1st July 2011, it has been mandatory for all hospitals to have electronically printed namebands (ISB 2009). Where possible, colour coding for individual risks should be avoided. If a healthcare organization believes colour coding is necessary to alert healthcare professionals to a known risk, e.g. patient allergy, then the NPSA (2007) recommends the use of only one colour, red. Box 13.4 sets out the recommended information to be included on the nameband (NPSA 2007).

Box 13.3 Pre-operative patient safety measures

- Namebands.
- Antiembolic stockings and prophylactic anticoagulation.
- Pre-operative fasting.
- Skin preparation.
- Marking skin for surgery.
- Pre-operative pregnancy testing.
- Preventing toxic shock syndrome from tampons.
- Assessment for latex allergy.
- Comprehensive pre-operative checks.

Box 13.4 Information to be included on a nameband

- Date of birth, in the format dd.mm.yyyy (e.g. 01-Mar-2013).
- Name (surname first in capitals followed by the first name with the first letter in capitals, e.g. MARSDEN, William).
- Patient's 10-digit NHS number.

Antiembotic stockings and prophylactic anticoagulation

Definition

Antiembotic stockings (also known as graduated elastic compression stockings or thromboembolic deterrents [TEDs]) and prophylactic anticoagulation (e.g. low molecular weight heparin) are used as a preventive measure against the formation of venous thromboembolism (VTE – blood clots).

Related theory

800 Venous thromboembolism is a condition where a blood clot is formed inside a vein. This is normally due to stasis of blood within the vessel, trauma to the vessel or an increase in the ability of the blood to clot (Figure 13.3, Figure 13.4). This most frequently happens in the deep veins of the leg which is termed a deep vein thrombosis or DVT. If one of these clots dislodges from the leg and travels to the lung via the bloodstream, it is called a pulmonary embolus or PE (Figure 13.5). This is a potentially fatal event (NICE 2010). Potential clinical signs of DVT or PE are outlined in Box 13.5.

In January 2010 NICE guidance *Venous Thromboembolism: Reducing the Risk* was issued. This updated guidance specified that VTE 'at-risk' patients must be assessed on admission and again for risk of VTE and bleeding within 24 hours of admission and prophylaxis commenced where necessary (NICE 2010). Venous thrombus risk factors include the following.

- Surgical patients, including day surgery patients, where total anaesthetic and surgery time is over 90 minutes or 60 minutes if surgery involves the pelvis or lower limbs
- Immobility, for example prolonged bedrest
- Active cancer
- Severe cardiac failure or recent myocardial infarction
- Acute respiratory failure
- Elderly

Figure 13.4 Deep vein thrombosis. *Source:* Adapted from The Royal Marsden NHS Foundation Trust (2010).

- Previous history of DVT or PE
- Acute infection/inflammation
- Diabetes
- Smoker
- Obesity
- Gross varicose veins
- Paralysis of lower limbs
- Clotting disorders
- Hormone replacement therapy
- Oral contraceptives (House of Commons Health Committee 2005, NICE 2010, Rashid et al. 2005, Scottish Intercollegiate Guidelines Network 2002).

All patients requiring an inpatient stay for surgery should have prophylactic treatment to reduce the risk of DVT, which may include prophylactic anticoagulation (e.g. low molecular weight heparin) and mechanical compression methods. Antiembolic stockings are the most common form of mechanical compression method, but extremely high-risk patients may also use intermittent pneumatic compression devices (e.g. Flowtron boots) or venous foot pumps (NICE 2010, Roderick et al. 2005, Scottish

Figure 13.3 Pulmonary embolism. *Source:* Adapted from The Royal Marsden NHS Foundation Trust (2010).

Figure 13.5 Thrombus. *Source:* Adapted from The Royal Marsden NHS Foundation Trust (2010).

Box 13.5 Signs of deep vein thrombosis/pulmonary embolism

- Complaints of calf or thigh pain.
- Erythema, warmth, tenderness and abnormal swelling of the calf or thigh in the affected limb.
- Numbness or tingling of the feet.
- Dyspnoea, chest pain or signs of shock.
- Pain in the chest, back or ribs which gets worse when the patient breathes in deeply.
- Coughing up blood.

Intercollegiate Guidelines Network., 2002) in the intraoperative and post-operative period (Figure 13.6, Figure 13.7). If antiembolic stockings are contraindicated (Box 13.6) then alternative forms of mechanical compression aids may need to be considered by the surgical team.

Patients should be given verbal and written information before surgery about the risks of VTE and the effectiveness of prophylaxis (NICE 2010) (see Figure 13.8 for an example of a patient information leaflet). It is estimated that 20% of patients undergoing major surgery will develop a DVT with the risk increasing to

Figure 13.6 Antiembolic stockings.

Figure 13.7 Flowtron machine and boots.

40% of patients undergoing major orthopaedic surgery (Scottish Intercollegiate Guidelines Network 2002). Mechanical compression methods reduce the risk of DVT by about two-thirds when used as monotherapy and by about half when added to pharmacological methods (Roderick et al. 2005). Graduated compression (antiembolic) stockings promote venous flow and reduce venous stasis not only in the legs but also in the pelvic veins and inferior vena cava (Hayes et al. 2002, Rashid et al. 2005, Roderick et al. 2005).

Stockings should be applied according to manufacturer's instructions and must be removed daily to assess the condition of the skin and tissues. Information concerning the frequency of stocking removal, daily skin care and assessment is outlined in the section on immobility in the post-operative section.

Box 13.6 Contraindications for antiembolism stockings

- Suspected or proven peripheral arterial disease.
- Peripheral arterial bypass grafting.
- Peripheral neuropathy or other causes of sensory impairment.
- Local condition in which stockings may cause damage, such as fragile tissue paper skin.
- Pressure sores to heels. Pressure sores are a complication of antiembolic stockings and stockings should not be applied (NICE 2005b).
- Use caution and clinical judgement when applying antiembolism stockings over venous ulcers or wounds.

The ROYAL MARSDEN

NHS Foundation Trust

Blood clot prevention

A guide for patients and carers

When I am in hospital what will be done to help prevent a VTE?

- **Stay hydrated** – if you are allowed to do so, drink plenty of fluid. However, if you are not allowed to do this, the doctors will give you fluids via a vein.
- **Move around** – keep mobile as much as you can. The physiotherapist will teach you some appropriate leg exercise.
- **Anti-embolic stockings** – If the doctor decides that you would be suitable for these, the nursing staff will fit you with a pair of stockings.
- **Intermittent calf pumps** – some surgical patients will have a special device which fits like a cuff around each calf (a bit like a blood pressure cuff). This will inflate and deflate alternately. These are designed to help prevent clot formation in the calf. They are not necessary for all surgical patients.
- **Medication (anticoagulants)** – your doctor might consider it necessary to prescribe you an anticoagulant (blood-thinning) drug to reduce your risk of developing a blood clot. Depending on the type of surgery you may be asked to continue this medication for 28 days following the operation.

Not all methods mentioned above are appropriate for all patients. Your doctor will assess which methods are most suitable for you as an individual.

If you are already taking blood-thinning medication such as warfarin please tell your doctor.

Figure 13.8 Patient information sheet: DVT. *Source:* Adapted from The Royal Marsden NHS Foundation Trust (2010).

Procedure guideline 13.1 Step-by-step guide to measuring and applying antiembolic stockings

Essential equipment

- Disposable tape measure (patient specific)
- Antiembolic stocking sizing chart
- Apron
- Patient records/documentation

Pre-procedure

Action

- 1 Assess and record in the patient's documentation the patient's risk factors for VTE, that is, DVT and PE.
- 2 Assess and record in the patient's documentation the patient's suitability for antiembolic stockings, identifying whether the patient has any contraindications to wearing antiembolic stockings (see Box 13.6).
- 3 Explain and discuss the procedure with the patient.

Rationale

All patients admitted to hospital should undergo a risk assessment for venous thrombosis to determine the most appropriate preventive measures, that is thromboprophylaxis (House of Commons Health Committee 2005, **C**; NICE, 2010a, **C**; Roderick et al. 2005, **R1a**; Scottish Intercollegiate Guidelines Network 2002, **C**). The higher the number of risk factors, the greater the risk for VTE (NICE 2010, **C**; Scottish Intercollegiate Guidelines Network 2002, **C**).

To comply with national guidelines and hospital policy/guidelines. To ensure that antiembolic stockings are used appropriately (All Wales Tissue Viability Nurse Forum 2009, **E**; House of Commons Health Committee 2005, **C**; NICE 2010, **C**; Rashid et al. 2005, **E**; Scottish Intercollegiate Guidelines Network 2002, **C**).

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**; NMC 2015, **C**).

Procedure guideline 13.1 Step-by-step guide to measuring and applying antiembolic stockings (*continued*)**Action Figure 5** Measuring thigh diameter.

(a)

(b)

Action Figure 6 (a) Ensuring heel is centred in heel pocket. (b) Pull stocking up over the ankle.**Pre-operative fasting****Definition**

Pre-operative fasting is the practice of a patient abstaining from oral food and fluid intake for a determined period of time before an operation is performed.

Related theory

General anaesthesia carries the risk of the patient inhaling gastric contents during induction, which could result in respiratory problems (including aspiration pneumonitis and aspiration pneumonia) or at worst acute respiratory failure and death (King 2010). This is due to the potential for airway reflexes (such as coughing or laryngospasm) or gastrointestinal motor responses (such as gagging or recurrent swallowing) occurring during surgery (AAGBI 2010). The lower oesophageal sphincter (LOS) is

functionally distinct from the oesophagus, and acts as a valve preventing the reflux of gastric contents. Barrier pressure is the difference between LOS pressure (normally 20–30 mmHg) and intragastric pressure (normally 5–10 mmHg) (King 2010). LOS pressure is reduced by several factors, including various drugs used during anaesthesia, including propofol and opioids. This drop in barrier pressure increases the risk of aspiration which increases if the gastric volume exceeds 1000 mL (King 2010). Surgery itself can be a factor as manipulation of organs in the chest or abdominal cavities may force gastric contents up the oesophagus (AAGBI 2010).

Gastric volume is influenced by the rate of gastric secretions (approximately 0.6 mL/kg/h), swallowing of saliva (1 mL/kg/h), ingestion of solids/liquids and the rate of gastric emptying (King 2010). In order to reduce this risk, patients need to be fasted pre-operatively for long enough to allow the stomach

to empty (AAGBI 2010, Benington and Severn 2007). Fasting before general anaesthesia aims to reduce the volume and acidity of stomach contents during surgery, thus reducing the risk of regurgitation/aspiration (Brady et al. 2003). Patients at greatest risk of aspiration are those undergoing unplanned surgery, obese patients, those with abdominal pathology but also inadequate level of anaesthesia (King 2010). Other examples are outlined in Box 13.7.

However, the psychological and physiological effects of hypoglycaemia and fluid deprivation can be very unpleasant, leading to severe thirst, hunger, irritability and an increased incidence of headache and can affect the incidence of post-operative nausea and vomiting (RCN 2005). Dehydration is a particular problem, resulting in an exaggerated hypotensive effect on induction of anaesthesia and making central vein location difficult (AAGBI 2010).

Ensuring that the patient understands the rationale for fasting is important in order to reduce anxiety. Historically, there has been much debate over an optimum pre-operative fasting time. Box 13.8 outlines current best practice pre-operative fasting guidelines for healthy adults undergoing elective surgery.

It is important to be aware that several factors can delay gastric emptying (O'Callaghan 2002). These include:

- reduced conscious level
- systemic opiate therapy
- recent history of difficulty in eating, swallowing, digesting food
- recent history of dyspepsia – heartburn, particularly on lying down or bending over
- upper gastrointestinal surgery
- anxiety
- pregnancy or labour
- abdominal pain
- renal failure
- diabetes.

Box 13.7 Predisposing factors for aspiration under general anaesthesia

Patient factors	Increased gastric content	Intestinal obstruction Non-fasted Drugs Delayed gastric emptying
	Lower oesophageal sphincter incompetence	Hiatus hernia Gastro-oesophageal reflux Pregnancy Morbid obesity Neuromuscular disease
	Decreased laryngeal reflexes	Head injury Bulbar palsy
	Gender	Male
	Age	Elderly
Operation factors	Procedure	Emergency Laparoscopic
	Position	Lithotomy
Anaesthetic factors	Airway	Difficult intubation Gas insufflation
	Maintenance	Inadequate depth

Source: Adapted from King (2010).

Box 13.8 Pre-operative fasting guidelines

- 6 hours fasting from solid food, provided this is a light meal (refer to local trust guidelines for examples of suitable light meal).
- Sweets, including lollipops, are solid food. A minimum pre-operative fasting time of 6 hours is recommended.
- Tea and coffee with milk are acceptable up to 6 hours before surgery.
- Clear fluids (those through which newsprint can be read) up to 2 hours prior to surgery (see Box 13.9).
- Patients being fed by nasogastric or gastrostomy tube should have their feed stopped 6 hours prior to surgery and water 2 hours prior to surgery.
- Chewing gum should be avoided on the day of surgery.
- Regular medication taken orally should be continued pre-operatively unless there is advice to the contrary. Patients can have up to 30 mL of water orally to help them take medication.

Source: Adapted from AAGBI (2010b), RCN (2005a).

805

Patients with hiatus hernia and suspected delayed gastric emptying are at high risk of aspirating. Advice on pre-operative fasting times should be given to these patients by the anaesthetist (AAGBI 2010, King 2010).

In patients with any suspicion of delayed gastric emptying, the anaesthetist responsible for performing the procedure will determine the period of pre-operative fasting. Patients undergoing emergency surgery should be treated as though they have a full stomach (RCN 2005) and the period of fasting will be prescribed by the anaesthetist responsible for the anaesthetic. It is important that all elderly patients, anyone who has undergone bowel preparation, sick patients and mothers who are breastfeeding should not spend long periods without hydration. In these groups intravenous fluids should be considered (AAGBI 2010).

It is recognized that fasting times may be prolonged due to alterations in the operating list. Some alterations are unavoidable, but patients should be kept informed of changes to the theatre list and those without disorders of gastric emptying allowed to continue drinking clear fluids up to 2 hours prior to rescheduled surgery (Box 13.9) (Powell-Tuck et al. 2011). Patients with disorders of gastric emptying or in cases where the theatre time is difficult to ascertain should be offered mouthwashes to keep their mouths moist and intravenous fluids considered if not contraindicated for the surgery being performed, e.g. liver surgery.

Skin preparation

Definition

The purpose of pre-operative skin preparation is to remove visible contaminants and to reduce the levels of naturally occurring skin flora, particularly *Staphylococcus aureus*, to reduce the risk of surgical site infection (Wicker and O'Neill 2010).

Box 13.9 Examples of clear fluids

- Water
- Tea/coffee *without* milk
- Fruit/herb tea
- Fruit squash
- Polycal diluted half and half with water
- Fortijuice
- Enlive

Related theory

Normal bacterial flora live in the nose, groin, armpit, gut, skin and hair of everybody. Organisms may become pathogenic when they move out of their normal area on the body to an open wound (Wicker and O'Neill 2010). NICE (2008) guidelines advise patients to shower or have a bath using soap, either the day before or on the day of surgery. Whilst there is no evidence concerning patient theatre attire, NICE (2008) guidelines advise that patients are given a clean theatre gown to wear and asked to remove their own clothing (depending on the operation). Theatre gowns should maintain the patient's comfort and dignity whilst allowing easy access to the operative site (NICE 2008). Furthermore, theatre gowns avoid placing patients' own clothes at risk of contamination from blood, body and washout fluids (Pudner 2010).

A controversial aspect of skin preparation concerns the removal of body hair from the surgical site. Current NICE (2008) guidance advises against routine hair removal to reduce the risk of surgical site infection. If hair has to be removed in order to adequately view or access the operative site then the best practice as shown in Table 13.4 is advised.

806

Marking skin for surgery

Definition

To identify unambiguously the intended site of surgical incision. The mark should be an arrow, drawn with an indelible, latex-free marker pen and should extend to, or near to, the exact incision site.

Related theory

The surgeon may need to mark an area of the body for surgery, e.g. a limb to be operated on or the position of an organ such as a specific kidney in a patient undergoing a nephrectomy. Marking the surgical site is essential for the planning of any surgical procedure and for the prevention of wrong-site surgery (Mears et al. 2009, NPSA 2005). The incidence of wrong-site surgery is low

but any error can be devastating and in some cases fatal. In 2005 the NPSA published recommendations promoting correct-site surgery. These establish a consistent method of marking patients prior to surgery and provide a checklist of steps to be taken to avoid errors.

The marking should be undertaken by the surgeon performing the operation or competent deputy (i.e. an individual capable of performing the procedure themselves) who will be present at the surgery, to ensure the correct site is marked and this should be checked against the patient's consent form (Haynes et al. 2009). The mark should be an arrow, drawn with an indelible, latex-free marker pen and should extend to, or near to, the exact incision site. The majority of surgical site marking pens contain gentian violet ink, which has antifungal properties (Pennsylvania Patient Safety Authority 2008). Other types of marking pens include permanent ink markers, which despite their lack of antifungal properties have not been found to affect the sterility of the surgical field (Zhao et al. 2009). Marking must be undertaken before pre-medication or anaesthesia so that patients can be involved in ensuring the mark is in the right place. It needs to remain visible after the application of antiseptic (aqueous or alcohol-based) skin preparation (e.g. povidone-iodine or chlorhexidine) and ideally remain visible after the application of theatre drapes (Mears et al. 2009, NPSA 2005). The surgical site mark should not be easily removed with skin preparation but should not be so permanent as to last weeks or months after the surgical procedure.

Following surgery, once the wound has healed, residual traces of the marker pen can be gently removed using warm, soapy water. It is important not to rub too hard to prevent irritating the skin as well as sinking the ink deeper into skin tissues, making it harder to extract. This process may need to be repeated over a series of days.

There are circumstances where marking may not be appropriate.

- Emergency surgery.
- Surgery on teeth or mucous membranes.
- Bilateral procedures such as tonsillectomy and squint surgery.
- Situations where laterality of surgery will be confirmed during the procedure (NPSA 2005).

Table 13.4 Skin preparation

Principle	Rationale
Electric clippers with a single-use disposable head should be used	Clippers do not come into contact with the skin and therefore reduce the risk of cuts and abrasions (JBI 2008, NICE 2008, Pudner 2010). Single-use head prevents cross-infection (AORN 2008). Electric clippers with single-use disposable heads are the most cost-effective method of hair removal (NICE 2008)
If hair removal is required to facilitate access or view of surgical site then where possible, this should be undertaken on the day of surgery	Undertaken as close to the surgery as possible (NICE 2008, Wicker and O'Neill 2010)
Only hair interfering with the surgical procedure should be removed	To prevent unnecessary trauma or visible difference for the patient (Murkin 2009, Wicker and O'Neill 2010)

If a patient refuses pre-operative skin marking, local policy should be followed but include documentation in the patient's nursing and medical notes and on the Surgical Safety Checklist (WHO 2008), clearly stating that the patient refuses marking.

There are some situations in which a specialist nurse may mark the skin. For example, stoma therapists mark the position on the patient's skin which is the optimum place for the stoma to be placed (see Chapter 5: Elimination).

Pre-operative pregnancy testing

Related theory

There is an increased risk of spontaneously aborting the fetus when undergoing surgery during the first trimester of pregnancy (Allaert et al. 2007). It is possible that this is affected by surgical manipulation and the patient's underlying medical condition rather than exposure to anaesthesia (Allaert et al. 2007, Kuczkowski 2004).

Prior to consenting to surgery, all female patients who have commenced menstruation (menarche) need to be informed of the risks surgery may pose to a pregnancy (NICE 2003). The clinician performing the procedure or the appropriately delegated representative (i.e. an individual capable of performing the procedure themselves) is responsible for informing patients of the risks of surgery and is therefore responsible for ensuring that a female patient has had her pregnancy status assessed

(DH 2001, GMC 2008). Once informed of the risks, the patient will need to take responsibility for her own contraception (NICE 2003).

All female patients who have commenced menstruation (menarche) should be considered for pregnancy testing if they express a concern that they may be pregnant or are undergoing gynaecology surgery (NICE 2003). Any pregnancy testing requires informed consent and documentation in the patient's medical record, including test results or patient refusal and the responsible surgical team must be informed prior to the initiation of surgery (NICE 2003). If a previously unknown pregnancy is detected, the risks and benefits of the surgery can be discussed with the patient. Surgery may be postponed or, if the decision is to go ahead, the anaesthetic and surgical approaches can be modified if necessary (NPSA 2010). In emergency situations, confirmation of pregnancy should not delay treatment and should be judged within the clinical assessment of risk.

Legal and professional issues

The practice of checking and documenting current pregnancy status in the immediate pre-operative period has been shown to be inconsistent (NPSA 2010). Pre-operative assessment may take place weeks in advance of a planned operation but pregnancy status may change in the intervening time, so pregnancy status must be rechecked by asking the patient in the immediate pre-operative period on the ward and documented in the perioperative documentation used by staff performing the final clinical and identity checks before the surgical intervention (NPSA 2010).

Prevention of toxic shock syndrome from tampon use

Definition

Staphylococcal toxic shock syndrome (TSS) is a rare, life-threatening systemic bacterial infection, historically associated with the use of superabsorbent tampons. TSS is characterized by high fever, hypotension, rash and multiorgan dysfunction (Deresiewicz 2004).

Related theory

Toxic shock syndrome occurs when the bacteria *Staphylococcus aureus* and *Streptococcus pyogenes*, which normally live harmlessly on the skin, enter the bloodstream and produce poisonous toxins. These toxins cause severe vasodilation which in turn causes a large drop in blood pressure (shock), resulting in dizziness and confusion. They also begin to damage tissue, including skin and organs, and can disturb many vital organ functions. If TSS is left untreated, the combination of shock and organ damage can result in death.

Whilst TSS can also affect men and children, the first reported cases of TSS involved women who were using tampons during menstruation (Eckert and Lentz 2012). Female patients of menstruating age therefore need to be made aware of the dangers of using tampons which can cause infection leading to TSS. At the time of admission, it is important to ask female patients if they are menstruating and to highlight the dangers of using tampons during surgery. If tampons are left *in situ* for longer than 6 hours, infection may develop. Nurses can offer a sanitary pad as an alternative.

Latex sensitivity and allergy

Related theory

Latex is a natural rubber composed of proteins and added chemicals. Its durable, flexible properties give it a high degree of protection from many micro-organisms, which makes it an ideal fibre to

use for many healthcare products. It currently provides the best protection against infection and gives the sensitivity and control needed in the healthcare field. It is found in the following products (AORN 2010, HSE 2004).

- Gloves
- Airways
- Intravenous tubing
- Stethoscopes
- Catheters
- Wound drains
- Dressings and bandages

Some of the proteins in the natural rubber latex can cause sensitivity and allergic reactions and the incidence of latex hypersensitivity seems to be increasing (Rose 2005). Powdered gloves can create the greatest risk as proteins leak into the powder which can become airborne when gloves are removed and inhaling the powder may lead to respiratory sensitization. The amount of latex exposure needed to produce sensitization is unknown. Sensitivity can be described as the development of an immunological memory to specific latex proteins, which can be asymptomatic. A substance which causes sensitization is one which is capable of causing an allergic reaction in certain people. Allergy is the visible reaction of the sensitivity, for example hives, rhinitis, conjunctivitis, anaphylaxis, which can be serious or potentially life-threatening (Table 13.5) (AORN 2010, HSE 2012).

Once sensitization has taken place, further exposure will cause symptoms to recur and increasing exposure to latex proteins increases the risk of developing allergic symptoms (HSE 2012); therefore sensitivities and allergies should be treated in the same way (AORN 2010). Routes of exposure include:

- direct external contact (i.e. to gloves or other latex products)
- airborne exposure
- direct contact of the mucous membranes
- internal patient exposure from healthcare provider use of natural rubber latex gloves during surgical procedures
- internally placed devices (e.g. wound drains) (AORN 2010).

Latex allergies are classified as: irritant contact dermatitis; type I and type IV reactions.

Legal and professional issues

Healthcare providers have an ethical responsibility to prevent latex sensitization and, because there is no cure, protection must be paramount. Employers should have a latex allergy policy and procedure which should provide information and instruction on measures to identify patients at risk, patient education, interventions to reduce undue latex exposure, recognizing symptoms of sensitization and the action to be taken if a sensitization is suspected (AORN 2010, HSE 2012).

Assessment and monitoring for symptoms of latex allergy in both the conscious and unconscious patient are required at all stages of perioperative care. The assessment should cover the following known risk factors for latex allergy.

- History of multiple surgeries beginning at an early age (e.g. spina bifida, urinary malformation).
- History of hayfever or asthma.
- History of an allergic reaction to latex. For example, a history suggestive of reactivity to latex may be gained by anecdotal accounts of swelling or itching of the lips when blowing up balloons, following dental examinations or swelling and itching of the hands when using household gloves.
- History of an allergic reaction during an operation.

Table 13.5 Allergic reactions

Reaction	Description	Symptoms
Irritation	Irritant contact dermatitis, a non-allergenic reaction caused by soaps, gloves, glove powder and hand creams	Dry, crusty, itchy skin Rashes and inflammation
Type I reaction: immediate hypersensitivity – occurs within minutes and can fade rapidly after removal of the latex	Immediate hypersensitivity, sometimes called immunoglobulin E response. Caused by exposure to proteins in latex on glove surface and/or bound to powder	Most severe reaction Wheal and flare response Irritant and allergic contact Dermatitis Facial swelling Rhinitis Urticaria Respiratory distress and asthma Rarely, anaphylactic shock
Type IV reaction: delayed hypersensitivity – usually occurring within 6–48 hours of contact	Sometimes known as allergic contact dermatitis, caused by exposure to chemicals used in latex manufacturing	Red, raised, palpable area with bumps, sores and cracks

Source: Adapted from AORN (2010), HSE (2004), Rose (2005).

- Past experience of itchy skin, skin rash or redness when in contact with rubber products.
- Past skin irritation from an examination by a doctor or dentist wearing rubber gloves.
- Past sneezing, wheezing or chest tightness when exposed to rubber (AORN 2010).

If a suspected or confirmed latex sensitivity or allergy is found, this information must be documented in the patient’s medical notes and communicated to all members of the healthcare team and departments that the patient may visit, including theatre, recovery, pathology and radiology (AORN 2010, Rose 2005). Box 13.10 outlines the pre-operative actions for patients with potential or confirmed latex allergy. The anaesthetist will need to be informed so that decisions can be made regarding potential allergy prophylaxis pre-operatively. A latex-safe environment is recommended – one where every reasonable effort has been made to prevent high-allergen and airborne latex sources from coming into direct contact with affected individuals. Latex-free alternative items should be collected and stored in a quick-access location for ease of access and identification. At present, best practice dictates that patients with a suspected or confirmed latex allergy be scheduled first on the morning list because it is assumed that the inactivity in the room during the previous evening hours causes the content of latex-coated powder in the ambient air to be lowest in the morning (AORN 2010, Rose 2005). Further guidance may be sought online from

Box 13.10 Pre-operative actions for patients with potential or confirmed latex allergy

- Notify operating theatre of potential or confirmed latex allergy 24–48 hours (or as soon as possible) before scheduled procedure.
- Identify the patient’s risk factors for latex allergy and communicate them to the healthcare team.
- Schedule the procedure as the first case of the day if the facility is not latex safe.
- Plan for a latex-safe environment of care.
- The theatre must be cleaned with latex-free gloves and equipment.
- All latex products must be removed or covered with plastics so that the rubber elements are not exposed.
- All healthcare staff in direct contact with the patient must wear vinyl gloves during procedures and in the vicinity of the patient.
- Secure latex-free products for all latex-containing items used by surgeons and anaesthetists.
- A latex-free contents box or trolley (this holds stock of all latex-free products that will be required during surgery and anaesthetic) should be ready in every theatre department and recovery room. There should be a list of all latex-free equipment with the manufacturers listed available in the box or trolley.
- Notify surgeon if no alternative product is available.
- Notify anaesthetist if latex-containing product to be used and develop plan of emergency care if necessary.
- Where a type I (immediate hypersensitivity reaction) allergy is suspected, suitable clinical management procedures must be ready for use in the event of the patient having a hypersensitivity reaction.

Source: Adapted from AORN (2004), AORN (2010).

the Association of Perioperative Registered Nurses (AORN: www.aorn.org).

There is also a voluntary scheme in place for reporting cases of latex sensitization, both of staff and patients, to the Medical Devices Agency (MDA), which is an executive agency of the Department of Health (HSE 2012).

Pre-operative theatre checklist

The pre-operative theatre checklist (see Procedure guideline 13.2: Pre-operative care: checking that the patient is fully prepared for surgery and Figure 13.9) is the final check between the ward and the operating theatre and should be completed as fully as possible to reduce the possibility of any complications during the period that the patient is put under anaesthetic or during surgery itself.

One item on the list is ensuring that blood results and X-rays or imaging accompany the patient. The blood results are important for assessing patient haemoglobin levels which will help in transporting oxygen and also the electrolytes to identify any imbalances such as low sodium or potassium as these can interfere with anaesthetic agents and can cause cardiovascular disturbances such as arrhythmias (Higgins and Higgins 2013) (Table 13.6, Table 13.7).

Prior to taking the patient to the operating theatre, the clinician performing the procedure should check that the patient still consents (see Consent section earlier in this chapter). Patients should not in any situation be given routine pre-operative medication before being asked for their consent to proceed with the treatment (NMC 2013).

Ward & Anaesthetic Room – Pre-operative Checklist

Each entry below must be ticked to indicate Yes, No, or N/A (not applicable) with the relevant details

1 st Check by Ward/Unit Nurse before pre-medication if prescribed or prior to leaving the ward				2 nd Check by Theatre Practitioner / Nurse in anaesthetic room / appropriate area		
SECTION A To be checked from nursing/medical notes/EPR	Yes	No	N/A	Yes	No	N/A
Consent to anaesthetic / operation form signed						
Patient has undergone pre-anaesthetic examination						
Medical case notes / Adult Peri-operative Care Plan to accompany patient						
Imaging / Blood Results / Electrocardiogram (ECG) accompany patient or available on PACS						
Confirm blood has been cross-matched and ordered						
Confirm Infection Status and swab results e.g. MRSA results and liaise with infection control, clinical team and theatres if appropriate						
SECTION B To be checked from nursing/medical notes/EPR	Yes	No	N/A	Yes	No	N/A
Confirm Pregnancy Status: Check and confirm pregnancy status on all women of childbearing age Date of last menstrual period:..... Pregnancy Test Date:..... Result:..... If positive, has the surgeon been informed: Yes: 0 No 0 Comments:						
1 st Check by Ward/Unit Nurse before pre-medication if prescribed or prior to leaving the ward				2 nd Check by Theatre Practitioner / Nurse in anaesthetic room / appropriate area		
SECTION C To be checked by observing/asking patient	Yes	No	N/A	Yes	No	N/A
Two Identification Bands (e.g. wrist & ankle) present and correct						
Red Identification Bands (in case of allergy) present and correct						
Operation Site Marked if appropriate						
Time of Last Food (24 Hr Clock):..... Time of Last Drink (24 Hr Clock):..... Type of Drink:.....						
Time pre-medication given (24 Hr Clock):.....						
Braces / Caps / Crowns / Bridge work / Loose Teeth (If Yes, specify)						
False Teeth / Dentures removed / with patient (Please circle) Supply denture pot with patient's details						

Figure 13.9 Pre-operative ward–theatre checklist.

Shower/Bath taken on day of surgery					
Valuables placed in hospital property					
Theatre gown					
Anti-embolic Stockings applied (please document why if removed)					
Cottonbased underwear worn or consent for removal of underwear					
Contact Lenses removed					
Glasses removed / worn / (Please circle) Supply patient's glasses case with patient's details Kept on Ward / Sent back to Ward / Kept in Operating Theatre					
Hearing Aid removed/to be removed by Anaesthetist (Please circle) Supply envelope with patient's details Kept on Ward / Sent back to Ward / Kept in Operating Theatre					
False Nails / Nail Varnish / Make Up removed (Please circle)					
Jewellery / Ring(s) / Metal Hair Clip(s) are removed or taped					
Body Piercing is removed or taped Area of piercing(s).....					
Prosthesis e.g. knee replacements, implants, pacemaker (specify):.....					
Waterlow Score:..... Pressure Area Problems / Aids (If Yes, specify)					
Time of last micturition OR urinary catheter / nephrostomy tube (please circle)					

	Signature	Full Name (PRINT)	Date	Time
Ward/Unit Nurse				
Ward/Escort Nurse (i.e. transfers/handovers patient to theatre staff)				
Theatre Practitioner / Nurse				

Figure 13.9 *Continued*

Table 13.6 Haematology values

Test	Reference range	Functions/additional information
Red blood cells (RBC)	Men: $4.5\text{--}6.5 \times 10^{12}/\text{L}$ Women: $3.9\text{--}5.6 \times 10^{12}/\text{L}$	The main function of the RBC is the transport of oxygen and carbon dioxide
Haemoglobin	Men: $13.5\text{--}13.5 \text{ g/dL}$ Women: $11.5\text{--}15.5 \text{ g/dL}$	Haemoglobin (Hb) is a protein pigment found within the RBC which carries the oxygen Anaemia (deficiency in the number of RBC or in the Hb content) may occur for many reasons. Changes to cell production, deficient dietary intake or blood loss may be relevant and need to be investigated further
White blood cells (WBC)	Men: $3.7\text{--}9.5 \times 10^9/\text{L}$ Women: $3.9\text{--}11.1 \times 10^9/\text{L}$	The function of the WBC is defence against infection. There are different kinds of WBC: neutrophils, lymphocytes, monocytes, eosinophils and basophils. Leucopenia is a WBC count lower than 3.7 and is usually associated with the use of cytotoxic drugs. Leucocytosis (high levels of neutrophils and lymphocytes) occurs as the body's normal response to infection and after surgery. Leukaemia involves an increased WBC count caused by changes in cell production in the bone marrow. The leukaemic cells enter the blood in increased numbers in an immature state
Platelets	Men: $150\text{--}400 \times 10^9/\text{L}$ Women: $150\text{--}400 \times 10^9/\text{L}$	Clot formation occurs when platelets and the blood protein fibrin combine. A patient may be thrombocytopenic (low platelet count) due to drugs/poor production or have a raised count (thrombocytosis) with infection or autoimmune disease
Coagulation/ international normalized ratio (INR)	INR range 2–3 (in some cases a range of 3–4.5 is acceptable)	Coagulation occurs to prevent excessive blood loss by the formation of a clot (thrombus). However, a clot that forms in an artery may block the vessel and cause an infarction or ischaemia which can be fatal. Aspirin, warfarin and heparin are three drugs used for the prevention and/or treatment of thrombosis. It is imperative that patients on warfarin therapy receive regular monitoring to ensure a balance of slowing the clot-forming process and maintaining the ability of the blood to clot

Table 13.7 Biochemistry values

Test	Reference range	Functions/additional information
Sodium	135–145 mmol/L	The main function of sodium is to maintain extracellular volume (water stored outside the cells), acid/base balance and the transmitting of nerve impulses. <i>Hypernatraemia</i> (serum sodium >145 mmol/L) may be an indication of dehydration due to fluid loss from diarrhoea, excessive sweating, increased urinary output or a poor oral intake of fluid. An increased salt intake may also cause an elevation. <i>Hyponatraemia</i> (serum sodium <135 mmol/L) may be indicated in fluid retention (oedema)
Potassium	3.5–5.2 mmol/L	Potassium plays a major role in nerve conduction, muscle function, acid/base balance and osmotic pressure. It has a direct effect on cardiac muscle, influencing cardiac output by helping to control the rate and force of each contraction. The most common cause of <i>hyperkalaemia</i> (serum potassium >5.2 mmol/L) is chronic renal failure. The kidneys are unable to excrete potassium. The level may be elevated due to an increased intake of potassium supplements during treatment. Tissue cell destruction caused by trauma/cytotoxic therapy may cause a release of potassium from the cells and an elevation in the potassium plasma level. It may also be observed in untreated diabetic ketoacidosis. Urgent treatment is required as hyperkalaemia may lead to changes in cardiac muscle contraction and cause subsequent cardiac arrest. The main cause of <i>hypokalaemia</i> (serum potassium <3.5 mmol/L) is the loss of potassium via the kidneys during treatment with thiazide diuretics. Excessive/chronic diarrhoea may also cause a decreased potassium level
Urea	2.5–6.5 mmol/L	Urea is a waste product of metabolism that is transported to the kidneys and excreted as urine. Elevated levels of urea may indicate poor kidney function
Creatinine	55–105 µmol/L	Creatinine is a waste product of metabolism that is transported to the kidneys and excreted as urine. Elevated levels of creatinine may indicate poor kidney function
Calcium	2.20–2.60 mmol/L	Most of the calcium in the body is stored in the bone but ionized calcium, which circulates in the blood plasma, plays an important role in the transmission of nerve impulses and for the functioning of cardiac and skeletal muscle. It is also vital for blood coagulation. High calcium levels (hypercalcaemia >2.6 mmol/L) can be due to hyperthyroidism, hyperparathyroidism or malignancy. Elevation in calcium levels may cause cardiac arrhythmia, potentially leading to cardiac arrest. Tumour cells can cause excessive production of a protein called parathormone-related polypeptide (PTHrP) which causes loss of calcium from the bone and an increase in blood calcium levels. This is a major reason for hypercalcaemia in cancer patients (Higgins and Higgins 2013). <i>Hypocalcaemia</i> (<2.20 mmol/L) is often associated with vitamin D deficiency due to inadequate intake or increased loss due to GI disease. Mild hypocalcaemia may be symptomless but severe disease may cause increased neuromuscular excitability and cardiac arrhythmias. It is also a common feature of chronic renal failure (Higgins and Higgins 2013)
C-reactive protein (CRP)	<10 mg/L	Elevation in the CRP level can be a useful indication of bacterial infection. CRP is monitored after surgery and for patients who have a high risk of infection. The CRP level can help monitor the severity of inflammation and assist in the diagnosis of conditions such as systemic lupus erythematosus (SLE), ulcerative colitis and Crohn's disease (Higgins and Higgins 2013)
Albumin	35–50 g/L	Albumin is a protein found in blood plasma which assists in the transport of water-soluble substances and the maintenance of blood plasma volume
Bilirubin	(total) <13 µmol/L	Bilirubin is produced from the breakdown of haemoglobin; it is transported to the liver for excretion in bile. Elevated levels of bilirubin may cause jaundice

Procedure guideline 13.2 Pre-operative care: checking that the patient is fully prepared for surgery*Essential equipment*

- Two namebands
- Theatre gown
- Cotton-based underwear or disposable pants can be worn if this does not interfere with surgery
- Antiembolic stockings
- Labelled containers for dentures, glasses and/or hearing aid if necessary
- Hypoallergenic tape
- Patient records/documentation including medical records, consent form, drug chart, X-ray films, blood test results, anaesthetic assessment, record and pre-operative checklist

(continued)

Procedure guideline 13.2 Pre-operative care: checking that the patient is fully prepared for surgery (continued)

Procedure

Action

- 1 Discuss with the patient:
 - if they know what surgery they are having and why
 - if they can tell you about the wound, any intravenous infusions or drains, etc. that they may expect after the surgery
 - if they have been told about levels of pain and how it will be controlled
 - how they can be involved in ensuring they recover as quickly as possible, etc.
- 2 Check that the patient has undergone relevant investigative procedures and that the results are included with the patient's notes. Examples include X-ray, ECG, MRI, CT, ECHO, blood test, urinalysis.
- 3 Confirm and document when the patient last had food or drink, ensuring that this complies with pre-operative instructions and document in pre-operative documentation.
- 4 Confirm and document which medications the patient has taken and when. Ensure this complies with pre-operative instructions and document in pre-operative documentation.
- 5 If the patient is female and of child-bearing age:
 - (a) check her pregnancy status and document the result in the pre-operative documentation. If a pregnancy test is required (e.g. if the patient expresses a concern that she may be pregnant or she is undergoing gynaecology surgery) (NICE 2003), test results should be given to the patient and documented in the pre-operative documentation
 - (b) if appropriate, ask the patient if she is menstruating and ensure that she has a sanitary towel in place and not a tampon.
- 6 In the presence of the patient, check the consent form is correctly completed, signed and dated.
- 7 If applicable, check the operation site has been marked correctly with the patient and the consent form.
- 8 Check that the patient has undergone pre-anaesthetic assessment by the anaesthetist.
- 9 Measure and record the patient's pulse, blood pressure, respirations, oxygen saturations, temperature, weight and blood sugar (if required) in pre-operative documentation.
- 10 Ask the patient to remove all jewellery, cosmetics and nail varnish. Wedding rings may be left on fingers, but must be covered and secured with hypoallergenic tape. Patients requesting to wear other forms of metal jewellery (e.g. chains) for personal or religious reasons will need to discuss this with the operating team.
- 11 If a patient has valuables, these must be recorded and stored away securely according to hospital policy.
- 12 Ask the patient to shower or bath as close to the planned time of the operation as possible and before a pre-medication is administered (if this has been prescribed). If the patient has long hair, this needs to be tied back with a non-metallic tie.
- 13 Apply antiembolic stockings according to local trust procedure (see Procedure guideline 13.1: Step-by-step guide to measuring and applying antiembolic stockings

Rationale

- To ensure that the patient understands the nature and outcome of the surgery, to reduce anxiety and possible post-operative complications (Walker 2002, **E**).
- To ensure all relevant information is available to the nurses, anaesthetists and surgeons (AORN 2000, **C**).
- To reduce the risk of regurgitation and inhalation of stomach contents on induction of anaesthesia. It can take 9 hours or more for a substantial meal to be emptied from the stomach (AAGBI 2010, **C**; King 2010, **C**; RCN 2005, **C**).
- To ensure the patient does not take and/or omit any medication which could adversely affect surgery e.g. continuation of high dose warfarin.
- To eliminate the possibility of unknown pregnancy prior to the planned surgical procedure (NPSA 2010, **E**).
- This is to prevent infection if the tampon is left in place for longer than 6 hours (www.tamponalert.org.uk, **C**).
- To comply with legal requirements and hospital policy and to ensure that the patient has understood the surgical procedure (NMC 2013, **C**).
- To ensure the patient undergoes the correct surgery for which they have consented (AORN 2000, **C**; Haynes et al. 2009, **C**).
- To ensure that the patient can be given the most suitable anaesthetic and any special requirements for anaesthetic have been highlighted (AORN 2000, **C**).
- To provide baseline data for comparison intra- and post-operatively. The weight is recorded so that the anaesthetist can calculate the correct dose of drugs to be administered (AORN 2000, **C**).
- Metal jewellery may be accidentally lost or may cause harm to the patient, for example diathermy burns. Facial cosmetics make the patient's colour difficult to assess. Nail varnish makes the use of the pulse oximeter, used to monitor the patient's pulse and oxygen saturation levels, impossible and masks peripheral cyanosis (Vedovato et al. 2004, **C**).
- To prevent loss of valuables. **E**
- To minimize risk of post-operative wound infection and prevent patient accidents when sedated (Loveday et al. 2014, **C**).
- For safety, to prevent hair getting caught in equipment and to reduce the risk of infection. **E**
- To reduce the risk of post-operative deep vein thrombosis or pulmonary emboli (NICE 2010, **C**).

<p>14 Ensure the patient is wearing two electronic namebands containing their full name, date of birth and NHS number. One should be placed on the patient's wrist and the other on the ankle. Prior to placing the namebands on the patient, the details should be verbally checked and confirmed as accurate by the patient and against the patient's medical notes. The namebands will be white unless local trust policy stipulates that colour coding is necessary to alert healthcare professionals to a risk, e.g. allergy, in which case the wristbands will be red (NPSA 2007).</p>	<p>To ensure correct identification and prevent possible patient misidentification (AORN 2000, C).</p> <p>To reduce allergic reactions to known causative agents and to alert all involved in the care of the patient in the operating theatre (AORN 2004, C).</p>
<p>15 Record whether the patient has dental caps, crowns, bridge work or loose teeth in the pre-operative checklist.</p>	<p>The anaesthetist needs to be informed to prevent accidental damage. Loose teeth or a dental prosthesis could be inhaled by the patient when an endotracheal tube is inserted. E</p>
<p>16 Document any patient prostheses in the pre-operative checklist and whether they are removable (e.g. artificial limb, dentures, hearing aid) or irremovable (e.g. pacemaker, knee replacement).</p> <p>Removable prostheses may be retained until the patient is in the anaesthetic room. Spectacles and hearing aids may be retained until the patient has been anaesthetized (these may be left in position if a local anaesthetic is used). Any prosthesis that is removed should be labelled clearly (ideally with a patient identifier) and retained in the recovery room.</p>	<p>To promote patient safety during surgery. For example, dentures may obstruct the airway, contact lenses can cause corneal abrasions. Internal non-removable prostheses may be affected by the electric current used in diathermy.</p> <p>To enable the patient to communicate fully, thus reducing anxiety and enabling the patient to understand any procedures carried out. E</p> <p>To enable patients with prosthetic limbs to mobilize independently to theatre.</p>
<p>17 Check whether the patient passed urine before pre-medication or anaesthetic.</p>	<p>To prevent urinary incontinence when sedated and/or unconscious and possible contamination of sterile area. E</p>
<p>18 Once the pre-operative checklist is fully completed, administer any pre-medication, if prescribed, in accordance with the anaesthetist's instructions.</p> <p>Patients who receive a sedative pre-medication should be advised to remain in bed and to use the nurse call system if assistance is needed.</p>	<p>Different drugs may be prescribed to complement the anaesthetic to be given, for example temazepam to reduce patient anxiety by inducing sleep and relaxation. E Questioning premedicated patients is not a reliable source of checking information as the patient may be drowsy and/or disorientated (AORN 2000, C).</p> <p>To reduce the risk of accidental patient injury as the pre-medication may make the patient drowsy and disorientated. E</p>
<p>19 Accompany the patient to theatre, taking their notes, medication chart, X-rays/scans, blood results, completed consent form and pre-operative checklist. The patient should be accompanied to the theatre by an appropriately trained healthcare professional.</p> <p>Mobile patients who have not received a sedative pre-medication will be able to walk to theatre wearing appropriately fitting footwear.</p> <p>Immobile patients or patients who have received a sedative pre-medication will need to be taken to theatre on a theatre trolley.</p>	<p>To prevent delays which can increase the patient's anxiety and to ensure that the anaesthetist and surgeon have all the information they require for safe treatment of the patient. E</p> <p>To reduce patient anxiety and ensure a safe environment during anaesthetic induction. E</p> <p>To reduce the risk of accidental patient injury. E</p> <p>To reduce the risk of accidental patient injury as the pre-medication may make the patient drowsy and disorientated. E</p>
<p>20 Give a full handover to the anaesthetic nurse or operating department practitioner on arrival in the anaesthetic room, using patient records and the pre-operative checklist. The escorting healthcare professional will stay with the patient until they have been fully checked in by the anaesthetic assistant/nurse.</p>	<p>To ensure the patient has the correct operation. To ensure continuity of care and to maintain the safety of the patient by exchanging all relevant information (AORN 2000, C).</p>

Intraoperative care

Intraoperative care: anaesthesia

Definition

Intraoperative care is the physical and psychological care given to the patient in the anaesthetic room and operating

theatre until transfer to the post-operative area. In the anaesthetic room patients are admitted and checked into the operating suite. The patient is normally transferred already anaesthetized into the theatre on a trolley and moved across to the operating table. For emergency surgery (e.g. dissecting aortic aneurysm or ruptured ectopic pregnancy) and in the case of bariatric patients, it is safer to induce anaesthesia inside the operating theatre with the patient already positioned on

the operating table (Leonard and Thompson 2008). A crucial role of the anaesthetic nurse is to support the patient who is often frightened or anxious due to the unfamiliar, often intimidating environment and apprehensive about both the anaesthesia and impending surgery (Lindwall et al. 2003, Mitchell 2010).

Related theory

The safe administration of anaesthesia has been evolving since the early 1840s. At this time surgery was often seen as a final attempt to save life and very few operations were performed. This was because surgery was very painful and patients were conscious during the procedure and could hear everything that was being said and done. In order to overcome these difficulties, surgeons would administer alcohol, morphine and other sedatives. This was usually ineffective and most patients were restrained either with straps or physically held down. Surgery (such as amputation of limbs) had to be performed speedily and often patients would either faint from pain or die from the bleeding.

814

Modern anaesthesia began in October 1846 when William Morton administered ether for the first time at Massachusetts General Hospital, Boston. This was shortly followed that year by James Robinson who administered the first ether anaesthetic in England. The following year James Simpson, Professor of Obstetrics, introduced chloroform anaesthesia in Edinburgh. Although chloroform had severe side-effects such as sudden death and delayed liver damage, it still became popular because it worked well and was easier to use than ether. John Snow, the first dedicated anaesthetist, administered chloroform to Queen Victoria during labour in 1853 (Simpson et al. 2002). Local anaesthetic (cocaine) was introduced in 1877 which progressed during the 1900s with newer, less toxic local anaesthetics which facilitated further developments such as infiltration anaesthesia, nerve blocks, spinal and epidural analgesia (Cobbold and Money 2010).

However, it was not until the turn of the 20th century that control of the airway, using tubes in the trachea to facilitate ventilation and prevent aspiration of stomach contents, and intravenous induction agents were introduced. This practice enabled patients to be anaesthetized more quickly and safely.

Modern general anaesthesia is usually described as a triad of components that include hypnosis (sleep), analgesia and muscle relaxation. The proportion of each component may vary according to the surgery. For example, modern muscle relaxants, which emerged from the 1940s, enable adequate relaxation of the abdomen (for example) without relying on very deep anaesthesia (from a single agent) to achieve the same effect (Simpson et al. 2002). Today anaesthesia is very safe and there are very few deaths – less than 1 in 250,000 directly related to anaesthesia (Royal College of Anaesthetists 2013).

Evidence-based approaches

Anticipated patient outcomes

- To ensure that the patient understands what will happen in the operating theatres at all times in order to minimize anxiety.
- To ensure that the patient has the correct surgery for which the consent form was signed.
- To ensure patient safety at all times and minimize post-operative complications by:
 - giving the required care for the unconscious patient
 - ensuring injury is not sustained from hazards associated with the use of swabs, needles, instruments, diathermy and power tools
 - minimizing post-operative problems associated with patient positioning, such as nerve or tissue damage

- maintaining asepsis during surgical procedures to reduce the risk of post-operative wound infection in accordance with hospital policies on infection control.

Legal and professional issues

The WHO Surgical Safety Checklist is a structured aid to enhance communication and improve safety within surgery (www.who.int/patientsafety/safesurgery/en/). It is mandated in many countries including the UK. The purpose of this checklist is to ensure that the correct procedure is performed on the correct patient, encourage team work and improve communication amongst the surgical team (Jones 2011). The safety checklist comprises three parts: sign in, time out and sign out (Box 13.11). Sign in is completed in the anaesthetic room before the patient is induced. It has to be read out loud with the anaesthetist and the anaesthetic assistant present. The checklist may be modified to ensure relevance within different surgical specialties/settings (WHO 2008). However, local modifications that increase the complexity of the checklist may negatively impact on team compliance (Alnaib et al. 2012).

Pre-procedural considerations

Pharmacological support

Prior to commencing anaesthesia, the patient is usually assessed by the anaesthetist and/or the nursing pre-assessment team. The type of anaesthetic administered will depend on a number of factors including the age/risk of the patient, planned surgery and patient/clinician preference. However, the following components are usually included.

- *Analgesia*: this will be administered intravenously with the muscle relaxants and sleep-inducing drugs. Drugs used are dependent on anaesthetic preference and technique. Commonly used agents include fentanyl, remifentanyl and morphine as well as non-steroidal anti-inflammatory drugs (NSAIDs) such as ketorolac. This is to ensure that the patient does not feel any pain at the time of skin incision, during the surgery and post-operatively.
- *Antiemetics* are given with analgesia. These medications, such as cyclizine, ondansetron and granisetron, moderate the side-effects of opioid analgesics and inhalational anaesthesia and reduce post-operative nausea and vomiting (PONV).
- *Induction agents* are drugs which help to induce unconsciousness. The mostly commonly used is propofol, a short-acting medication that can also be used to maintain anaesthesia as an intravenous infusion.
- *Inhalation agents*: after induction, the anaesthesia can be maintained by either inhalational agents or intravenous infusion (propofol). Examples of inhalation agents are sevoflurane and isoflurane. While these are very effective, they are associated with a higher incidence of PONV (Apfel et al. 2005). These are administered through vaporizers which are attached to the anaesthetic machines (Figure 13.10).
- *Muscle relaxants* are the last drugs to be administered during induction as they relax all muscles (except the cardiac muscle), leading to paralysis. This is done when patients are unconscious otherwise it would be a very frightening experience for them to be aware but unable to move. The most commonly used relaxants/paralysing agents are atracurium, vecuronium and rocuronium.

Specific patient preparation

When the patient arrives in the anaesthetic room, it is important to check their details to ensure that the correct patient is being received. At this point, consent is verified with the patient in order to confirm the planned surgery and the patient's identity. This completes the final phase of the pre-operative checklist. As this is the final patient check prior to commencing anaesthesia and surgery, it is crucial to ensuring the patient's safety.

Box 13.11 WHO Surgical Safety Checklist

DATE:
THEATRE:

The ROYAL MARSDEN

PATIENT DETAILS

Last name
First name
DOB
Hospital number

SURGICAL SAFETY CHECKLIST

V3.1 pilot

CHECK IN

Has the patient confirmed their identity, procedure, site and consent?

Has the patient identity been confirmed with two staff members?

Is the site marked?

Does the patient have:
A known allergy?
A difficult airway?
Aspiration risk?

What are the patient-specific concerns?
ASA grade
Are the required blood products available?
Have required antibiotic been given?
Is glycaemic control an issue?
Are warming devices prepared for use?
Has the VTE assessment been completed?
Are VTE prophylaxis devices in place for use?

TIME OUT

Are the regular team member names written on the board?

Have new team members been introduced?

Is the patient's name and planned procedure confirmed?

Is anticipated blood loss >500mL ?
Blood is/not in the fridge

Are there specific equipment or investigation requirements?

Are there any critical or unusual steps the team needs to know?

Has the sterility of the instruments been confirmed?

SIGN OUT

Has the name of the procedure been recorded?

Is the instrument and sharps count correct?

Have the specimens been labeled?

Were there any problems during this case?

Could they have been dealt with differently?

Is the operation note written?

Is the immediate post-op plan agreed?

Procedure guideline 13.3 Caring for the patient in the anaesthetic room

<i>Essential equipment</i> <ul style="list-style-type: none">• Suction• Anaesthetic machine<ul style="list-style-type: none">– Airway equipment• Medical gases (including back-up O₂ cylinders)• Monitoring equipment<ul style="list-style-type: none">– Emergency drugs	
<i>Pre-procedure</i>	
Action	Rationale
1 Greet the patient by name. Confirm with the ward nurse that it is the correct patient for the scheduled operation.	To reduce patient anxiety. P
<i>Procedure</i>	
2 Identify the patient by checking the identification band (name and patient number) against the patient's notes and the operating list.	To safeguard against patient misidentification (AFPP 2011, C).
3 Check and confirm the correct completion of the pre-operative checklist.	To ensure that all the listed measures have been completed and that any additional information has been recorded. E
4 Check that the results of the investigative procedures, for example blood results, X-rays, and so on, are included with the patient's notes.	To ensure that all the required results are available for the theatre team's use. E
5 Maintain a calm, quiet environment and explain all the procedures to the patient, including the monitoring of blood pressure, pulse and oxygen saturation.	To reduce anxiety and enhance the smooth induction of anaesthesia (Mitchell 2010, E).
6 When the patient is anaesthetized, ensure that the eyes are closed and secured with hypoallergenic tape/padding.	To prevent corneal damage due to eyes drying out or accidental abrasion. For longer cases a sterile lubricant may also be applied to the surface of the eye (White and Crosse 1998, E).
<i>Post-procedure</i>	
7 When the patient has been anaesthetized, they are transferred into the operating theatre.	

Intraoperative care: theatre

Related theory

Before surgical intervention (skin incision)
The team in theatre normally consists of at least one surgeon (often more, including surgical trainees), an anaesthetist and the theatre staff which as well as Registered Nurses often also includes registered ODPs and healthcare assistants. Within this team there will be a scrub nurse (or ODP) who works in the sterile field, managing the instrumentation, swabs and sutures and assisting the surgeon. There will normally be at least one circulating person who remains outside the sterile field and provides items as required for the scrub nurse/ODP. There will also be a designated nurse/ODP who assists the anaesthetist (Figure 13.11).

Once the patient has been positioned on the operating table, before surgical intervention, the theatre team will complete the second section of the WHO safety checklist which is 'time out'. This ensures that the team is fully aware and readily equipped for any eventuality that may arise during the procedure. The WHO checklist (part 2) 'time out' has to be read out loud for all team members to hear and respond to and has to be completed before the start of any surgical intervention such as the first skin incision (see Box 13.11).

Control of infection and asepsis in the operating theatre
As part of intraoperative care, the aim of operating theatres is to provide an environment that minimizes the presence of pathogens (both airborne and surface). The general principle is that

Figure 13.11 Surgical team.

the actual operating theatre is the cleanest area within the suite as this is the area where patients are at most risk of surgical site infection. Ventilation systems within theatres support this principle by using positive pressure ventilation to carry pathogens away from the surgical wound (Al-Benna 2012).

Large quantities of bacteria are present in the nose and mouth, on the skin, hair and the attire of personnel. The skin of staff becomes dispersed in the air and is a potential source of wound infection (Sivanandan et al. 2011). Therefore staff working in operating theatres wear clean scrub suits and lint-free surgical hats to eliminate the possibility of these bacteria, hair or dandruff being shed into the environment (AFPP 2011). Well-fitting shoes with impervious soles should be worn and regularly cleaned to remove splashes of blood and body fluids (Woodhead et al. 2002). Face-masks are worn to prevent droplets falling from the mouth into the operating field. The extent to which facemasks are capable of preventing droplet spread is disputed (Lipp and Edwards 2002). It is, however, accepted that masks offer protection to the wearer from blood splashes and for safety reasons should be worn by the scrub team. Instruments must be handled carefully and needle holders and forceps used to manipulate sutures to minimize the risk of needlestick or sharps injury.

Minimally invasive surgery (laparoscopic surgery) and robotically assisted laparoscopic surgery

Abdominal and pelvic surgeries are often performed using this technique. Laparoscopy is often referred to as keyhole surgery and involves the introduction of a number of small ports through the skin to allow access into the abdominal cavity. Specialized cameras, lights and instruments (Figure 13.12) are introduced through these ports in order to perform this minimally invasive surgery.

Minimally invasive surgery involves the insufflation of the abdomen with carbon dioxide (CO_2). This is necessary in order to expand the space in which the surgeon is operating to facilitate the surgery and is known as pneumoperitoneum (Figure 13.13). Carbon dioxide is used as, unlike air or oxygen, it does not support combustion in the presence of electricity and is readily excreted by the patient via the respiratory system. Prolonged insufflation may cause hypothermia as, although the gas is equal to room temperature, the temperature in the abdomen decreases because of the high gas flow and the volume of gas used (Jacobs et al. 2000). Sharma et al. (1997) refer to the increased risk of hypercarbia and surgical emphysema during insufflation with CO_2 . Careful monitoring and recording of the patient's vital signs, including oxygen

Figure 13.13 Pneumoperitoneum/port placement.

saturation and expiratory gas levels, are therefore essential during laparoscopy.

Haemorrhage can occur during any surgical procedure and may be difficult to detect and control in laparoscopic procedures. Therefore the theatre staff should always have the equipment necessary to convert to an open procedure. Theatre staff must also ensure that equipment is used safely and according to the manufacturer's instructions.

Robotic surgery

Robotic surgery is a relatively recent development (the Da Vinci system was licensed in 2000). The robot is controlled remotely by the surgeon who sits at a console inside the theatre. The robot is able to manipulate instruments (introduced laparoscopically) through 360° which is something even the most talented and dextrous surgeon cannot do. This means that robotic surgery is of particular value in confined, hard-to-reach spaces such as the pelvis. Therefore it is most commonly used in urological and gynaecological surgery. In common with regular laparoscopic surgery, patients often spend a much shorter time in hospital compared to those having open surgery for the same procedure. The market is currently dominated by one single supplier, Integra, which manufactures the Da Vinci surgical robot (Figure 13.14).

Staff involved with robotic surgery have to receive special training in order to set up and assist with robotic procedures (Figure 13.15). The robot is a sophisticated and very expensive item of equipment and a dedicated team of staff are often assigned to this speciality (Figure 13.16).

Evidence-based approaches

Positioning of the patient on the table

The position of the patient on the operating table must be such as to facilitate access to the operative site(s) by the surgeon, and the patient's airway for the anaesthetist. It will also be dependent upon the type of surgery being performed, position of monitoring equipment and intravenous devices *in situ*. It should not compromise the patient's circulation or respiratory system or cause damage to the skin or nerves.

Pre-operative assessment will identify patients who may need extra precautions during positioning because of their weight, nutritional state, age, skin condition or pre-existing disease. The increased numbers of obese patients requiring surgery present specific challenges and staff must be familiar with the weight

Figure 13.12 Laparoscopic equipment.

Figure 13.14 Da Vinci surgical robot.

Figure 13.17 Lithotomy position.

limits of patient trolleys and operating tables. Many departments now have specialist bariatric equipment for the safe positioning of obese patients (Bale and Berreclough 2010).

Pre-existing conditions such as backache or sciatica can be exacerbated, particularly if the patient is in the lithotomy position (Figure 13.17), as the sciatic nerve can be compressed against the poles (AFPP 2011). Most post-operative palsies are due to incorrect positioning of the patient on the operating table (Beckett 2010). Consideration by and co-operation of all theatre personnel can help prevent many of the post-operative complications related to intraoperative positioning and this remains a team responsibility (AFPP 2011, Beckett 2010).

All movements of the limbs of the unconscious patient should take into account the anatomy and natural planes of movement of that limb to avoid stretching and pressure on the related nerve planes (AFPP 2011). Hyperabduction of the arm when placed on a board, for example, could stretch the brachial plexus, causing some post-operative loss of sensation and reduced movement of the forearm, wrist and fingers. To prevent this, the board should be angled at 45° and not 90° with hands facing more towards the feet rather than the head (Figure 13.18). The ulnar and radial nerves may be affected by direct pressure as a result of insufficient padding on arm supports.

Figure 13.18 Armboard.

Figure 13.19 Lloyd Davies position.

Compartment syndrome is a life-threatening complication of the Lloyd Davies position (Figure 13.19) and occurs when perfusion falls below tissue pressure in a closed anatomical space or compartment such as hand, forearm, buttocks, legs, upper arms and feet. It develops through a combination of prolonged ischaemia and reperfusion of muscle within a tight osseofascial compartment (Raza et al. 2004). Untreated, it can lead to necrosis, functional impairment, possible renal failure and death (Callum and Bradbury 2000, Paula 2002).

If patients are placed in Lloyd Davies position and Trendelenburg tilt for longer than 4 hours, the legs should be removed from the support every 2 hours, or as close to 2 hours as possible, for a short period of time to prevent reperfusion injury (Raza et al. 2004). The use of compression stockings and intermittent compression devices in the Lloyd Davies position should be approached with caution as these devices may contribute to compartment syndrome (Malik et al. 2009). The use of these devices will depend on the clinical judgement of the surgeon and anaesthetist and the physical status of the patient.

Methods of infection prevention

It is imperative that during surgical procedures, infection control and prevention are maintained at all times. The area immediately around the patient and the instrument trolley is known as the sterile field. Only those staff who have donned sterile gloves and gowns after washing and decontaminating their hands and forearms (scrubbing-up) can enter the sterile field. Pre-surgical hand washing or scrubbing up (Figure 13.20) is an essential step in the prevention of infection during surgery.

The aim of surgical hand antisepsis is to remove dirt and transient micro-organisms and also to reduce to a minimum resident micro-organisms on the hands, nails and forearms (AORN 2013). For minor surgical procedures, current research supports a 1-minute hand wash with a non-antiseptic soap followed by hand rubbing with liquid aqueous alcoholic solution prior to the first procedure of the day and before any subsequent procedures.

Figure 13.20 Surgical scrub.

(Tanner et al. 2007). This has been shown to be as effective as traditional hand scrubbing with an antiseptic soap containing 4% chlorhexidine gluconate or 7.5% povidone-iodine in preventing surgical site infection (Parienti et al. 2002). However, for more major cases it is usual to perform surgical hand antisepsis using either a solution containing chlorhexidine or iodine. The duration of the wash is usually 2–5 minutes (AFPP 2011). The six steps of hand washing should be followed and also the arms up to the elbow should be washed (Loveday et al. 2014).

Surgeons and staff who are working within the sterile field wear sterile surgical gowns. These gowns are designed to function as both a sterile barrier between the wearer's body and the surgical field and as protection for the wearer against exposure to blood, body fluids and tissue. The gown should be resistant to microbial and liquid penetration and minimize the release of particles (AFPP 2011).

Surgical gloves have a dual role, acting as a barrier for personal protection from the patient's blood and other exudates and preventing bacterial transfer from the surgeon's hand to the operating site. Surgical gloves must conform to international standards and different types are used for various procedures. It is essential that the glove is the correct size, not only for reasons of comfort but also for dexterity and sensitivity. It is common practice for many surgeons and theatre staff to double glove. Evidence suggests that double gloving significantly reduces the number of perforations to the innermost glove, thus reducing infection rates during surgical procedures (Tanner and Parkinson 2006).

Prior to skin incision, the skin of the patient is cleaned with an antiseptic solution. The purpose of this is to reduce the amount of both transient and resident skin bacteria. Most surgical wound infections are caused by bacteria living on the

patient's own skin. Several types of skin preparation are used but commonly include povidone-iodine or chlorhexidine gluconate. These agents are included in either aqueous or alcoholic solutions. Which is used depends on both the condition of the patient's skin and whether they are allergic to either of the agents (AFPP 2011).

Legal and professional issues

Transferring and positioning

When a patient is transferred between the trolley or bed and operating table, adequate personnel should be present to ensure patient and staff safety (AFPP 2011). It is recommended that an approved sliding device is used to transfer patients from trolley to operating table, in compliance with national legislation on manual handling and local hospital policy/guidelines.

Safe manual handling and the safety of the patient depend on the participation of the correct number of staff in the specified handling manoeuvre. There should be a minimum of four staff: one at either end of the patient to support the head and the feet and one on either side. Additional staff and/or specialist transfer devices may be required if the patient weighs over 90 kg (Figure 13.21).

Once the patient has been positioned safely, the intermittent compression device is attached. Figure 13.22 shows the Flowtron machine used in prevention of deep vein thrombosis in conjunction with venous compression garments.

Pre-procedural considerations

Equipment

In the operating room, the staff should ensure that all equipment is ready and checked before the first patient is sent for.

Anaesthetic machine and patient monitoring (Figure 13.23)

This allows the anaesthetists to administer the correct proportions of oxygen, air and inhalational agents. Cardiovascular and respiratory monitoring is essential throughout the anaesthetic and surgery and includes ECG, blood pressure, respiratory rate/volume, oxygen saturation and expired CO₂ monitoring. To ensure adequate depth of anaesthesia, either the expired anaesthetic agent or brain electrical activity is monitored by the anaesthetist (depending on the anaesthetic technique).

Suction unit (Figure 13.24)

This is attached to the anaesthetic machine and is used in the event of obstruction (to clear secretions) or to remove regurgitated stomach contents.

Vaporizer

This is also attached to the anaesthetic machine and is used to administer inhalational anaesthetic agents.

Scavenging system

This removes the inhalational agents that the patient exhales so it is important to ensure that this is operational. Contamination of the atmosphere with these agents can be harmful to staff (Beths 2006).

Operating table (Figure 13.25)

As part of the equipment check, the operating table is assessed to ensure it is fully operational and performs all the required functions to enable correct positioning of the patient. The height of the operating table is adjusted in relation to the height of the surgeon and team to prevent any unnecessary strain on the back and neck. Modern operating tables are powered by a battery that needs to be charged when not in use. Therefore it is essential that the table is plugged into the main power supply at the end of the operating list.

(c)

(d)

(e)

(f)

Figure 13.21 Lateral transfer.

Diathermy machine (Figure 13.26)

Diathermy (or electrosurgery) is used routinely during surgery to cut tissue and control haemorrhage by sealing bleeding vessels. It uses heat from electricity and this is achieved by passing a normal electrical current through the diathermy machine which converts it into a high-frequency alternating current. There are two types of diathermy.

- *Monopolar*: this works by producing current from an active electrode such as the diathermy forceps, which is then returned

back to the machine through the patient's body via another electrode, such as a patient diathermy plate/pad, which creates a complete circuit. It is the most commonly used type of electrosurgery as a wider range of effects can be achieved (cutting, coagulating, fulgurating). The current is delivered by the surgeon operating a hand switch or foot pedal.

- *Bipolar*: this does not require a patient diathermy plate/pad to complete the circuit. The current produced by the machine passes down one side of the forceps prong, through the tissue and back to the machine via the other side of the forceps

Figure 13.22 Flowtron boots and heel pads.

822

prong (rather than through the patient's body and returning to the machine via the plate/pad). Again the surgeon operates the device by a hand switch or foot pedal. Bipolar diathermy is often used in laparoscopic surgery and in hand/foot surgery (AFPP 2011).

Diathermy is potentially hazardous to the patient if used incorrectly. The main risk when using diathermy is of thermoelectrical burns. The most common cause is incorrect application of the patient plate or a break in the connecting lead (Vedovato et al. 2004); burns can also be caused if the patient comes into contact with metal which allows the current to earth through the patient's skin. The machine automatically switches off or alarms if the neutral electrodes come loose from the patient. However, if the patient is in contact with metal, this is harder to identify. Care must therefore be taken during positioning that no part of the patient's body is in contact with metal and that the return electrode (plate/pad), if used, is placed close to the operative site (AFPP 2011).

It is important that theatre staff know how to test and use diathermy equipment to prevent patient injury (Molyneux 2001, Wicker and O'Neill 2010). This involves checking that the cables and plugs are not damaged and indicator lights are all in working order. It is also important that the theatre staff check the equipment before every operating list to ensure that the alarms are

Figure 13.24 High vacuum suction unit.

operational (these should alert the surgical team if the circuit is broken, e.g. the plate/pad detaches from the patient) (AFPP 2011). If the patient's position is changed during the operation, the diathermy patient plate should be rechecked to ensure that it is still in contact and that the connecting clamp or lead is not causing pressure to the skin. Use of diathermy and the plate position should

Figure 13.23 Anaesthetic machine and patient monitoring.

Figure 13.25 Operating table.

Figure 13.26 Diathermy equipment.

be noted on the nursing care plan and the patient's skin condition (plate site, pressure areas and other areas where exposure to metal could have occurred) should be assessed before the patient is transferred from theatre.

Other causes of burns include alcohol-based skin preparations or other liquids pooling around the plate site. When using alcohol-based skin preparations, the skin should be dried or the alcohol allowed to evaporate before diathermy is used to avoid the risk of ignition (AFPP 2011, Fong et al. 2000).

The use of diathermy during surgical procedures results in a smoke by-product from the coagulation or cutting of the tissue. This smoke plume can be harmful to the perioperative team as it may contain:

- toxic gases and vapours such as benzene, hydrogen cyanide and formaldehyde
- bio-aerosols
- dead and live cellular material, including blood fragments
- viruses (Allen 2004).

To reduce the risk to staff and patients, an efficient filtered evacuation system should be used, such as a smoke evacuation machine; piped hospital suction must not be used (Scott et al. 2004). The patient suction unit is also checked to ensure that it is patent and the suction power is adequate to withdraw excessive bodily fluids from the operating site.

Operating lights (Figure 13.27)

The lights must be bright enough to ensure that the procedure is fully illuminated but not generate excess heat which would dry

Figure 13.27 Operating lights.

Equipment for laparoscopy procedure

- Camera system (consisting of light source, camera, insufflator, DVD recorder and monitors × 2) (Figure 13.28).
- Laparoscope (Figure 13.29).

Figure 13.28 Laparoscopic stack system.

Figure 13.29 Laparoscope.

Figure 13.30 Laparoscopic equipment.

- 824 • Laparoscopy-specific instruments (scissors, biopsy forceps, grabbers, dissectors, ports, retrieval pouches, insufflating tube, light lead) (Figure 13.30).

The equipment used for laparoscopic surgery is very specialized. The AORN recommends that all equipment is regularly and competently maintained and a maintenance record kept in a log (AORN 2000, Wicker and O'Neill 2010). Policies should be developed for the checking procedure, and all staff thoroughly

instructed in the operation of laparoscopic equipment. The staff must be able to properly check the equipment prior to use to ensure the clarity of colour and picture and set the pressure and flow rate of the insufflator for inflating the abdomen with carbon dioxide. The surgeon will determine the level to achieve and this will be activated at the beginning of the procedure.

Procedure guideline 13.4 Operating theatre procedure: maintaining the safety of a patient while undergoing surgery

Pre-procedure	
Action	Rationale
1 Prior to transferring the patient from the trolley to the operating table, check with the anaesthetist that the patient's airway is protected, patent and safe.	To prevent complications with airway/breathing. E
2 There must be adequate staff (a minimum of 4 is recommended) to transfer the patient onto the operating table. The team must ensure that the brakes on the trolley and operating table have been applied. Ensure the patient's head and limbs are supported when transferring to the operating table. When transferring anaesthetized patients, the anaesthetist takes charge of the patient's head and airway and co-ordinates the transfer. See Figure 13.21.	To prevent patient injury during the transfer between trolley and operating table (AORN 2001, C).
3 When positioning the patient, the theatre staff ensure that limbs are supported and secure on the table and that bony prominences are padded/cushioned.	If the patient is unconscious and unable to maintain a safe environment, support is necessary to prevent injury. Nerve damage due to compression or stretching must be prevented.
4 The patient's position will be dictated by the nature of the surgery and can include lateral (Action figure 4a) and prone positions (Action figure 4b) and the theatre staff will verify the position with the surgeon and anaesthetist and prepare any required positioning equipment/devices.	The patient is at risk from skin/nerve damage during surgery, especially if it is prolonged. Measures must be taken to preserve the integrity of the skin (e.g. use of pressure-relieving mattress/pads). Positioning must take into account the natural movement of the back, neck and limbs to safeguard against injury (AFPP 2011, C).
5 Cover the patient with a gown or blanket. The patient must remain covered until immediately before surgery.	To maintain the patient's dignity. To help prevent a reduction in body temperature or accidental hypothermia. E

6 Use a warming mattress and/or blanket on the operating table (**Action figure 6**). Both intravenous and irrigation fluids should be warmed prior to administration. The theatre staff must ensure that patient and fluid warming devices are available for every operating list.

To help maintain the patient's body temperature, prevent inadvertent perioperative hypothermia and reduce post-operative complications due to hypothermia (NICE 2008, **E**).

7 Ensure the diathermy patient plate is attached securely in accordance with the manufacturer's instructions and sited correctly as close to the operative site as possible (**Action figure 7**).

To ensure that no injury is sustained from the use of diathermy during surgery.

8 Before, during and at the end of surgery, theatre staff perform thorough counts of surgical instruments, swabs, sutures, needles and blades (**Action figure 8**). If an item is not accounted for prior to closure of the surgical wound, the surgeon is notified.

To ensure that all items used in surgery are accounted for at the end of the operation in order to guard against items being retained inside the patient's body following surgery (AFPP 2011, **C**).

9 The scrub nurse/ODP is responsible for ensuring the wound is covered with an appropriate surgical dressing (**Action figure 9**).

The dressing facilitates healing by preventing the wound from drying out and also acting as barrier against external contaminants which can cause wound infection (Wicker and O'Neill 2010, **E**). To reduce the risk of injury to the patient and staff (Loveday et al. 2014, **C**).

10 After the surgery has concluded, the theatre staff follow hospital policy regarding the disposal of sharps and clinical waste that are no longer required.

11 The scrub nurse/ODP is responsible for ensuring that any tissue samples, organs or swabs taken from the patient during the surgery are correctly labelled with the patient details and the exact nature of the specimen before being sent for histological/microbiological examination as specified by the operating surgeon.

The examination of specimens within the laboratory will decide any subsequent treatment for the patient. It is essential that labelling and documentation accompanying the specimen are accurate and that it arrives in the laboratory within the specified time frame (AFPP 2011, **C**).

12 The scrub nurse/ODP together with the anaesthetist and the other theatre staff take responsibility for the safety and well-being and dignity of the patient during the phase between the surgery finishing and the transfer/handover to the post-operative care team. During this period, when patients who have undergone general anaesthesia are usually emerging from the anaesthetic, the theatre staff prepare to hand over the patient and ensure that the relevant documentation has been completed. This is also when the time-out phase of the WHO Surgical Safety Checklist is completed by the whole theatre team (see Box 13.11). The patient will require reassurance and safe transfer from the operating table to a trolley/bed.

Intraoperative care: post-anaesthetic care unit (PACU)

Definition

Post-anaesthetic recovery involves the short- to medium-term care required by patients (following general, epidural or spinal anaesthesia)

during the immediate post-operative period until they are stable, conscious, orientated and safe to transfer back to the ward, day unit or higher dependency area. The post-anaesthetic recovery room is an area within the operating department specifically designed, equipped and staffed for the support, monitoring and assessment of patients immediately following anaesthesia and surgery.

Transfer of patient from operating theatre to post-anaesthetic care unit

The patient is transferred from the operating theatre to the PACU by the anaesthetist and/or anaesthetic nurse/ODP and/or the scrub nurse/ODP. It is the anaesthetist's responsibility to ensure the safe transfer of the patient. The patient should be assessed as stable prior to leaving the operating theatre and the anaesthetist will decide on the level of monitoring required which will depend on the distance of the transfer, the patient's level of consciousness and both their cardiovascular and respiratory status.

Oxygen is usually administered to the patient during the transfer unless they did not receive supplemental oxygen during the procedure. It is vital that the anaesthetist flush the patient's IV lines to ensure that there are no residual anaesthetic drugs remaining (AAGBI et al. 2013).

Evidence-based approaches

Post-anaesthetic care

Post-anaesthetic care can best be described and understood as a series of nursing procedures performed sequentially and simultaneously on patients immediately post anaesthesia/surgery. These patients will display varying degrees of responsiveness and physical and emotional states.

The recovery period is potentially hazardous. Therefore, when the patient arrives in the PACU, individual nursing care is required until the nurse is satisfied that the patient can maintain their own airway and is sufficiently oxygenated (AAGBI et al. 2013, AFPP 2011).

Procedure guideline 13.5 Handover in post-anaesthetic care unit: scrub nurse/ODP to recovery practitioner

827

Procedure

Action

- 1 Accompany the patient with the anaesthetist to the recovery area. Hand over the following:
 - the surgical procedure performed
 - information including allergies or pre-existing medical conditions, for example diabetes mellitus
 - the patient's cardiovascular state and type of anaesthesia administered
 - the presence, position and nature of any drains, infusions or intravenous or arterial devices
 - information about any anxieties of the patient expressed before surgery, such as a fear of not waking after anaesthesia or fear about coping with pain
 - specific instructions from the surgeon/anaesthetist for post-operative care.

Rationale

To ensure continuity and effective communication of care for the patient. To ensure that the recovery practitioner has all the information required to assess the patient's recovery needs. **C**

The actual procedure performed may be different from the proposed procedure. **E**

To highlight specific potential post-operative complications to be assessed and monitored. **E**

To safely maintain the patient's cardiovascular system and airway immediately post-operatively. **E**

To ensure care and management of these drains are continued and the positioning of the patient is assessed to prevent any occlusion of drains or infusions. **E**

To ensure that the recovery practitioner can respond appropriately as the patient regains consciousness and to enable assessment of the efficacy of subsequent nursing interventions. **E**

To facilitate effective communication of the patient's care and treatment and to ensure that the appropriate post-operative clinical care is delivered. **E**

Post-procedure

- 2 Record all information in the perioperative nursing care plan.

Pre-procedural considerations

Equipment required in the PACU

Whereas in the past, post-anaesthetic care meant a relatively brief period of observation in an area close to theatres, it has now evolved into a distinct critical care area where patients of varying dependency receive specialist clinical care from trained staff using a variety of drugs, monitoring and equipment (AAGBI et al. 2013). The following items are the minimum required in each bed space (Figure 13.31). The equipment should be compatible between the operating theatres and the PACU. It must be arranged for ease of access and always be clean and in full working order.

- *Patient monitoring:* pulse oximetry, non-invasive blood pressure monitoring, ECG, invasive pressure monitoring, temperature monitoring and capnography.
- *Basic equipment for airway maintenance:* wall-mounted piped oxygen with tubing and facemask (with both fixed and variable settings), a Mapleson C breathing circuit and a self-inflating resuscitator bag, for example Ambu-bag with facemask, a full range of oral and nasopharyngeal airways. These allow for maintenance of the airway, delivery of oxygen and artificial ventilation of the patient should it be necessary. Spare oxygen cylinders with flowmeters should also be available in case of piped oxygen failure.

Figure 13.31 Recovery bay.

- *Suction*: regulator with tubing and a range of oral and endotracheal suction catheters. An electric-powered portable suction machine should also be available in case of pipeline vacuum failure.
- *Sphygmomanometer and stethoscope*: in case of failure of the electronic patient monitor, manual blood pressure monitoring equipment must always be available.
- Electrical sockets and individual lamps.
- *Miscellaneous items*: receivers, tissues, disposable gloves, sharps container and waste receptacle (AAGBI et al. 2013, AFPP 2011).

Other equipment should be available centrally for respiratory and cardiovascular support.

- *Intubation and difficult airway equipment*: fiberoptic laryngoscopes with spare batteries and a range of blades (including McCoy tip), range of endotracheal tubes, bougies, Magill forceps, syringe and catheter mount. This is to ensure that the patient can be intubated quickly during an emergency.
- *Ventilator*: to ensure that the patient can be mechanically ventilated if extubated too early, not fully reversed from the anaesthetic.
- *Range of tracheostomy tubes and tracheal dilator*: in case an emergency tracheostomy needs to be performed.
- *Intravenous infusion sets, cannula, central venous catheters and a range of intravenous fluids*.

- *Defibrillator*: required during a cardiac arrest to restart the heart.
- *Nerve stimulators* should be available to monitor level of neuromuscular blockade.
- *Patient and fluid warming devices* to maintain normothermia and correct inadvertent perioperative hypothermia.

The relevant resuscitation equipment, drugs, fluids and algorithms should be immediately available for the management of both surgical and anaesthetic complications. Ideally these items are contained in dedicated trolleys (AAGBI et al. 2013, AFPP 2011).

PACU staff

No less than two staff (at least one must be a registered practitioner) should be present when there is a patient in the PACU who does not fulfil the discharge criteria. The staffing level should allow one-to-one observation of every patient by an anaesthetist or registered PACU practitioner until the patient has regained control of their airway, is haemodynamically and respiratory stable and able to communicate. One member of staff present should be a certified Acute Life Support (ALS) provider. Life-threatening complications can occur during the immediate post-operative/anaesthesia phase. Any failure to provide adequate care could have devastating consequences for patients, their families and staff. Patients must be kept under clinical observation at all times. The frequency of the observations is dependent upon the procedure performed, the physical status of the patient and the stage

Box 13.12 Minimum information to be recorded for patients in the post-anaesthesia care unit

- Level of consciousness.
- Patency of the airway.
- Respiratory rate and adequacy.
- Oxygen saturation.
- Oxygen administration.
- Blood pressure.
- Heart rate and rhythm.
- Pain intensity on an agreed scale.
- Nausea and vomiting.
- Intravenous infusions.
- Drugs administered.
- Core temperature.
- Other parameters depending on circumstances, e.g. urinary output, central venous pressure, expired CO₂, surgical drainage volume.

of recovery. Box 13.12 outlines the minimum information that should be routinely monitored/recorded for patients in PACU.

Complications

Pain

Pain is the most common adverse effect of surgery for the majority of patients (McMain 2010). Pain is a subjective experience and patients in the PACU should receive both effective and empathetic care to relieve their pain (AFPP 2011). A patient should not be discharged from the PACU until satisfactory pain control has been achieved. PACU staff must be trained and competent in the use of intravenous analgesia, patient-controlled analgesia, management of epidurals, spinals and peripheral nerve blocks (AAGBI et al. 2013). It is important to recognize that pain may not only be due to the surgery. Other reasons include pre-existing medical conditions, poor positioning during surgery, headache as a result of anaesthetic drugs and muscle aches from the use of depolarizing muscle relaxants (suxamethonium) (Wicker and O'Neill 2010).

Nausea and vomiting

Post-operative nausea and vomiting (PONV) may arise from many causes. These include hypotension, swallowing of blood (for example in oral surgery), abdominal surgery, anxiety, but most commonly, as a side-effect of opioid administration. Nausea, vomiting and retching may exist independently and therefore require individual assessment (AFPP 2011). No patient should be

discharged from the PACU unless their PONV is controlled and suitable medication prescribed (AAGBI et al. 2013).

Hypothermia

Inadvertent perioperative hypothermia (which is defined as below 36.0°C) is a common but preventable complication of surgery and is associated with poor outcomes for patients. Adult surgical patients may develop hypothermia at any stage of the perioperative journey though the elderly, malnourished and those who have undergone long surgery or where large amounts of blood or fluid replacement therapy have been used are especially at risk (Nunney 2008).

During the first 30–40 minutes of anaesthesia, a patient's temperature can fall to below 35.0°C. Reasons for this include:

- loss of the behavioural response to cold
- impairment of thermoregulatory heat-preserving mechanisms (due to general or regional anaesthesia)
- anaesthesia-induced peripheral vasodilation (with associated heat loss)
- the patient becoming cold while waiting for surgery in the pre-operative area (NICE 2008).

On admission to the PACU, the patient's temperature should be measured and documented. If it is below 36.0°C, active warming should be commenced until the patient is warm/discharged from the recovery room. They should not be discharged until the temperature is 36.0°C or above. Hypothermia produces symptoms which mimic those of other post-operative complications, which may result in inappropriate treatment. Hypothermia interferes with the effective reversal of muscle relaxants, so monitor patients who are shivering, restless, confused or with respiratory depression. Shivering puts an increased demand on cardiopulmonary systems as oxygen consumption is increased (Feldmann 1988, Frank et al. 1993). Other complications such as arrhythmias or myocardial infarct can result and the longer the duration of the post-operative hypothermia, the greater the patient mortality (Crayne and Miner 1988).

Other complications

When emerging from the final stage of anaesthesia, some patients can behave in an emotional and disinhibited fashion, at variance with their normal behaviour (Eckenhoff et al. 1961, Radtke et al. 2008). Therefore it is important to establish a rapport with each individual to gain the patient's confidence and co-operation and to aid assessment. These displays are always transient and fortunately patients seldom have any recollection of them. All actions must be accompanied by commentary and explanation regardless of the patient's apparent responsiveness, as the sense of hearing returns before the patient's ability to respond (Levinson 1965, Starritt 1999).

Procedure guideline 13.6 Safe management of the patient in the PACU

The following recommended actions are not necessarily listed in order of priority. Many will be carried out simultaneously and will depend on the patient's condition, type of surgery and level of consciousness.

Procedure

Action

- 1 Assess the patency of the airway by feeling for movement of expired air.
- 2 Listen for inspiration and expiration. Observe any use of accessory muscles of respiration and check for tracheal tug which might indicate airway obstruction.

Rationale

To determine the presence of any respiratory depression or neuromuscular blockade. Observe chest and abdominal movement, respiratory rate, depth and pattern (Drummond 1991, C).

To ensure airway is clear and laryngeal spasm is not present. **E**

(continued)

Procedure guideline 13.6 Safe management of the patient in the PACU (*continued*)

3	If indicated, support the chin with the neck extended.	In the unconscious patient the tongue is liable to fall back and obstruct the airway, and protective reflexes are absent. E
4	Suction of the upper airway is indicated if: <ul style="list-style-type: none"> gurgling sounds are present on respiration blood secretions or vomitus are evident or suspected the patient is unable to swallow the patient is unable to cough adequately or at all. Suction must be applied with care to avoid damage to mucosal surfaces and further irritation or initiation of a gag reflex or laryngeal spasm. 	Foreign matter can obstruct the airway or cause laryngeal spasm in light planes (induction and emergence) of anaesthesia. Foreign matter can also be inhaled when protective laryngeal reflexes are absent (Dhara 1997, C).
5 (a)	Apply a facemask and administer oxygen at the rate prescribed by the anaesthetist.	To maintain adequate oxygenation. Oxygen should be administered to all patients in the recovery room (Nimmo et al. 1994, C).
(b)	If an endotracheal tube or laryngeal mask is in position, check whether the cuff or mask is inflated and administer oxygen by means of a T-piece system.	
6	Check the colour of lips and conjunctiva, then peripheral colour and perfusion (skin temperature and peripheral pulse).	Central cyanosis indicates impaired gaseous exchange between the alveoli and pulmonary capillaries. Peripheral cyanosis indicates low cardiac output (Nimmo et al. 1994, C).
7	Record blood pressure, pulse and respiratory rate measurements on admission to the PACU and at a minimum of 5-minute intervals unless the patient's condition dictates otherwise.	To enable any fluctuations or gross abnormalities in cardiovascular and respiratory functions to be detected immediately (Peskett 1999, C). To assess cardiovascular function and establish a post-operative baseline for future comparisons (Peskett 1999, C).
8	Obtain full handover from the surgical/anaesthetic team.	To ensure effective communication of the patient's care and treatment and to aid the planning of subsequent care. E
9	Check the temperature of the patient.	Peri- and post-operative hypothermia is common and preventable.
10	Check and observe wound site(s), dressings and drains on admission to the PACU and at regular intervals. Note and record leakage/drainage on the post-operative chart and also on the drain bottle/bag.	To assess and monitor for signs of haemorrhage (Eltringham et al. 1989, C).
11	Check that intravenous infusions are running at the correct prescribed rate in accordance with local policy and the site of the venous access device is assessed as patent in accordance with local protocol.	Care of venous devices/sites prevents complications and ensures that fluid replacement and balance are achieved safely. E
12	Check the prescription chart for medications to be administered during the immediate post-operative period, for example analgesia and antiemetics.	To treat and prevent symptoms such as pain and nausea swiftly and appropriately and further monitor their effectiveness. E
13	Orientate the patient to time and place as frequently as is necessary.	To alleviate anxiety, provide reassurance and gain the patient's confidence and co-operation. Pre-medication and anaesthesia can induce a degree of amnesia and disorientation. C
14	Give mouth care including moistened mouth swabs, sips of water and petroleum jelly for the lips.	Pre-operative fasting, drying gases and manipulation of lips, and so on, leave mucosa vulnerable, sore and foul tasting. E
15	After regional and/or spinal anaesthesia, assess the return of sensation and mobility of limbs. Check that the limbs are anatomically aligned.	To prevent inadvertent injury following sensory loss (AAGBI 2002, C).

Problem-solving table 13.1 Prevention and resolution (Procedure guideline 13.6)

Problem	Cause	Prevention	Suggested action
Airway obstruction.	Tongue occluding the airway.	Do not remove the laryngeal mask or the Guedel airway until the patient starts responding to commands.	Support chin forward from the angle of the jaw. If necessary, insert a Guedel airway. Use a nasopharyngeal airway if the teeth are clenched or crowned.
	Foreign material, blood, secretions, vomitus.	Use suction to remove secretions when removing airway.	Apply suction. Always check for the presence of a throat pack.

Problem	Cause	Prevention	Suggested action
	Laryngeal spasm.	Do not remove airway until patient responds to commands and ensure oxygen flow is high (5–10 litres) on arrival in PACU.	Increase the rate of oxygen. Assist ventilation with an ambu-bag and facemask. If there is no improvement, inform anaesthetist and have intubation equipment ready. Offer the patient reassurance by talking to them and telling them what you are doing.
Hypoventilation.	Respiratory depression from medications, for example opiates, inhalations, barbiturates.	Monitor depth and rate of respiration before administering analgesia.	Inform the anaesthetist, keeping oxygen on, and administer antagonist on instruction, for example naloxone (opiate antagonist), doxapram (respiratory stimulant). Note: if naloxone is given it can reverse the analgesic effects of opiates and has a duration of action of only 20–30 minutes. The patient must be observed for signs of returning hyperventilation (Nimmo et al. 1994).
	Decreased respiratory drive from a low partial pressure of carbon dioxide (PaCO_2), loss of hypoxic drive in patients with chronic pulmonary disease.	Ensure that Venturi masks are available and close to hand in the recovery bay.	Administer oxygen using a Venturi mask with graded low concentrations (Atkinson et al. 1982).
	Residual neuromuscular blockade from continued action of non-depolarizing muscle relaxants, potentiation of relaxants caused by electrolyte imbalance, impaired excretion with renal or liver disease. Signs include: difficulty breathing/speaking, generalized weakness, visual disturbances, patient distress.		Inform the anaesthetist, have available neostigmine and glycopyrrolate, or atropine, potassium chloride and 10% calcium chloride. Often the blockade is mild and will wear off in minutes without treatment, but it is extremely frightening and patients will need continuous reassurance that their condition is not unnoticed and is resolving and that they will not be left alone.
Hypotension.	Hypovolaemia.	Increase the rate of fluids and ensure more fluids are prescribed.	Take manual reading of the blood pressure. Take central venous pressure (CVP) readings if catheter is in place. Give oxygen. Lower the head of the trolley unless contraindicated, for example hiatus hernia, gross obesity. Check the record of anaesthetic agents used which might cause hypotension, for example enflurane, beta-blockers, nitroprusside, opiates, droperidol, sympathetic blockade following spinal anaesthesia. Check the peripheral perfusion. If the CVP is low, increase intravenous infusion unless contraindicated, for example congestive cardiac failure. Check drains and dressings for visible bleeding and haematoma. Inform the anaesthetist or surgeon.
Hypertension.	Pain.	Ensure pain is assessed as soon as patient is responding to commands and scores are recorded.	Treat pain with prescribed analgesia and provide a quiet environment to enable patient to rest/sleep. Pain from certain operation sites can also be alleviated by changing the patient's position.
	Fluid overload.	Slow the intravenous rate.	Check fluid balance sheet and the rate of intravenous infusion.
	Distended bladder.	Check if the bladder is distended and catheter is patent.	Offer a bedpan or urinal and if necessary catheterize the patient.

(continued)

Problem-solving table 13.1 Prevention and resolution (Procedure guideline 13.6) (*continued*)

Problem	Cause	Prevention	Suggested action
	Some anaesthetic drugs given during reversal of anaesthetic.	Ensure the anaesthetist monitors patient when reversing effects of anaesthetic drugs.	Check the prescription chart for those patients on regular antihypertensive therapy. If the situation is not resolved, inform the anaesthetist. Also check patient's past medical history.
Bradycardia.	Very fit patient, opiates, reversal agents, beta-blockers, pain, vagal stimulation, hypoxaemia from respiratory depression.	Ensure oxygen is administered and anaesthetist identifies any adverse episodes of bradycardia during surgery.	Connect the patient to the ECG monitor to exclude heart block and monitor cardiac activity. Ascertain pre-operative cardiac function. Check the prescription chart and anaesthetic sheet for medication administered that may cause bradycardia. Inform and liaise with the anaesthetist.
Tachycardia.	Pain, hypovolaemia, some anaesthetic drugs, for example ephedrine, septicaemia, fear, fluid overload.	Ensure pain is managed and intravenous fluids are administered.	Assess patient's pain and provide analgesia. Check the anaesthetic chart to ascertain which anaesthetic drugs were used. Connect the patient to the ECG monitor to exclude ventricular tachycardia. Provide reassurance for the patient. Assess fluid balance.
Pain.	Surgical trauma, worsened by fear, anxiety and restlessness.	Administer analgesia after assessing patient's pain.	Provide prescribed analgesia and assess its efficacy. Reassure and orientate the patient. Try positional changes where feasible; for example, after breast surgery raise the back support by 20–40°; abdominal or gynaecological surgery patients may be more comfortable lying on their side. Elevate limbs to reduce swelling where appropriate. If significant relief is not obtained, inform the anaesthetist and the pain control specialist nurse.
Nausea and vomiting.	Anaesthetic agents, opiates, hypotension, abdominal surgery, pain; high-risk patients who have a history of post-operative nausea and vomiting.	Administer antiemetics with the analgesia and ensure intravenous fluids are administered as prescribed.	Administer intravenous antiemetics and monitor effectiveness. Encourage slow, regular breathing. If the patient is unconscious, turn onto the side, tip the head down and suck out pharynx; give oxygen.
Hypothermia.	Depression of the heat-regulating centre, vasodilation, following abdominal surgery, large infusions of unwarmed blood and fluids.	Measure and record the patient's temperature upon arrival in the PACU and maintain temperature using a Bair Hugger.	Use extra blankets or a Bair Hugger (Kumar et al. 2005). Monitor the patient's temperature. Administer warm intravenous fluids. Bladder irrigation may also be warmed to normal body temperature.
Shivering.	Some inhalational anaesthetics, hypothermia.	Measure and record the patient's temperature on arrival in the PACU and maintain temperature using a Bair Hugger. Measure temperature every 30–60 mins.	Give oxygen, reassure the patient and take their temperature. Provide a Bair Hugger and warm blankets.
Hyperthermia.	Infection, blood transfusion reaction.	Measure and record temperature at least every 30–60 mins.	Give oxygen, use a fan or tepid sponging if this is warranted. Medical assessment of antibiotic therapy and obtaining blood cultures. Administer intravenous paracetamol if prescribed.
	Malignant hyperpyrexia (above 40°).	This may be identified during the anaesthetic. All anaesthetic and theatre personnel must know the location of the emergency drug (dantrolene) which is kept in every operating theatre suite.	Malignant hyperpyrexia is a medical emergency. Dantrolene is used to treat this life-threatening condition.

Problem	Cause	Prevention	Suggested action
Oliguria.	Mechanical obstruction of catheter, for example clots, kinking. Inadequate renal perfusion, for example hypotension, systolic pressures under 60 mmHg, hypovolaemia, dehydration. Renal damage, for example from blood transfusion, infection, drugs, surgical damage to the ureters.	Check patency and drainage upon arrival in the PACU and every 30–60 mins.	Check the patency of the catheter. Consider bladder irrigation. If clots present, inform surgeon. Take blood pressure and CVP if available. Increase intravenous fluids. Inform the anaesthetist. Inform the anaesthetist or surgeon.

Post-procedural considerations

Discharge from PACU

Discharge from the PACU is ultimately the responsibility of the anaesthetist but is usually delegated to the PACU practitioner who uses discharge criteria to assess whether the patient has achieved the optimum recovery, enabling them to return to the ward safely. In the event of complications or deterioration, the anaesthetist must be informed and should assess the patient before their return to the ward (AAGBI et al. 2013, AFPP 2011).

The PACU must specify minimum criteria that patients must meet prior to their discharge to the general ward or other clinical areas (Box 13.13).

Post-operative care

Definition

Post-operative care is the physical and psychological care given to the patient immediately after transfer from the recovery room to the ward. Post-operative care continues until the patient is discharged from hospital, and in some cases continues on as ambulatory care as an outpatient.

Box 13.13 Minimum criteria for discharge of patients from the post-anaesthesia care unit

- The patient is fully conscious, able to maintain a clear airway and has protective airway reflexes.
- Breathing and oxygenation are satisfactory.
- The cardiovascular system is stable, with no unexplained cardiac irregularity or persistent bleeding. The specific values of pulse and blood pressure should approximate to normal pre-operative values or be at an acceptable level, ideally within parameters set by the anaesthetist, and peripheral perfusion should be adequate.
- Pain and post-operative nausea and vomiting should be adequately controlled, and suitable analgesic and antiemetic regimens prescribed.
- Temperature should be within acceptable limits. Patients should not be returned to the ward if significantly hypothermic.
- Oxygen therapy should be prescribed if appropriate.
- Intravenous cannulae should be patent, flushed if necessary to ensure removal of any residual anaesthetic drugs and intravenous fluids should be prescribed if appropriate.
- All surgical drains and catheters should be checked.
- All health records should be complete and medical notes present.

Evidence-based approaches

Principles of care

Although different surgical procedures require specific and specialist nursing care, the principles of post-operative care remain the same, underpinned by the application of evidence-based care. Optimal management of patients throughout the post-operative phase requires appropriate clinical assessment, monitoring and timely and accurate documentation. The nursing care given during the post-operative period is directed towards the prevention of those potential complications resulting from surgery and anaesthesia. Potential complications are outlined in Figure 13.32.

Figure 13.32 Post-operative complications.

Anticipated patient outcomes

Safety of the patient at all times and the minimizing of post-operative complications by:

- delivering the required nursing care for the post-operative patient. This includes fully informing the patient of the post-operative care requirements so that they can enhance their recovery, facilitating earlier discharge home
- optimizing the patient’s post-operative physical and psychological condition to minimize the risk of potential post-operative complications occurring. This is achieved through comprehensive nursing assessment and planning to ensure early identification and management of any post-operative complications.

Post-operative observations

Evidence-based approaches

Principles of care

Regular monitoring and accurate reporting of the patient’s clinical observations in the post-operative period are an essential part of the planned surgical care pathway, which can identify potential complications. Post-operative observations are outlined in Table 13.8. A clear physiological monitoring plan should be made for each patient, detailing frequency of observations and parameters (NCEPOD 2011). All nurses should be aware of the parameters for these observations and what is normal for the patient under observation. Post-operative observations should be compared with baseline observations taken pre-operatively, during surgery and in the recovery area (Liddle 2013). The regularity of post-operative observations should be determined in accordance with local policies or guidelines and will be affected by the type of surgery performed as well as the method of pain control (e.g. epidural) and as indicated by the patient’s clinical condition. All vital signs and assessments should be recorded in accordance with guidelines for record keeping (NMC 2010).

Table 13.8 Post-operative observations

Routine post-operative observations include:	Normal range:
• Blood pressure	• <101–149 mmHg systolic
• Pulse (rate, rhythm and amplitude)	• 51–100 beats per minute
• Respiration rate (rate, depth, effort and pattern)	• Respirations: 9–14 per minute
• Peripheral oxygen saturation	• >95% on room air
• Temperature	• 36.1–37.9°C
• Accurate fluid balance (to include input and output)	• Desired balance guided by surgeons and surgery performed
• Pain score	• Verbal numeric pain scale: 0–1/10 at rest; 3/10 on movement/coughing
• Sedation score	• Sedation score: 0/4 (see Chapter 11: Observations)
Additional observations if clinically indicated:	
• Blood glucose	• 4–7 mmol/L
• Central venous pressure	• 5–10 cm H ₂ O
• Neurological response	• Glasgow Coma Scale: 14–15/15 or AVPU: AV

Source: Adapted from Bickley et al. (2009), DH (2000), Liddle (2013).

Critical care outreach and acute care teams have long encouraged the use of early warning scoring (EWS) systems to enable a more timely response to, and assessment of, acutely ill patients (Royal College of Physicians 2012). EWS is a simple physiological scoring system, based on the observations previously outlined, that identifies patients at risk of deterioration who may require increased levels of care (DH 2000, NICE 2007) (see Chapter 11: Observations).

Legal and professional issues

The National Confidential Enquiry into Patient Outcome and Death (NCEPOD 2011) report established that patients whose clinical condition was deteriorating post-operatively were not always identified and referred for a higher level of care. When assessing the post-operative patient, it is vital that the patient is observed for signs of haemorrhage, shock, sepsis and the effects of analgesia and anaesthetic (Liddle 2013). It is therefore imperative that nurses are able to interpret the results of post-operative observations and, if reliant on appropriately trained care assistants to take the observations, that nurses themselves interpret the results, thereby ensuring that patients who require a higher level of care are given immediate priority.

If obtaining blood pressure measurements using an electronic sphygmomanometer, the trained health professional should be aware that errors in measurement can occur. For example, a weak, thready or irregular pulse may not be identified by the monitor and/or produce an inaccurate blood pressure reading. Best practice indicates that prior to using an electronic sphygmomanometer, the patient’s pulse should be palpated for rate, rhythm, volume and character. If an irregular, weak or thready pulse is identified, then the patient’s blood pressure should be measured with a manual sphygmomanometer to ensure accuracy of the reading. This information should be clearly documented to alert other health professionals. It is therefore essential that trained health professionals develop the skill and dexterity to monitor patients’ vital signs with traditional manual equipment (see Chapter 11: Observations).

It has also been reported that pulse oximeters can be open to misinterpretation and therefore should not replace a respiratory assessment, which is an early and sensitive indicator of deterioration (NCEPOD 2011) (see ‘Ineffective breathing pattern’).

An abnormal pulse oximeter recording may be due to shivering, peripheral vasoconstriction or dried blood on the finger probe. Prior to taking a recording, appropriately trained health-care professionals should ensure that the finger probe is clean, residual nail varnish (if applicable) is removed and the position of the probe is changed regularly to prevent fingers becoming sore.

Haemodynamic instability

Related theory

Haemodynamic instability is most commonly associated with an abnormal or unstable blood pressure, especially hypotension (Anderson 2003). A reduction in systolic blood pressure following surgery can indicate hypovolaemic shock, a condition in which the blood vessels do not contain sufficient blood (Hatfield and Tronson 2009). Bleeding is the most common cause but other causes can occur when tissue fluid is lost from the circulation, for example bowel obstruction and nausea and vomiting (Hughes 2004). Hatfield and Tronson (2009, p.348) outline three stages of hypovolaemic shock.

- *Compensated shock*: blood flow to the brain and heart is preserved at the expense of the kidneys, gastrointestinal system, skin and muscles.
- *Decompensated shock*: the body’s compensatory mechanisms begin to fail and organ perfusion is severely reduced.
- *Irreversible shock*: tissues become so deprived of oxygen that multiorgan failure occurs.

Evidence-based approaches

Principles of care

During compensated shock, some patients can lose up to 30% of their circulatory volume before the effects of hypovolaemia are reflected in the systolic blood pressure measurements or heart rate (Hughes 2004). Therefore, when assessing post-operative patients it is also useful to consider the early signs of reduced tissue perfusion in detecting signs of hypovolaemic shock, which include:

- restlessness, anxiety or confusion (as a result of cerebral hypoperfusion or hypoxia)
- increased respiratory rate, becoming shallow (frequently occurring before signs of tachycardia and hypotension)
- rising pulse rate (tachycardia as the heart attempts to compensate for the low circulatory blood volume)
- low urine output of <0.5 mL/kg/h (as the kidneys experience a reduction in perfusion and pressure, which activates the renin-angiotensin system in an attempt to conserve fluid and increase circulatory blood volume)
- pallor (pale, cyanotic skin) and later sweating
- cool peripheries (pale, cyanotic lips and nailbed), resulting in a poor signal on the pulse oximeter
- visible bleeding and haematoma from drains and wounds (Anderson 2003, Hatfield and Tronson 2009, Jevon and Ewens 2012).

In most cases, if impending hypovolaemic shock is recognized and treated promptly, its progression through the aforementioned stages of shock can be circumvented (Hatfield and Tronson 2009). Irrespective of the cause of hypovolaemic shock, the aim of treatment is to restore adequate tissue perfusion (Hughes 2004). Excessive blood loss might require blood transfusion and occasionally surgical intervention. However, if signs are in the compensatory phase, fluid resuscitation with crystalloid or colloid and increased oxygenation to maintain saturation above 95% are sufficient to promote recovery for many patients.

Ineffective breathing pattern

Related theory

Respiratory function post-operatively can be influenced by a number of factors:

- increased bronchial secretions from inhalation anaesthesia
- decreased respiratory effort from opiate medication
- pain or anticipated pain from surgical wounds
- surgical trauma to the phrenic nerve
- pneumothorax as a result of surgical or anaesthetic procedures
- co-morbidity, for example asthma, chronic obstructive airways disease (COAD).

All factors affecting adequate expansion of the lung and the ejection of bronchial secretions will encourage the development of atelectasis and consolidation of the affected lung tissue (AAGBI 2002). To prevent this, deep breathing exercises (DBE), coughing exercises and early mobilization may be undertaken post-operatively. DBE help remove mucus which can form and remain in the lungs due to the effects of general anaesthetic and analgesics (which depress action of cilia of the mucous membranes lining the respiratory tract and the respiratory centre in the brain). DBE prevent pneumonia by increasing lung expansion and preventing the accumulation of secretions. DBE also initiate the coughing reflex; voluntary coughing in conjunction with DBE facilitates the expectoration of respiratory tract secretions. A physiotherapist will often provide pre-/post-operative advice and/or assessment for DBE. Note that the patient will require adequate analgesia and support for the wound to enable DBE and mobilization.

Evidence-based approaches

Principles of care

Respiratory rate and function is often the first vital sign to be affected if there is a change in cardiac or neurological state. It is therefore imperative that this observation is performed accurately; however, studies show it is often omitted or poorly assessed (NPSA 2007). Routine post-operative respiratory observations will include:

- airway
- respiratory rate (regular and effortless), rhythm and depth (chest movements symmetrical)
- *respiratory depression*: indicated by hypoventilation or bradypnoea, and whether opiate-induced or due to anaesthetic gases
- listening for audible signs of stridor, wheeze or secretions
- observing any changes in the patient's colour for signs of peripheral/central cyanosis
- *pulse oximetry*: should be above 95% on air, unless the patient has lung disease, and maintained above 95% if oxygen therapy is prescribed to prevent hypoxia or hypoxaemia
- *use of oxygen therapy*: flow and method of delivery
- observing any chest drains (if applicable).

Oxygen is administered to enable the anaesthetic gases to be transported out of the body, and is prescribed when patients have an epidural, patient-controlled analgesia or morphine infusion. Nurses should ensure and record the following.

- Oxygen therapy is prescribed.
- Oxygen is administered at the correct rate.
- Continuous oxygen therapy is humidified to prevent mucous membranes from drying out.
- The skin above the ears is protected from elastic on the mask/nasal prongs.

Fluid balance

Definition

The balance of the input and output of fluids in the body to allow metabolic processes to function correctly (Welch 2010).

Evidence-based approaches

Principles of care

Iatrogenic factors potentially contributing to fluid imbalance (circulating and tissue fluid volumes) in the post-operative patient are outlined in Box 13.14. Some patients may require fluid replacement in the post-operative period to ensure an adequate fluid balance, avoiding dehydration and the resulting concentration of the blood that, along with venous stasis, is conducive to thrombus formation (Hughes 2004, NICE 2010).

Box 13.14 Iatrogenic factors with potential to contribute to fluid imbalance

- Pre-operative bowel preparation.
- Pre-operative fasting times.
- Potential fluid volume excess.
- Fluid loss perioperatively.
- Inappropriate fluid prescription.
- Reduced intake post-operatively.
- Ongoing losses from bleeding.
- Paralytic ileus and/or vomiting.

Source: Adapted from Anderson (2003), Hatfield and Tronson (2009).

Post-operative fluid replacements should be based on the following considerations:

- maintenance requirements
- extra needs resulting from systemic factors (e.g. pyrexia, losses from surgical drains)
- requirements resulting from third space losses, for example oedema and ileus (Doherty and Way 2006, NICE 2013, Powell-Tuck et al. 2011).

Daily maintenance fluids for sensible losses (i.e. measurable losses, e.g. urine output) and insensible losses (i.e. not measurable, e.g. sweating) will be dependent upon age, gender, weight and body surface area and will increase with pyrexia, hyperventilation and conditions that increase the catabolic rate.

Deciding on the optimal amount and composition of intravenous fluids to be administered and the best rate at which to give them can be a difficult and complex task, and decisions must be based on careful assessment of the patient's individual needs (NICE 2013). Where possible and clinically indicated, euvolaemic and haemodynamically stable patients should return to oral fluids as soon as possible (Powell-Tuck et al. 2011). If intravenous fluids are required, the most commonly used replacement fluids are crystalloids and colloids, which have different effects on a range of important physiological parameters (Perel et al. 2013). All patients continuing to receive intravenous fluids need regular monitoring. This should initially include at least daily reassessments of clinical fluid status, laboratory values (urea, creatinine and electrolytes) and fluid balance charts, along with weight measurement twice weekly (NICE 2013).

In December 2013, NICE published guidance outlining recommendations and algorithms for the general principles for managing intravenous fluids for adults in hospital. Refer to the guid-

ance (www.nice.org.uk/nicemedia/live/14330/66015/66015.pdf) for information/algorithms on the following: patient assessment; fluid resuscitation; routine maintenance fluids; replacement and redistribution.

Legal and professional issues

The NCEPOD (2011) found there was insufficient recording of post-operative fluid balance in 30% of patient data reviewed. Post-operatively, it is essential that accurate fluid balance charts are maintained, outlining all fluid input (intravenous and oral) and output (e.g. urine, vomiting, wound exudate, drains, nasogastric drainage, stoma). This will facilitate the early identification of fluid loss or excess, which should be raised with a surgical colleague for appropriate management. If intravenous fluids are required, details of the fluids administered must be clearly recorded and easily accessible (Powell-Tuck et al. 2011). Fluid requirements should be frequently re-evaluated with intravenous prescriptions being rewritten every 12–24 hours or more often if clinically indicated.

Surgical drains

Definition

A device, such as a tube, inserted intraoperatively into a body cavity (e.g. bladder, chest wall) or opening of a surgical wound to facilitate discharge of fluid or air.

Related theory

Surgical drains are used in many different types of surgery with the aim of decompressing, draining or diverting either fluid (blood, pus, gastric fluids, lymph or urine) or air from the site of surgery (Hatfield and Tronson 2009).

Drains can be open or closed and are made from latex, silicone or PVC (Table 13.9; Figure 13.33). All drains induce some degree of

Table 13.9 Open and closed drains

Type of drain	Example
<p>Open drains are ‘open’ to the air with the exudate ‘passively’ collecting onto a sterile dressing, e.g. gauze (if only minimal) or a drainage bag (if copious) from the surgical wound bed. These drains are cheap, simple and versatile and can be used in any part of the body in both clean and infected wounds. They can be brought out through the end of a wound or more commonly through a separate stab incision. It is important to suture open drains to the skin to prevent them from falling out. As these drains are ‘open’, there is an associated risk of infection; however, the development of deep infection from retrograde tracking of micro-organisms is rare owing to the continuous outward flow of exudate</p> <p>Closed drains are ‘closed’ to the air with the fluid collecting into a sealed collection system (bags or bottles); thus the drain contents remain clean. Closed drains can be divided broadly into those that employ suction (active drains, e.g. Redivac, chest) and those that do not (passive drains).</p> <ul style="list-style-type: none">– Closed non-suction drains (passive) work by pressure gradient, gravity effect, capillary action or a combination of these (Hatfield and Tronson 2009, Ngo et al. 2004). They are commonly used after abdominal/pelvic surgery. They are characterized by a collapsible plastic bag on the end of the drainage tubing.– Closed suction drains (active) combine gravity drainage with active suction created by the drainage system, which also acts as a reservoir for drained fluid. They are commonly used in the subcutaneous tissues after abdominal, breast, plastic or orthopaedic surgery to obliterate dead spaces and prevent blood or serous fluid collections. They typically comprise a fine-bore tube with an end hole and multiple side perforations/drainage holes. These are either attached to a pre-vacuumed hard plastic bottle, e.g. Redivac (see Figure 13.33c), or to a soft concertina-style bottle (designed to be squeezed before connection to generate negative pressure) (see Figure 13.33d). For suction to be effective, all drainage holes must be located inside the drainage cavity (i.e. inside the skin)	<p><i>Penrose drains:</i> thin-walled soft rubber latex tubes which collapse to resemble a flat ribbon. Being very soft, they are considered safe to lay adjacent to bowel or other internal organs. <i>Yates drains:</i> quite flat but composed of multiple small tubules stuck side by side and are much stiffer. The tubules can be peeled off longitudinally to create any width of drain required. <i>Corrugated drain:</i> wavy strips of PVC, still relatively stiff. They usually have a radiopaque strip down the middle (see Figure 13.33a)</p> <p>Examples include urinary catheter (Foley), nasogastric tube (Ryle), Robinson’s, Bonanno catheter (see Figure 13.33b)</p>

(a)

(b)

(c)

(d)

Figure 13.33 (a) Corrugate, Yates and Penrose drains. (b) Robinson's drain attached to sterile closed drainage bag. (c) Redivac drain. (d) Concertina drain.

tissue reaction (inflammation, fibrosis) as they are foreign bodies; however, the softer the drain, the less likely it is to cause tissue erosion. The type of drain used will be determined by the substance being drained (e.g. viscous versus thin fluid), the reason for the drain, drain location and volume of drainage (Ngo et al. 2004, Walker 2007).

Evidence-based approaches

Principles of care

While drains serve an important function, they are also associated with complications such as haemorrhage, tissue inflammation,

retrograde bacterial migration and drain entrapment (Walker 2007). It is therefore essential that nurses are familiar with the monitoring and management of surgical drains, but also the process involved in their removal.

The management of a surgical drain is determined by its type, purpose and location (refer to your trust's local procedural guidelines). If a patient has more than one drain, each one should be numbered to prevent confusion. Drains should be firmly secured at the exit site (e.g. with a suture) and if attached to a drainage bag or bottle, they should also be secured at one other point (e.g. with adhesive tape).

To minimize the risk of cross-infection, the drainage bag or bottle should not be placed directly on the floor but should be placed below the level of the wound to facilitate drainage. Drainage output should be measured and recorded on the fluid balance chart as accurate 24-hour totals are necessary for making decisions about drain management. This should be undertaken as clinically indicated (e.g. each time clinical observations are recorded). In particular, nurses should monitor changes in the character (colour, viscosity, odour) or volume of drainage fluid. Unexpected drainage volume (too high or low) or type (unexpected fluids, e.g. blood in urinary catheter) should always prompt further investigation by the clinical team and could indicate that something is wrong (see Problem-solving table 13.2). The length of the drainage tubing (from drain exit point) should also be documented on nursing/surgery documentation and regularly observed for signs of dislodgement (withdrawal or retraction). Furthermore, drain tubing and connections should be regularly inspected for signs of disconnection (e.g. suction pressure source), damage, blockages (viscous fluid, e.g. blood clots, pus, gastric contents) or kinks. For wound drains, it is also important that nurses observe the skin surrounding the drain site for signs of swelling, infection or haematoma. Swabs of wound/drain sites

should only be taken if infection is suspected, e.g. inflammation of wound margins, pain, oedema, pyrexia and/or purulent exudates.

Drains should be emptied frequently using clean technique/standard precautions to reduce the strain on the suture line and ensure maximum drainage (Lippincott Williams & Wilkins 2012). However, the dangers of introducing infection should be weighed against the need to empty the drain. Vacuum bottles (e.g. Redivac bottles) and underwater sealed drains (e.g. chest drains) are not emptied but renewed when full (see Procedure guideline 13.8: Closed drainage systems: changing a vacuum bottle).

With the exception of urinary catheters and Ryle's tubes, surgical drains are usually removed once the drainage has stopped or become less than approximately 25–50 mL/day. In some instances drains are 'shortened' by withdrawing them gradually (typically 2 cm/day) before they are completely removed or fall out, to promote gradual closure of the tract. The drain may also be 'cut and bagged' to facilitate easier mobilization. In each of these circumstances, the decision is taken by the surgical team. See Procedure guidelines 13.9, 13.10 and 13.11 for instructions concerning surgical wound drain shortening and removal.

Procedure guideline 13.7 Drainage systems: changing the dressing around the drain site for both open and closed drains

Essential equipment

- Dressing trolley or other suitable surface (cleaned according to local trust guidelines) and detergent wipe
- Apron
- Sterile fluids for cleaning and/or irrigation, e.g. sodium chloride 0.9%
- Appropriate absorbent dry dressing. Special features of a dressing should be referred to in the patient's nursing care plan
- Dressing pack, including sterile towel, gauze and gallipot, disposable bag
- Gloves: one disposable pair, one sterile pair
- Alcohol handrub or hand-washing facilities (see local trust guidelines)
- Hypoallergenic tape

Optional equipment

- Any extra equipment that may be needed during procedure, for example sterile scissors, forceps, microbiological swab

Pre-procedure

Action

- 1 Check the medical notes to identify which drain is to be removed. Explain and discuss the procedure with the patient and gain their consent and co-operation.
- 2 Check patient comfort, for example position and pain level. Offer the patient analgesia as described on their chart or encourage self-administration via a PCA pump (if applicable) and allow appropriate time for medication to take effect.
- 3 Clean trolley/tray (see local trust guidelines) and gather equipment, checking the sterility and expiry date of equipment and solutions, and place on the bottom of the trolley.
- 4 Take the trolley/tray to the bed and adjust the bed to the correct height to avoid stooping.
- 5 Wash and dry hands thoroughly and put on apron.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, **C**; Walker 2007, **C**).
- To promote comfort (NMC 2015, **C**).
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To promote good manual handling. **E**
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).

Procedure

- 6 Remove dressing pack from the outer pack and place on top of the clean dressing trolley/tray. Using aseptic technique, open packaging for other equipment required during procedure (e.g. sterile gloves, dressing, etc.) and place on the sterile field.

To minimize the risk of infection (Fraise and Bradley 2009, **E**).

7 Expose drain site, adjusting the patient's clothes to expose the wound, taking care to maintain their dignity.	To minimize the amount of skin exposed; to maintain dignity. E
8 Wearing disposable gloves, remove the dressing covering the drain site and place in a soiled dressing bag away from the sterile field. (a) Closed drains may have a small sterile gauze dressing surrounding the exit site. (b) Open drains will be covered with either a wound drainage bag (if copious exudate) or a small, absorbent, non-adhesive sterile gauze dressing (if only minimal exudate). Once the drainage bag/dressing has been removed from an open drain, the volume and character of exudate should be measured and recorded. If requested by surgical team, gauze dressings can be weighed once saturated to ascertain volume of drainage.	To minimize the risk of infection (Fraise and Bradley 2009, E).
9 Observe the drain to ensure the skin suture holding the drain in position is intact.	To ensure drain is well secured and not withdrawn/retracted. Dislodgement can increase the risk of infection, erosion into adjacent structures (e.g. blood vessels/organs) and irritation to surrounding skin. E
10 Observe skin surrounding drain site for signs of excoriation, fluid collection, infection (inflammation of wound margins, pain, oedema, purulent exudate, pyrexia). NB: Swabs of wound/drain sites should only be taken if infection is suspected.	Recognize and treat suspected complications (Fraise and Bradley 2009, E ; Walker 2007, E).
11 Using aseptic technique, clean the surrounding skin with an appropriate sterile solution such as 0.9% sodium chloride.	To minimize the risk of infection (Fraise and Bradley 2009, E).
12 If appropriate, cover the drain site as follows. (a) Closed drains should only be covered with a non-adherent, absorbent dressing if there is exudate or to promote patient comfort. (b) Open drains should be covered with a wound drainage bag (if exudate copious) or a small, absorbent, non-adhesive sterile gauze dressing (if only minimal exudate).	To allow effluent to drain, prevent excoriation of the skin, promote patient comfort and contain any odour. E
Post-procedure	
13 If applicable, tape dressing securely. If the drain is attached to a drainage bag or bottle, it should also be secured at one other point (e.g. with adhesive tape).	To prevent drain coming loose. E
14 If the drain is attached to a drainage bag or bottle, this should not be placed on the floor but placed below the level of the wound to allow drainage. If the drain is attached to a suction drain, ensure this is working correctly.	To ensure continuity of drainage. Ineffective drainage can result in oedema/haematoma (Hess 2005, E). To minimize the risk of cross-infection.
15 Check dressing/bag is secure and comfortable for the patient.	For patient comfort. E
16 Dispose of all clinical equipment in clinical waste bag or sharps bin according to local trust guidelines.	To ensure safe disposal. E
17 Document in patient's notes that the dressing has been changed, reporting any unusual signs or complications to surgical colleagues (Fraise and Bradley 2009; NMC 2010). If the volume of exudate on the dressing has been measured, this should be documented on the fluid balance chart.	To ensure effective communication and instructions for ongoing care. For accurate documentation of drainage (NMC 2010, C).

Procedure guideline 13.8 Closed drainage systems: changing a vacuum bottle

(NB: this guideline is not for underwater sealed drains, e.g. chest drain)

Essential equipment

- Dressing trolley or other suitable surface (cleaned according to local trust guidelines) and detergent wipe
- Apron
- Sterile fluids for cleaning and/or irrigation, e.g. sodium chloride 0.9%

(continued)

Procedure guideline 13.8 Closed drainage systems: changing a vacuum bottle (*continued*)

- Vacuum drainage bottle, e.g. Redivac
- Dressing pack, including sterile towel, gauze and gallipot, disposable bag
- Gloves: one disposable pair, one sterile pair
- Alcohol handrub or hand-washing facilities

Optional equipment

- Any extra equipment that may be needed during procedure, for example a clamp (although this is usually part of the drainage system in place) or hypoallergenic tape (to place on side of vacuum bottle to facilitate measurement of drain exudate)

Pre-procedure**Action****Rationale**

- 1 Explain and discuss the procedure with the patient and gain their consent and co-operation.
- 2 Clean trolley/tray and gather equipment, checking the sterility and expiry date of equipment and solutions, and place on the bottom of the trolley.
- 3 Take the trolley/tray to the bed and adjust the bed to the correct height to avoid stooping.
- 4 Wash and dry hands thoroughly and put on apron and disposable gloves.

- To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, **C**; Walker 2007, **C**).
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To promote good manual handling. **E**
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).

Procedure

- 5 Remove dressing pack from the outer pack and place on the top of the clean dressing trolley/tray. Using aseptic technique, open packaging for other equipment required during procedure (e.g. sterile gloves, vacuum bottle, etc.) and place on the sterile field.
- 6 Clean hands with alcohol gel. Seal off the bottle by closing both sliding clamps on the drainage tubing leading from the patient and the bottle connector.
- 7 Put on sterile gloves and, using non-touch technique, place sterile field/towel under drain tubing at connection point between the vacuum bottle and drain tubing.
- 8 Disconnect the bottle by unscrewing the Luer-Lok, clean the end of the tube with a sterile solution (sterile water or 0.9% NaCl) and securely screw new sterile bottle into the connecting tube at the Luer-Lok.
- 9 Unclamp both tubing clamps. Suction is established if the concertina bung remains compressed.
- 10 Check the drainage tubing is secured with adhesive tape dressing at one point (other than at entry site).
- 11 Vacuum bottle should not be placed on the floor but placed below the level of the wound to allow drainage.

- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To prevent air and contamination entering the wound via the drain. **E**
- To minimize the risk of infection (Fraise and Bradley 2009, **E**).
- To maintain sterility. **E**
- To re-establish the drainage system. **E**
- To prevent drain coming loose. **E**
- To ensure continuity of drainage. Ineffective drainage can result in oedema/haematoma (Hess 2005, **E**). To minimize the risk of cross-infection.

Post-procedure

- 12 Measure the contents of the used drainage system and document any additional drainage in the appropriate documents.
- 13 Place used vacuum drainage system into the clinical waste bag and dispose of according to local trust policy.
- 14 Document in patient's notes that the vacuum bottle has been changed (Fraise and Bradley 2009; NMC 2010).

- To maintain an accurate record of drainage from the wound (NMC 2010, **E**).
- To safely dispose of used system. **E**
- To ensure effective communication and instructions for ongoing care and accurate documentation of drainage (NMC 2010, **C**).

Procedure guideline 13.9 Wound drain removal: closed drainage system**Essential equipment**

- Dressing trolley or other suitable surface (cleaned according to local trust guidelines) and detergent wipe
- Apron
- Stitch cutter
- Sterile fluids for cleaning and/or irrigation, e.g. sodium chloride 0.9%
- Appropriate absorbent dry dressing. Special features of a dressing should be referred to in the patient's nursing care plan
- Dressing pack, including sterile towel, gauze and gallipot, disposable bag
- Gloves: one disposable pair, one sterile pair
- Sterile dressing
- Alcohol handrub or hand-washing facilities
- Hypoallergenic tape

Optional equipment

- Any extra equipment that may be needed during procedure, for example microbiological swab, sterile specimen pot

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient and gain their consent and co-operation.	To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, C ; Walker 2007, C).
2 Check patient comfort, for example position and pain level. Offer the patient analgesia according to chart or encourage self-administration via a PCA pump (if applicable) and allow appropriate time for medication to take effect. Another member of staff may be needed to reassure the patient during the procedure.	To promote comfort (NMC 2015, C).
3 If applicable, release vacuum on the drainage bottle by clamping the tubing coming from the patient; keep clamp on green connection open. Loosen the Luer-Lok to allow air into the bottle. Reattach the Luer-Lok and release clamp coming from the patient. Leave for 2–3 minutes. Note amount of drainage in the bottle.	This releases the vacuum and prevents suction during the removal of the drain which may cause tissue damage or pain (Walker 2007, C).
4 Clean trolley/tray and gather equipment, checking the sterility and expiry date of equipment and solutions, and place on the bottom of the trolley.	To minimize the risk of infection (Fraise and Bradley 2009, E).
5 Take the trolley/tray to the bed and adjust the bed to the correct height to avoid stooping.	To promote good manual handling. E
6 Wash and dry hands thoroughly and put on apron.	To minimize the risk of infection (Fraise and Bradley 2009, E).

Procedure

7 Remove dressing pack from the outer pack and place on the top of the clean dressing trolley/tray. Using aseptic technique, open packaging for other equipment required during procedure (e.g. sterile gloves, dressing, etc.) and place on the sterile field.	To minimize the risk of infection (Fraise and Bradley 2009, E).
8 Expose drain site, adjusting patient's clothes to expose wound, taking care to maintain their dignity.	To minimize the amount of skin exposed; to maintain dignity. E
9 Wearing disposable gloves, remove the dressing covering the drain site and place in a soiled dressing bag away from the sterile field.	To minimize the risk of cross-infection (Fraise and Bradley 2009, E).
10 Wash and dry hands thoroughly and put on apron and sterile gloves using aseptic technique.	To minimize the risk of infection. Use of aseptic technique is essential when caring for and removing drains because micro-organisms may pass through the drain to tissue and body cavities, which may result in infection and surgical complications (Fraise and Bradley 2009, E ; Walker 2007, C).

(continued)

Procedure guideline 13.9 Wound drain removal: closed drainage system (continued)

- | | |
|---|---|
| 11 Observe skin surrounding drain site for signs of excoriation, fluid collection, infection (inflammation of wound margins, pain, oedema, purulent exudate, pyrexia). If the drain site appears inflamed or purulent, a swab should be obtained and sent for microbiology and sensitivity analysis. | To recognize and treat suspected complications (Fraise and Bradley 2009, E ; Walker 2007, C). |
| 12 The skin surrounding the drain site should only be cleansed (with 0.9% sodium chloride) if necessary, that is, the drain site is purulent or to ensure the suture is visible and accessible. | To reduce the risk of infection (Fraise and Bradley 2009, E ; Walker 2007, C). |
| 13 Using non-touch technique, place sterile field under drain tubing and gently lift up the knot of the suture with sterile forceps. Use the stitch cutter to cut the shortest end of the suture as close to the skin as possible and remove the suture with the forceps. | To allow space for the scissors or stitch cutter to be placed underneath. To minimize cross-infection by allowing the suture to be liberated from the drain without drawing the exposed part through tissue (Pudner 2010, E). |
| 14 Warn the patient of the pulling sensation they will experience and reassure throughout. | To promote comfort and co-operation (Walker 2007, C). |
| 15 Fold up a sterile gauze swab several times to create an absorbent pad (Ngo et al. 2004). Loosening up of the drain should be done if possible, especially for a drain that has been in for some time. For round drains, this can be done by gently rotating the drain to 'break' it free. For flat ones, gentle movement from side to side can achieve this. | To minimize pain and reduce trauma. E
Drains that have been left in for an extended period will sometimes be more difficult due to tissue growing around the tubing (Walker 2007, C). |
| 16 With gloved hand, place one finger on each side of the drain exit site, first stabilizing the skin around the drain with firm pressure. With the other hand, the drain should be firmly grasped as close to the skin as possible and gently removed. Steady gentle traction should be used to remove the drain rather than sudden jerky movements. If there is resistance, place free gloved hand against the tissue to oppose the removal from the wound. Maintain gentle pressure for a few seconds until the drainage/bleeding has stopped or is minimal. | Firm grasp of shortest length should be done to minimize patient discomfort. This is especially important for supple drains such as those made from silicone or rubber which can stretch for some distance then suddenly break free (Walker 2007, C). |
| 17 The edge of the drain should be clean cut and not jagged. The drain should be inspected to ensure that it is intact. If there is any doubt that the drain is not intact, the surgeons should be contacted to inspect the drain before disposal. | This clean appearance ensures that the whole drain has been removed. E |
| 18 Cover the drain site securely with a sterile dressing and tape. A wound management bag may be placed over a mature exit site if fluid discharge remains high after drain removal. | To prevent infection entering the drain site. E
To prevent fluid collection/haematoma. |
| 19 If the site is inflamed or there is a request for the tip to be sent to microbiology, cut it cleanly with sterile scissors and place in a sterile specimen container, maintaining asepsis. | To recognize and treat suspected infection (Fraise and Bradley 2009, E ; Walker 2007, C). |
| 20 Check dressing/bag is secure and comfortable for the patient. | To promote patient comfort. E |

Post-procedure

- | | |
|--|--|
| 21 Measure and record the contents of the drainage bottle in the appropriate documents. | To maintain an accurate record of drainage from the wound and enable evaluation of state of wound (NMC 2010, C). |
| 22 Dispose of all clinical equipment in clinical waste bag or sharps bin according to local trust guidelines. | To safely dispose of used equipment. E |
| 23 Document in patient's notes that the drain has been removed, reporting complications to surgical colleagues (Fraise and Bradley 2009, NMC 2010). | To ensure effective communication and instructions for ongoing care. To ensure accurate documentation of drainage. |
| 24 Observe drain site dressing for signs of excess fluid discharge (soaked dressing). On routine dressing change, observe site for signs of infection (inflammation, oedema, purulent exudate, pyrexia) and obtain a wound swab if appropriate. Report any unusual signs or complications and record in appropriate documentation (see Procedure guideline 13.7: Drainage systems: changing the dressing around the drain site for both open and closed drains). | To recognize and treat potential complications (Fraise and Bradley 2009, E ; Walker 2007, C). To ensure accurate documentation of any unusual signs or complications (NMC 2010, C). |

Procedure guideline 13.10 Wound drain shortening for open drainage systems**Essential equipment**

- Dressing trolley or other suitable surface and detergent wipe
- Apron
- Stitch cutter
- Sterile fluids for cleaning and/or irrigation, e.g. sodium chloride 0.9%
- Appropriate absorbent dry dressing. Special features of a dressing should be referred to in the patient's nursing care plan
- Sterile safety pin
- Dressing pack, including sterile towel, gauze and gallipot, disposable bag
- Gloves: one disposable pair, one sterile pair
- Sterile dressing
- Alcohol handrub or hand-washing facilities
- Hypoallergenic tape

Optional equipment

- Any extra equipment that may be needed during procedure, for example microbiological swab, sterile specimen pot

Pre-procedure

Action	Rationale
1 Check the medical notes to identify which drain is to be shortened. Explain and discuss the procedure with the patient and gain their consent and co-operation.	To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, C).
2 Check patient comfort, for example position and pain level. Offer the patient analgesia according to chart or encourage self-administration via a PCA pump (if applicable) and allow appropriate time for medication to take effect. Another member of staff may be needed to reassure the patient during the procedure.	To promote comfort (NMC 2015, C).
3 Clean trolley/tray and gather equipment, checking the sterility and expiry date of equipment and solutions, and place on the bottom of the trolley.	To minimize the risk of infection (Fraise and Bradley 2009, E).
4 Take the trolley/tray to the bed and adjust the bed to the correct height to avoid stooping.	To promote good manual handling. E
5 Wash and dry hands thoroughly and put on apron.	To minimize the risk of infection (Fraise and Bradley 2009, E).

Procedure

6 Remove dressing pack from the outer pack and place on the top of the clean dressing trolley/tray. Using aseptic technique, open packaging for other equipment required during procedure (e.g. sterile gloves, dressing, etc.) and place on the sterile field.	To minimize the risk of infection (Fraise and Bradley 2009, E).
7 Expose drain site, adjusting patient's clothes to expose wound, taking care to maintain their dignity.	To minimize the amount of skin exposed; to maintain dignity. E
8 Wearing disposable gloves, remove the dressing covering the drain site and place in a soiled dressing bag away from the sterile field.	To minimize the risk of cross-infection (Fraise and Bradley 2009, E).
9 Wash and dry hands thoroughly and put on apron and sterile gloves using aseptic technique.	To minimize the risk of infection (Fraise and Bradley 2009, E). Use of an aseptic technique is essential when caring for and removing drains because micro-organisms may pass through the drain to tissue and body cavities, which may result in infection and surgical complications (Walker 2007, E).
10 Observe skin surrounding drain site for signs of excoriation, fluid collection, infection (inflammation of wound margins, pain, oedema, purulent exudate, pyrexia). If the drain site appears inflamed or purulent, a swab should be obtained and sent for microbiology and sensitivity analysis.	To recognize and treat suspected complications (Fraise and Bradley 2009; Walker 2007, E).
11 The skin surrounding the drain site should only be cleansed (with 0.9% sodium chloride) if necessary, that is, the drain site is purulent or to ensure the suture is visible and accessible.	To reduce the risk of infection (Fraise and Bradley 2009, E).

(continued)

Procedure guideline 13.10 Wound drain shortening for open drainage systems (*continued*)

- | | | |
|----|--|--|
| 12 | Using non-touch technique, place sterile field under drain tubing. If the drain is sutured in place, gently lift up the knot of the suture with sterile forceps (Action figure 12). Use the stitch cutter to cut the shortest end of the suture as close to the skin as possible and remove the suture with the forceps. | To allow space for the scissors or stitch cutter to be placed underneath. To minimize cross-infection by allowing the suture to be liberated from the drain without drawing the exposed part through tissue (Pudner 2010, E). |
| 13 | Warn the patient of the pulling sensation they will experience and reassure throughout. | To promote comfort and co-operation (Walker 2007, E). |
| 14 | With a gloved hand, place one finger on each side of the drain exit site, first stabilizing the skin around the drain with firm pressure. With the other hand, grasp the drain firmly as close to the skin as possible and gently ease out of wound to the length requested by surgeons. Steady gentle traction should be used to ease the drain out rather than sudden jerky movements. If there is resistance, place free gloved hand against the tissue to oppose the removal from the wound. | Firm grasp of shortest length should be done to minimize patient discomfort. This is especially important for supple drains such as those made from silicone or rubber which can stretch for some distance then suddenly break free (Walker 2007, E).
To allow healing to take place from base of wound. E |
| 15 | Using gloved hand, place a sterile safety pin through the drain as close to the skin as possible, taking great care not to stab either yourself or the patient (Action figure 15). Sterile tape should be used to secure the drain to the skin. | To prevent retraction of drain into the wound and minimize the risk of cross-infection and sharps injury. E
Additional measure to prevent the drain from falling out. |
| 16 | Cover the drain site with a suitably sized sterile gauze dressing (taped securely) or a wound drainage bag (depending upon volume of exudate). | To prevent infection entering the drain site. E
To prevent fluid collection/haematoma. |
| 17 | Check dressing/bag is secure and comfortable for the patient. | To promote patient comfort. |

Post-procedure

- | | | |
|----|---|---|
| 18 | Dispose of all clinical equipment in clinical waste bag or sharps bin according to local trust guidelines. | To safely dispose of used equipment. E |
| 19 | Document in patient's notes that the drain has been withdrawn, clearly stating: <ul style="list-style-type: none"> • length of drain withdrawn (in centimetres) • length of drain left visible from wound exit site to end of drain (in centimetres) • any complications during procedure. Report complications to surgical colleagues (Fraise and Bradley 2009, NMC 2010). | To ensure effective communication and instructions for ongoing care (NMC 2010, C). |
| 20 | Observe drain site dressing for signs of excess fluid discharge (soaked dressing). On routine dressing change, observe site for signs of drain retraction or withdrawal or infection (inflammation, oedema, purulent exudate, pyrexia) and obtain a wound swab if appropriate. Report any unusual signs or complications and record in appropriate documentation (see Procedure guideline 13.7: Drainage systems: changing the dressing around the drain site for both open and closed drains). | To recognize and treat potential complications (Fraise and Bradley 2009; Walker 2007, E). To ensure accurate documentation of any usual signs or complications (NMC 2010, C). |

Action Figure 12 Use forceps to gently lift the knot of the suture.

Action Figure 15 Position of safety pin through open drain to prevent retraction.

Procedure guideline 13.11 Wound drain shortening for closed drainage systems

Also known as 'cut and bag' procedure

Essential equipment

- Dressing trolley or other suitable surface and detergent wipe
- Apron
- Stitch cutter
- Sterile fluids for cleaning and/or irrigation, e.g. sodium chloride 0.9%
- Appropriate absorbent dry dressing. Special features of a dressing should be referred to in the patient's nursing care plan
- Sterile safety pin
- Dressing pack, including sterile towel, gauze and gallipot, disposable bag
- Gloves: one disposable pair, one sterile pair
- Two-piece wound drainage bag
- Alcohol handrub or hand-washing facilities
- Hypoallergenic tape

Optional equipment

- Any extra equipment that may be needed during procedure, for example microbiological swab, sterile specimen pot

Pre-procedure

Action	Rationale
1 Check the medical notes to identify which drain is to be shortened (cut and bagged). Explain and discuss the procedure with the patient and gain their consent and co-operation.	To ensure that the patient understands the procedure and gives their valid consent and participates in care (NMC 2013, C).
2 Check patient comfort, for example position and pain level. Offer the patient analgesia according to chart or encourage self-administration via a PCA pump (if applicable) and allow appropriate time for medication to take effect. Another member of staff may be needed to reassure the patient during the procedure.	To promote comfort (NMC 2015, C).
3 Clean trolley/tray and gather equipment, checking the sterility and expiry date of equipment and solutions, and place on the bottom of the trolley.	To minimize the risk of infection (Fraise and Bradley 2009, E).
4 Take the trolley/tray to the bed and adjust the bed to the correct height to avoid stooping.	To promote good manual handling. E
5 Wash and dry hands thoroughly and put on apron.	To minimize the risk of infection (Fraise and Bradley 2009, E).

Procedure

6 Remove dressing pack from the outer pack and place on the top of the clean dressing trolley/tray. Using aseptic technique, open packaging for other equipment required during procedure (e.g. sterile gloves, dressing, etc.) and place on the sterile field.	To minimize the risk of infection (Fraise and Bradley 2009, E).
7 Expose drain site, adjusting patient's clothes to expose wound, taking care to maintain their dignity.	To minimize the amount of skin exposed; to maintain dignity. E
8 Wearing disposable gloves, remove the dressing covering the drain site and place in a soiled dressing bag away from the sterile field.	To minimize the risk of cross-infection (Fraise and Bradley 2009, E).
9 Wash and dry hands thoroughly and put on apron and sterile gloves using aseptic technique.	To minimize the risk of infection (Fraise and Bradley 2009, E). Use of an aseptic technique is essential when caring for and removing drains because micro-organisms may pass through the drain to tissue and body cavities, which may result in infection and surgical complications (Walker 2007, E).
10 Observe skin surrounding drain site for signs of excoriation, fluid collection, infection (inflammation of wound margins, pain, oedema, purulent exudate, pyrexia). If the drain site appears inflamed or purulent, a swab should be obtained and sent for microbiology and sensitivity analysis.	To recognize and treat suspected complications (Fraise and Bradley 2009, E ; Walker 2007, E).
11 The skin surrounding the drain site should only be cleansed (with 0.9% sodium chloride) if necessary, that is, the drain site is purulent or to ensure the suture is visible and accessible.	To reduce the risk of infection (Fraise and Bradley 2009, E).

(continued)

Procedure guideline 13.11 Wound drain shortening for closed drainage systems (*continued*)

12	Using non-touch technique, place sterile field under drain tubing. Using the sterile scissors, cut the drain approximately 7–10 cm from the patient's skin, taking care to securely hold the drain in place at the patient's side with a gloved hand.	To prevent retraction of the drain back into the body (retained drain) if drain cut too short.
13	Measure the contents of the drainage bag and place in a soiled dressing bag away from the sterile field.	To maintain an accurate record of drainage from the wound (NMC 2010, C).
14	Remove the sticky backing from the flange of the two-piece drainage bag and carefully place over the drainage tube and onto the skin. Check the aperture on the flange fits snugly around the drain tube. Hold flange in place for a few minutes to ensure a good seal.	To prevent excoriation of the surrounding skin. E
15	Using gloved hand, place a sterile safety pin through the drain as close to the skin as possible, taking great care not to stab either yourself or the patient.	To prevent retraction of drain into the wound and minimize the risk of cross-infection and sharps injury.
16	Carefully place the drainage bag over the drain and click into place.	To prevent infection entering the drain site. E To prevent fluid collection/haematoma.
17	Check dressing/bag is secure and comfortable for the patient.	To promote patient comfort. E

Post-procedure

18	Measure and record the contents of the drainage bag in the appropriate documents.	To maintain an accurate record of drainage from the wound and enable evaluation of state of wound (NMC 2010, C).
19	Dispose of all clinical equipment in clinical waste bag or sharps bin according to local trust guidelines.	To safely dispose of used equipment. E
20	Document in patient's notes that the drain has been cut and bagged, clearly stating: <ul style="list-style-type: none"> length of drain left visible from wound exit site to end of drain (in centimetres) any complications during procedure. Report complications to surgical colleagues (Fraise and Bradley 2009, NMC 2010).	To ensure effective communication and instructions for ongoing care (NMC 2010, C).
21	Observe drain site dressing for signs of excess fluid discharge (soaked dressing). On routine dressing change, observe site for signs of drain retraction or withdrawal or infection (inflammation, oedema, purulent exudate, pyrexia) and obtain a wound swab if appropriate. Report any unusual signs or complications and record in appropriate documentation (see Procedure guideline 13.7: Drainage systems: changing the dressing around the drain site for both open and closed drains).	To recognize and treat potential complications (Fraise and Bradley 2009, E ; Walker 2007, E). To ensure accurate documentation of any usual signs or complications (NMC 2010, C).

Problem-solving table 13.2 Prevention and resolution (Procedure guidelines 13.7, 13.8, 13.9, 13.10, 13.11)

This refers to open and closed drainage systems only (not chest drains). The surgical team must be contacted in the event of any of the following problems occurring.

Problem	Cause	Prevention	Action
1 Blocked drain. Blockage should be suspected when there is a sudden drop in drainage output, lower output than expected, or no output at all.	Overly tight sutures, kinking. Ingrowth or collapse of surrounding tissues. Debris accumulation and blood clots in the lumen. Commonly a drain is blocked due to luminal debris which may not be visible from external inspection.	Drain tubing and connections should be regularly inspected for blockages or kinks.	Surgical team should be informed prior to any action being taken. (a) 'Milk' Manual 'milking' of debris out through the drain can help to dislodge the obstruction or break it up into smaller debris. This can be done by gently squeezing the tube between your thumb and index finger while moving your fingers along the tubing towards the suction bottle.

Problem	Cause	Prevention	Action
<p>ALERT: Unexpected fall in drain output may result from drain dislodgement rather than blockage. Advice should be obtained from the surgical team prior to any intervention.</p>			<p>(b) <i>Aspirate</i></p> <p>After ruling out external compression, a drain can usually be unblocked by aspirating the drain according to local trust guidelines.</p> <p>ALERT: This should not be undertaken without instruction from surgical team.</p> <p>(c) <i>Flush</i></p> <p>Failing aspiration and milking, one may attempt to flush the drain with sterile saline using aseptic technique according to local trust guidelines. This can push back in any debris too large to be aspirated through the drain. Flushing also helps to re-establish drainage where tissue collapse or adhesion around the drain interferes with its function.</p> <p>ALERT: No attempts should be made to flush a drain without instruction and guidance from the surgical team who inserted the drain.</p>
2 Leaking drain.	<p>Determined by site of leakage.</p> <p>Leakage occurring around the exit site of a suction drain is usually due to a blocked drain rather than a perforation in the drain. The drainage fluid may find its way out along the external surface of the drain when the lumen is blocked.</p> <p>Leakage around the tubing or connections is due to damaged tubing or connections.</p> <p>Skin incision too big for the drain.</p>	<p>Drain tubing and connections should be regularly inspected for blockages, kinks or damaged tubing/connectors. Ensure the drainage bag is lower than the drain site.</p>	<p>Blocked drain – unblock drain using methods outlined in point 1: Blocked drain.</p> <p>Connections – using aseptic technique, replace the tubing according to manufacturer's instructions and tighten connections as appropriate.</p> <p>Reduce size of skin incision – if skin incision is too big, report to surgical team for guidance. They may either consider an additional suture or may cut and bag the drain to collect the leaking exudate. See Procedure guideline 13.11 for 'cut and bag' procedure.</p>
3 Loose drain.	<p>Causes may include drain-securing suture cutting through the skin, loose knot tying or traction on the drain.</p>	<p>The majority of drains need to be well secured, preferably at two points. Regular observation of drain to check it is firmly secured at its exit site (e.g. with a suture) and one other point (e.g. with adhesive tape).</p> <p>Awareness of length of drain from exit site at skin to drainage bag (if applicable) – documented in nursing/medical notes.</p>	<p>Surgical team should be informed prior to any action being taken.</p> <p>Loose drains must be resecured appropriately and promptly. If the suture around the drain appears loose, the surgical team should be contacted immediately, who may consider placing a stitch through the skin next to the drain exit site under local anaesthetic, then tying the suture securely around the drain.</p> <p>Extra security can be provided by taping the drain/tubing to the skin. Open drains should be prevented from falling into the drainage cavity, e.g. by passing a large sterile safety pin through the drain. See point 15 in Procedure guideline 13.10 for guidance on how to perform this procedure.</p>
4 Drain retraction.	<p>Drain retraction is due to a loose drain being pushed inwards, e.g. during dressing change or from patient movement.</p>	<p>Virtually all drains need to be well secured, preferably at two points. Regular observation of drain to check it is firmly secured at its exit site (e.g. with a suture) and one other point (e.g. with adhesive tape).</p>	<p>Surgical team should be informed prior to any action being taken for guidance.</p> <p>(a) <i>Resecure</i></p> <p>This should be dealt with as a loose drain (see point 3: Loose drain).</p>

(continued)

Problem-solving table 13.2 Prevention and resolution (Procedure guidelines 13.7, 13.8, 13.9, 13.10, 13.11) (continued)

Problem	Cause	Prevention	Action
		Awareness of length of drain from exit site at skin to drainage bag (if applicable) – documented in nursing/medical notes.	<p>ALERT: Drains suspected to have partially retracted inside a wound should be left in place and properly resecured by a member of the surgical team and a safety pin placed through the tubing to prevent further retraction (see Procedure guidelines 13.10 and 13.11).</p> <p>ALERT: Attempts to pull the drain back out should be avoided unless the distance of retraction is known, e.g. drain retraction witnessed or length at skin surface marked. Otherwise any attempt to pull the drain back out may lead to it being dislodged altogether.</p> <p><i>(b) Reposition</i></p> <p>Drains that have clearly retracted inwards should be pulled out by a member of the surgical team to a length that allows removal at a later date before being resecured.</p> <p>ALERT: A drain that is ‘cut and bagged’ must always be secured with a large, sterile safety pin placed through the external tubing close to the skin to prevent retraction (see Procedure guideline 13.10).</p>
5 Drain appears to be falling/fallen out.	<p>This is due to:</p> <ul style="list-style-type: none"> – failure of the sutures to secure the drain – tethering of the drain or drainage bottle/bag – breakage of the drain – tugging of the drain by the patient/staff – retraction of the drain. 	<p>All drains need to be well secured, preferably at two points. Regular observation of drain to check it is firmly secured at its exit site (e.g. with a suture) and one other point (e.g. with adhesive tape).</p> <p>Awareness of length of drain from exit site to drainage bag (if applicable) – documented in nursing/medical notes.</p>	<p>In this event a member of the surgical team should be contacted immediately for guidance.</p> <p><i>(a) Resecure</i></p> <p>A drain that has only partially migrated out should be resecured and the surgical team informed. It should not be pushed back in as the externalized part is now contaminated.</p> <p><i>(b) Examine</i></p> <p>If a drain has fallen out completely, the tube must be inspected to ensure that the drain is intact and saved for inspection by the surgeon. Also ensure that no part of the drain is left inside. If there is any doubt, an X-ray should be performed to ensure no part of the drain remains inside the body. The surgeon will decide if the drain requires replacement and make the necessary arrangements. A wound management bag may be placed over the exit site to catch any ongoing drainage from a mature tract.</p>
6 Broken drain/tubing/retained drain.	<p>This is usually from repetitive physical trauma with potential contributing factors including:</p> <ul style="list-style-type: none"> – manufacturing defects – drain weakness as a result of prolonged use – contact with digestive enzymes in body fluids – accidental tethering of the tube/bag. <p>A high-risk factor is a drain that is ‘cut and bagged’ without use of a safety pin.</p>	<p>All drains need to be well secured, preferably at two points. Regular observation of drain to check it is firmly secured at its exit site (e.g. with a suture) and one other point (e.g. with adhesive tape).</p>	<p>In this event a member of the surgical team should be contacted immediately for guidance.</p> <p><i>(a) Replacement</i></p> <p>If breakage occurs to the external part of the drain or tubing, then the drain might still be able to function. It may be reconnected to a new reservoir or have tubing replaced as appropriate. A safety pin should be placed through the tubing to prevent retraction.</p>

Problem	Cause	Prevention	Action
			<p>(b) Removal</p> <p>If the break is flush with the skin exit site, the surgeon should be contacted immediately and then it should be VERY CAREFULLY removed by the surgeon so as not to push it further inside the wound. The surgeon will perform this using aseptic technique taking care to avoid pushing the broken part further inside or creating tissue bleeding which may further obscure vision. If the surgeon is unable to remove the drain, intraoperative removal under X-ray guidance or an open procedure may be necessary.</p>
7 Inflamed drain exit site	<p>Minimal redness can often be seen around drain exit sites due to local irritation.</p> <p>Cellulitis at the drain exit site may appear as a more pronounced zone of redness, warmth and tenderness. Fever and/or tachycardia may also be present as part of systemic inflammatory response.</p> <p>Purulent discharge at the drain exit site may persist around drains which have been in place beyond the acute post-operative phase. However, the discharge must be examined by the surgical team to distinguish between purulent drainage fluid coming up around the outside of the drain and local abscess collection (unusual).</p>	<p>Well-secured drain to prevent local irritation to skin at drain exit site. All drains need to be well secured, preferably at two points. Regular observation of drain to check it is firmly secured at the exit site (e.g. with a suture) and one other point (e.g. with adhesive tape). Cleanliness of site.</p>	<p><i>Irritation:</i> if local irritation is suspected, no treatment is required other than good wound care according to local trust guidelines to keep drain exit site clean and dry and regularly monitoring drain to ensure it is firmly secured at the exit site (e.g. with a suture) and one other point (e.g. with adhesive tape).</p> <p><i>Cellulitis:</i> surgical team should be informed if cellulitis is suspected as this can indicate inadequate drainage. Antibiotics are NOT indicated unless there is significant associated cellulitis or systemic immunosuppression.</p> <p><i>Purulent discharge:</i> if an abscess has been excluded, then local care for a small wound should be given according to local trust guidelines. Where there is an abscess collection, the treatment in some cases is drainage by a member of the surgical team using appropriate aseptic technique. This can usually be done by a simple incision after infiltration with local anaesthetic. Antibiotics are NOT indicated unless there is significant associated cellulitis or systemic immunosuppression.</p>
8 Atypical drainage fluids.	<p>Unexpected fluids coming up from around a drain or in the drain lumen may be due to:</p> <ul style="list-style-type: none"> – anastomotic leaks – drain erosion into adjacent structures, e.g. bowel, bladder or blood vessels. The likelihood of tissue erosion is increased by fragility of the local tissues (e.g. in the presence of local inflammation, infection or necrosis), the use of large or rigid drains, and the use of continuous high-pressure suction which sucks surrounding tissues into the drain holes. <p><i>Blood</i></p> <p>Bleeding can be deep or superficial, early or delayed.</p> <p><i>Early bleeding:</i> usually results from a vessel being accidentally pierced by the trocar during insertion or by the drain stitch.</p>	<p>Well-secured drain to minimize risk of tissue erosion into adjacent structures.</p>	<p>In this event a member of the surgical team should be contacted immediately for guidance.</p> <p>(a) Bleeding</p> <p>The team registrar or consultant must be notified of any significant bleeding.</p> <p>Superficial bleeding will usually settle with local pressure but on occasion may require additional suturing by a member of the surgical team. Deep bleeding may need angiography or surgery.</p>

Problem-solving table 13.2 Prevention and resolution (Procedure guidelines 13.7, 13.8, 13.9, 13.10, 13.11) (*continued*)

Problem	Cause	Prevention	Action
	<i>Delayed bleeding:</i> may indicate erosion of a vessel by the drain anywhere along the drain tract. Erosion into blood vessels may appear as an initial 'herald bleed' consisting of a brief and brisk fresh bleed which may be followed by a more catastrophic haemorrhage at a later stage.		(b) <i>Anastomotic leak or tissue erosion</i> There are several approaches including observation only, reducing or stopping suction (if applicable), partial withdrawal of the drain, removal of the drain or intraoperative repair. The approach taken will be determined by the surgical team. Anastomotic leaks may be verified by testing for appropriate biochemical markers, e.g. amylase for suspect pancreatic anastomotic leak or creatinine for urinary tract anastomotic leak. If the concentration of the particular biochemical marker in the drainage fluid is significantly higher than the serum concentration then leakage should be suspected.
850 9 High drainage output.	Unless it is suspected that the drain is blocked, sudden increase in drain output usually signifies a complication, e.g. anastomotic leak or erosion into adjacent organs (see point 8).	n/a	In this event a member of the surgical team should be contacted immediately for guidance. Management steps appropriate to the cause should be undertaken.
10 Vacuum failure for suction drains. When the vacuum suction reservoir fills with air, loss of vacuum has occurred.	This may be the result of: – an air leak in the actual drain or the connecting tubing – a problem with the actual reservoir, e.g. failure to close a cap or presence of a puncture in the reservoir – less commonly, this may be due to the development of a communication between the drainage cavity and the external environment (e.g. wound dehiscence) or an adjacent hollow viscus (e.g. fistula development).	Drain tubing and connections should be regularly inspected to ensure the maintenance of the vacuum within the bottle (according to manufacturer's instructions).	If the vacuum of the drainage system is continually being lost, check all connections for evidence of an air leak and for any wound drain perforations exposed above skin level. Any drain hole outside the skin should be covered with occlusive dressing/bandaging using aseptic technique to stop the air leak. Air leaks elsewhere in the system should be stopped preferably by tightening of connections and/or replacement of any defective component. Otherwise occlusive tape may also be used to seal such defects. If no air leak or suction reservoir defect is found, an opened wound edge or some abnormal communication from the drainage cavity ought to be suspected. The surgical team must be notified.
11 Drain appears stuck and will not come out on attempted removal.	Potential causes include: – stitches remain <i>in situ</i> – the drain may just have been in for so long that tissue has grown into it, or perhaps tissue has been sucked into the side holes.	Check operation notes to determine number and types of sutures <i>in situ</i> prior to attempting drain removal.	Recheck operation notes to ensure all non-absorbable stitches have been removed. Loosening up of the drain should be done if possible, especially for a drain that has been in for some time. For round drains, this can be done by gently rotating the drain to release it. For flat drains, gentle movement from side to side can achieve this. NB: Removal using excess force should not be attempted. Assistance from the surgical team should be sought if the drain does not come easily.

Surgical wounds

Definition

A surgical wound is an incision through the skin made by a cutting instrument (e.g. scalpel) to allow the surgeon to gain access to the deeper tissues or organs. Surgical wounds are made in a sterile environment, where many variables can be controlled such as bacteria, size, location and the nature of the wound itself (Toon et al. 2013).

Related theory

Surgical wounds are usually closed fully at the end of the procedure (primary closure), using one of four devices depending on the type of surgery and determined by surgeon preference: sutures (absorbable and non-absorbable), adhesive skin closure strips (e.g. Steri-Strips), tissue adhesive and staples. Non-absorbable sutures, Steri-Strips and staples will need to be removed but only on the advice of the surgical team, usually 7–10 days post-operatively.

Dressings for surgical wounds

Related theory

The location of the wound and the method of wound closure usually determine whether the wound is dressed or not. In a closed surgical wound (i.e. one closed by sutures or clips), the main functions of a wound dressing are to:

- promote healing by providing a moist environment without causing maceration (softening and deterioration) of the surrounding skin
- protect the wound from potentially harmful agents (e.g. bacterial contamination) or injury
- allow appropriate assessment of the wound post-operatively
- absorb exudates, e.g. blood or haemoserous fluids
- ease discomfort (preventing the wound rubbing on clothing) (NICE 2008).

NICE (2008) describes three categories of wound dressing used post-operatively.

- *Passive*: designed solely to cover the wound, neither promoting nor intentionally hindering the wound-healing process, e.g. 'gauze-like' materials.
- *Interactive*: designed to promote the wound-healing process through the creation and maintenance of a warm, moist environment underneath the chosen dressing, e.g. alginates, foams, hydrocolloids, semi-permeable film.
- *Active*: designed to manipulate or alter the wound-healing environment to either restimulate or further promote the healing process, e.g. collagen, negative pressure therapy (see Chapter 15: Wound management).

Current guidance recommends that surgical incisions should be covered with an appropriate interactive dressing at the end of an operation (NICE 2008). However, a systematic review published by the Cochrane Library in 2011 (Dumville et al. 2011), evaluating the clinical effectiveness of wound dressings for preventing surgical site infection (SSI), concluded that there is no evidence to suggest that applying a wound dressing to a surgical wound healing by primary intention reduces the risk of surgical site infection. Whether or not a dressing is applied in theatre will be determined by the type of surgery performed and surgical advice.

When dressings are applied in theatre, it is recommended that they are not removed unless exudate, commonly termed

Figure 13.34 Surgical wound dressings.

'strike-through', is evident or clinical signs of local or systemic infection (e.g. malodour, fever) occur. Unless contraindicated, dressings changes required within 48 hours of surgery should be undertaken using aseptic non-touch technique and sterile normal saline (see Chapter 3: Infection prevention and control). Whilst some dressings allow early bathing or showering of the rest of the patient after 48 hours, this should be confirmed with the surgeon performing the procedure (NICE 2008).

Studies have demonstrated that it is unnecessary to dress surgical wounds after 72 hours as a surgical wound which has good apposition is sealed against pathogenic invasion by epithelialization in approximately 48–72 hours (Dumville et al. 2011, Toon et al. 2013); however, the application of wound dressings and their removal and subsequent renewal will depend upon local trust protocols. If a dressing is required, it should be changed using aseptic non-touch technique, to prevent micro-organisms being introduced into the wound (NICE 2008).

The choice of dressing will depend on which qualities are required (i.e. absorptive or supportive) and according to surgical recommendation (Dumville et al. 2011). Gauze-based dressings should not be used to dress surgical wounds as these can completely adhere to the wound and become part of the healing tissue, causing excessive pain and wound damage (Vermeulen et al. 2005). Patient education and psychological support will be required prior to exposing a wound as it may cause patient distress.

On discharge, the patient should be referred to a community nurse and/or be educated about how to care for the surgical wound. Verbal and written information should be given to the patient and include observing for signs of infection and swelling/seroma formation and information on how to seek support/advice if such an event arises (Figure 13.34).

Surgical wound complications

Surgical wound complications are important causes of early and late post-operative morbidity (Mizell 2012). Surgical wounds in normal, healthy individuals heal through an orderly sequence of physiological events that include inflammation, epithelialization, fibroplasia and maturation. Failure of wound healing following surgery can lead to various complications including dehiscence, surgical site infection, seroma and haematoma.

Problem-solving table 13.3 Surgical wound complications: prevention and resolution

The surgical team must be contacted in the event of any of the following problems occurring.

Problem	Potential causes/risk factors	Prevention	Action
<i>Dehiscence</i> : partial or total disruption of any or all layers of the surgical wound.	<ul style="list-style-type: none"> • Systemic factors such as diabetes mellitus, cancer, immunosuppression. • Local factors: <ul style="list-style-type: none"> – inadequate closure of surgical wound site – tight suturing can tear the skin and affect vascularity of the wound edges, and may result in necrosis and wound breakdown – increased intra-abdominal pressure (ileus) – suboptimal wound care – impaired wound healing caused by infection, seroma, haematoma, drains – impaired wound healing caused by poor perfusion of wound bed due to risk factors including: smoking, male gender, obesity, rheumatoid arthritis, malnutrition. 	<p>Reduction in risk factors (refer to cause) identified through comprehensive pre-assessment.</p> <p>Adequate closure of surgical wound intraoperatively.</p>	<p>Action is dependent upon level of dehiscence, which can range from a sudden discharge of fluid or cellulitis along the suture line to the splitting open of the skin layers to complete dehiscence of the muscle and fascia, exposing internal organs, and occasionally incisional hernia with outer layers intact. NB: If dehiscence is suspected then a member of the surgical team should be contacted immediately for guidance.</p> <p><i>Minor dehiscence</i>: local care for a small wound should be given according to local trust guidelines. Wound manager bags are occasionally indicated to drain the excessive exudate from a partially dehisced wound, particularly if skin integrity is compromised.</p> <p><i>Partial (deep) or full dehiscence</i>: in this event, a member of the surgical team should be contacted immediately for guidance. Management steps appropriate to the cause should be undertaken.</p>
<i>Surgical site infection (SSI)</i> : when pathogenic organisms multiply in a wound, giving rise to local and systemic signs and symptoms. SSI can occur at the incision site or in subcutaneous dead space. Symptoms include localized erythema, purulent exudates, tenderness, wound odour at the incision site. In more serious cases, systemic signs of infection including temperature and raised white cell count may be present. Infection in the surgical wound may prevent healing taking place so that the wound edges separate or it may cause an abscess to form in the deeper tissues.	<ul style="list-style-type: none"> • Systemic factors such as diabetes mellitus, cancer, immunosuppression. • Local factors: <ul style="list-style-type: none"> – inadequate closure of surgical wound site – suboptimal wound care – impaired wound healing caused by poor perfusion of wound bed due to risk factors including: smoking, male gender, rheumatoid arthritis, malnutrition. • Obesity – causes increased subcutaneous dead space, rendering the patient more susceptible to incidence of infection. • Drains and sutures. • Poor hand hygiene contaminating surgical site. 	<p>Reduction in risk factors (refer to cause) identified through comprehensive pre-assessment.</p> <p>Adequate closure of surgical wound intraoperatively.</p> <p>Optimal wound care.</p>	<p>Some signs of SSI including erythema and tenderness are also seen in the normal post-operative inflammatory response, lasting up to 48 hours. Persistent inflammation beyond this period or the presence of pus or purulent discharge, or pyrexia of the patient may indicate infection. NB: If infection is suspected then a member of the surgical team should be contacted immediately for guidance.</p> <p>A swab, pus sample and blood cultures (if systemic signs of infection, e.g. pyrexia, are present) should be taken to identify the causative micro-organism and appropriate treatment commenced to eradicate it. Antibiotics will usually only be given if adjacent tissue is inflamed or there are systemic signs of infection. In more serious cases, infected wounds may need to be opened and explored or debrided.</p>
<i>Haematoma</i> : collection of blood. The blood seeps from blood vessels that are cut during the operation to remove tissue.	<ul style="list-style-type: none"> • Inadequate haemostasis. • Use of coagulants. • Obesity – causes increased subcutaneous dead space, rendering the patient more susceptible to haematoma formation. 	<p>Adequate haemostasis.</p> <p>Reduction in risk factors (refer to cause) identified through comprehensive pre-assessment.</p>	<p>Action is dependent upon manifestation. Haematomas can be asymptomatic or manifest as swelling with pain. They can cause the incision to separate and predispose to wound infection since bacteria can gain access to deeper layers and multiply uninhibited in the stagnant blood.</p> <p><i>Small haematomas</i>: can be managed expectantly and may resolve with no intervention as, once the small vessels heal, no further blood collects and the haematoma will gradually be absorbed by the body.</p> <p><i>Large haematomas</i>: may require drainage under sterile conditions by needle aspiration. This will be undertaken by a member of the surgical team.</p>

Problem	Potential causes/risk factors	Prevention	Action
<i>Seroma</i> : collection of serous fluid. The fluid seeps from small blood and lymph vessels that are cut during the operation to remove the tissue or lymph nodes. Most frequently seen under split-thickness skin grafts and in areas with large dead spaces (e.g. axilla, groin, neck or pelvis).	<ul style="list-style-type: none"> • Challenging dissection. • Obesity – causes increased subcutaneous dead space, rendering the patient more susceptible to seroma formation. 	Reduction in risk factors (refer to cause) identified through comprehensive pre-assessment.	<p>Action is dependent upon manifestation. Seromas can be asymptomatic or manifest as swelling with pain. Seromas can cause the incision to separate and predispose to wound infection since bacteria can gain access to deeper layers and multiply uninhibited in the stagnant fluid.</p> <p><i>Small seromas</i>: can be managed expectantly and may resolve with no intervention as, once the small vessels heal, no further fluid collects and the seroma will gradually be absorbed by the body, usually over 1 month.</p> <p><i>Large seromas</i>: may require drainage under sterile conditions by needle aspiration. This will be undertaken by a member of the surgical team.</p>
<i>Allergic reaction</i> : local rash, redness, itching at site of surgical wound.	<ul style="list-style-type: none"> • Allergic reaction to surgical dressing or topical ointment applied intraoperatively. 	Identification of allergies identified through comprehensive pre-assessment.	<p>Removal of allergen (dressing or ointment). If a severe allergic reaction then give antihistamine.</p> <p>Documentation of allergy according to local policy, e.g. updating patient records to alert other healthcare professionals; informing patient.</p>

Urinary output and catheters

Related theory

It is important that patients pass urine within 6–8 hours of surgery or pass more than 0.5 mL/kg/h (i.e. half the patient's body-weight, for example 60 kg = 30 mL) if a urinary catheter is *in situ* (Liddle 2013). Urinary catheters are used to relieve or prevent urinary retention and bladder distension, or to monitor urine output. Most urinary catheters are inserted urethrally but, where this is contraindicated, suprapubic catheters can be used (see Chapter 5: Elimination).

Evidence-based approaches

Principles of care

Urine output should be measured and accurately recorded on the fluid balance chart. This should be undertaken as clinically indicated (e.g. hourly in the immediate post-operative period). Nurses should also monitor and report changes in the character (colour, viscosity, odour) or volume of urine output, e.g. oliguria (urine output of less than 0.5 mL/kg/h for two consecutive hours in the catheterized patient) could indicate the patient is hypovolaemic and should be reported to surgical staff immediately (once catheter tubing has been checked to confirm it is not kinked or blocked). If a patient does not have a catheter *in situ*, it is important that the patient is asked to pass urine into a jug/commode so that the volume of urine can be measured and recorded.

The inability to pass urine post-operatively is usually caused by a condition called neurogenic bladder, a type of bladder dysfunction that interferes with the nerve impulses from the brain to the bladder, preventing it from emptying. For patients with no history of difficulty urinating prior to surgery, the problem is often attributed to a combination of risk factors that include abdominal surgery, general anaesthesia and pain medications and fluids given perioperatively. Signs that a patient is in urinary retention include the patient reporting discomfort or pain

or a full bladder and inability to urinate, despite feeling the urge. A bladder scan can be used to determine the residual volume of urine in the bladder and if encouraging the patient to urinate on several occasions is unsuccessful then an in/out urinary catheter can be inserted to drain the bladder. No attempts should be made to catheterize the patient without seeking confirmation from the surgical team that this is the appropriate course of action to take.

Bowel function

Related theory

Gastrointestinal (GI) peristalsis usually returns within 24 hours after most operations that do not involve the abdominal cavity and within 48 hours after laparotomy (Crainic et al. 2009). Patients undergoing abdominal surgery experience reduced GI peristalsis due to surgical manipulation of the bowel and post-operative opioid medication (Litkouhi 2013). The motility of the small intestine is affected to a lesser degree, except in patients who have had small bowel resection or who were operated on to relieve small bowel obstruction (Crainic et al. 2009). Prolonged inhibition of GI peristalsis (more than 3 days post surgery) is referred to as paralytic ileus (Litkouhi 2013). The duration of post-operative ileus correlates with the degree of surgical trauma, occurring less frequently following laparoscopic than open surgery (Baig and Wexner 2004). Traditional interventions to prevent post-operative ileus or stimulate bowel function after surgery include:

- decompression of the stomach until return of bowel function with a nasogastric tube
- reduction in opioid use
- early mobilization of the patient to stimulate bowel function
- early post-operative feeding (Crainic et al. 2009, Nelson et al. 2005).

Post-operative ileus usually leads to slight abdominal distension and absent bowel sounds. Return of peristalsis is often noted by the patient as mild cramps, passage of flatus and return of appetite. Unless clinically indicated, food or enteral feeds should be withheld until there is evidence of return of normal GI motility.

Evidence-based approaches

Principles of care

Post-operatively, nurses should monitor and document when patients pass flatus, when bowels first open and ongoing bowel movements to facilitate early identification of return to GI motility or if complications are arising (e.g. prolonged ileus or infection). Bowel motions should be documented according to the Bristol Stool Chart and any abnormalities, e.g. blood or pale stools, should be escalated to the surgical team. If the patient has undergone abdominal surgery or if clinically appropriate, the surgical team should also be made aware of any evidence of return to GI motility so that food or enteral feeds can be recommenced if clinically indicated (see Chapter 5: Elimination).

Nutrition

Related theory

For normally nourished patients, the primary objective of post-operative care is restoration of normal GI function to allow adequate food and fluid intake and rapid recovery. Prolonged delays in oral feeding may compromise post-operative nutrition, which can lead to poor wound healing, susceptibility to infection and the need for nutritional support (Litkouhi 2013, SIGN 2012). Post-operatively, energy and protein requirements depend on body composition, clinical status and mobility. Surgery places the body under extraordinary stressors (hypo/hypervolaemia, bacteraemia, medications) and wound healing requires the intake of appropriate vitamins (A, C, zinc) and adequate calories from protein (see Chapter 7: Nutrition, fluid balance and blood transfusion).

Evidence-based approaches

Principles of care

Surgery may exert a detrimental effect on appetite and the ability to maintain adequate nutritional intake post-operatively. Causative factors include the surgery itself; post-operative nausea and vomiting; anorexia; altered bowel movements (constipation, ileus, diarrhoea); medication; oral candida; sore mouth; dysphagia and/or early satiety.

Unless contraindicated by the surgery performed (e.g. major abdominal or head and neck surgery) or the patient's current clinical status (e.g. risk of pulmonary aspiration, vomiting and/or ileus), the majority of patients will be able to meet their nutritional requirements orally in the post-operative period. If clinically indicated, any food or drink taken by the patient should be accurately recorded (volume and type of food) on a food chart and fluid balance chart. It is essential that appropriately trained healthcare professionals undertake ongoing oral and nutritional screening assessments in accordance with local trust policy, put preventive measures in place (e.g. good oral hygiene, offering appetising food and drink, provide assistance with eating and drinking) and alert the dietician/surgeon when there is cause for concern (see Chapter 7: Nutrition, fluid balance and blood transfusion). Any patient unable to meet their nutritional requirements orally will require referral to a dietician who will assess the patient's nutritional requirements and tailor any nutritional replacement (oral, e.g. nutritional supplements, enteral or parenteral) to their needs.

Post-operative nutritional support has potentially serious complications (NICE 2006). Enteral nutrition uses the

physiological route of nutrient intake, is cheaper and is generally safer, and should be the preferred method of nutritional support, in the presence of a functioning gastrointestinal tract (SIGN 2012). Types of enteral feed tubes include nasogastric, nasoduodenal, nasojejunal, gastrostomy or jejunostomy (see Chapter 7: Nutrition, fluid balance and blood transfusion). Whilst enteral feeding is the preferred route of nutritional support (NCCAC and NICE 2006), parenteral nutrition may be indicated for some post-operative patients who have undergone major abdominal surgery or those with prolonged ileus, uncontrolled vomiting or diarrhoea, short bowel syndrome or gastrointestinal obstruction.

Legal and professional issues

In the fourth Nutrition Screening Week survey (spring 2011), undertaken by the British Association for Parenteral and Enteral Nutrition (BAPEN 2012), malnutrition was found to affect one in four adults on admission to hospitals. The survey found that nutritional screening policies and practice vary between and within healthcare settings, and so malnutrition continues to be under-recognized and undertreated (BAPEN 2012). It is therefore essential that screening and ongoing assessment of nutritional screening are undertaken by healthcare professionals with the appropriate skills and training.

The Francis Report (Francis 2013) highlights that nutrition and hydration are still not being recognized as an essential part of an individual's recovery from illness in hospital. In line with the Francis Report, it is essential that the environment is conducive to enabling patients to eat. This encompasses the implementation of protected mealtimes, assistance to eat and drink (including provision of eating aids), provision of regular snacks and maintenance of oral hygiene (Box 13.15).

Post-operative pain

Effective management of pain following surgery requires that information about the patient's goals for pain relief, previous history with analgesics, and type of surgical procedure is used to guide decisions about analgesic regimens (Bell and Duffy 2009, Layzell 2008). It is imperative that the patient's pain is managed well, initially by the anaesthetist and then the ward staff and pain team to ensure that the patient has adequate analgesia but is alert enough to be able to communicate and co-operate with staff (Liddle 2013). Analgesics are selected based on the location of surgery, degree of anticipated pain and patient characteristics, such as co-morbidities, and routes of administration and dosing schedules are determined to maximize the effectiveness and safety of analgesia while minimizing the potential for adverse events (Layzell 2008).

Pain management can be delivered using the following routes: oral, rectal, epidural, intravenous, including patient-controlled analgesia (PCA) and opioid continuous infusion (Liddle 2013). A pain tool, e.g. verbal numeric rating score, should be used to assess the effectiveness of prescribed analgesia and action taken if the patient's pain is not controlled. See Chapter 8: Patient comfort and end-of-life care for further information concerning effective management of pain following surgery, including assessment tools.

Immobility

Related theory

Post-operatively, patients are at increased risk of developing deep vein thrombosis (DVT) as a result of muscular inactivity, post-operative respiratory and circulatory depression, abdominal and pelvic surgery, prolonged pressure on calves (e.g. from lithotomy poles), increased production of thromboplastin as a result of surgical trauma and pre-existing coronary artery disease (Rashid et al. 2005). To prevent this complication, many patients undergoing surgery will be treated with anticoagulants, for example low molecular weight heparin subcutaneous injections

Box 13.15 Francis Report recommendations for nutrition

- Food and drink that are, as far as possible, palatable to patients must be made available and delivered to them at a time and in a form they are able to consume.
- Food and drink should, where possible, be delivered to patients in containers and with utensils which enable them to feed themselves, taking account of any physical incapacity.
- Systems, such as specially marked trays or jugs or other prompts, should be employed to remind staff of those patients who need assistance with eating and drinking.
- It is essential that appropriate assistance is made available to patients needing it as and when necessary to consume food or drink.
- No meal or drink should ever be left out of reach of patients able to feed themselves.
- Where patients have not eaten or drunk what is provided at mealtimes this must be noted and the reasons established. Steps should also be taken to remedy the deficit in nutrition and hydration.
- Proper records should be kept of the food and drink supplied to and consumed by elderly patients or as clinically indicated.
- Time for meals should be protected in the daily schedule, but if it is necessary for therapeutic reasons to interrupt mealtimes for a patient, alternatives should be made available.
- For patients capable of eating out of bed, where possible, facilities should be made available on the ward for them to eat at tables.
- Mealtimes should be considered as an opportunity for non-intrusive forms of observation and interaction where this is desirable and appropriate.
- Patients' supporters should not be prevented from joining them at mealtimes provided that this does not interfere with the preservation of appropriate levels of nutrition and hydration or with other patients on the ward, and should be encouraged to help with feeding where this is needed and they wish to provide such help.
- Feedback should be regularly obtained (preferably in real time) from patients, supporters and volunteer helpers on the quality of food and drink and about any necessary adjustments required for individual patients.

or a continuous heparin infusion if the patient was previously anticoagulated (NICE 2010) (see Pre-operative section: Antiembolic stockings and prophylactic anticoagulation for information relating to DVTs and their prevention). Unless contraindicated, patients will also be wearing antiembolic stockings. Stockings should only be removed for up to 30 minutes daily; however, they can be removed more frequently if clinically indicated, e.g. patient complains of pain or discomfort. Patients should be supported to provide daily skin hygiene by careful washing and application of an emollient cream if the skin is dry. Appropriately trained healthcare professionals should also undertake a daily assessment of the following:

- the fit of the stocking – checking for any change in leg circumference
- consideration of abnormalities or complications of antiembolic stockings, e.g. any discoloration, numbness or tingling, swelling or coldness of the toes/feet; pressure sores; circulation difficulties (e.g. arterial occlusion, thrombosis, gangrene), which can be linked to the tourniquet effect of bunched-up stockings

combined with swelling of the leg (House of Commons Health Committee 2005, SIGN 2012).

If the stocking no longer fits, i.e. painful/uncomfortable, loose or tight, there are circulation difficulties or skin damage, remeasure and replace with the correct size of stockings if appropriate, ensuring that they fit smoothly with no wrinkles (see Procedure guideline 13.1: Step-by-step guide to measuring and applying antiembolic stockings).

Post-operative instructions should describe any special positioning of the patient. Where a patient's condition allows, early mobilization (wearing non-slip slippers or shoes to prevent falls) is encouraged to reduce venous stasis unless otherwise contraindicated. For patients on bedrest, a physiotherapist should provide the patient with verbal and written information about deep breathing and leg exercises (flexion/extension and rotation of the ankles). Furthermore, patients on bedrest should be encouraged to change position hourly to minimize atelectasis and circumvent the development of pressure sores (Terrence and Serginson 2000). Patients on bedrest may also have intermittent pneumatic compression or foot impulse devices in addition to graduated compression/antiembolic stockings whilst in hospital (NICE 2010).

Ongoing care on discharge

Related theory

All patients, whether day case, short or long stay, those with few needs or those with complex needs, should receive comprehensive discharge planning. Post-operatively, discharge planning needs to be tailored to the individual needs of the patient, particularly in relation to advice and information on recovery and self-management (DH 2004) (see Chapter 2: Assessment and discharge).

The increase in same-day surgical admissions combined with shorter hospital stays means that more post-operative recovery, including wound healing, takes place at home. This means that where appropriate, patients need to have assimilated the knowledge of usual post-operative outcomes and management with the ability to recognize when professional intervention and/or advice are required.

Surgery can be physically and psychologically stressful, resulting in patients forgetting pre-operative information/teaching (Mitchell 2005). Nurses therefore need to reinforce pre-operative education post-operatively, ensuring that information and discussions are tailored to the patient's individual needs, taking into account their level of anxiety and distress (Mitchell 2005). Ongoing assessment of the patient's understanding of the information given should be carried out and documented. Nurses should teach the patient and carers any necessary skills (including how to use equipment), allowing sufficient time to practise before discharge. This will enable the patient to be as independent as possible post-operatively and promote an understanding of any self-care initiatives required on discharge. This should be supported with centralized evidence-based written information concerning post-discharge care at home.

- 14.13** Arterial cannula: removal 923

Overview

This chapter provides an overview of vascular access devices inserted in a vein or an artery. The variety of common devices used for both peripheral and central access will be described along with their insertion, care and removal. The taking of blood samples is covered in Chapter 10: Interpreting diagnostic tests.

Vascular access devices

Definition

A vascular access device (VAD) is a device that is inserted into either a vein or an artery, via the peripheral or central vessels, to provide for either diagnostic (blood sampling, central venous pressure [CVP] reading) or therapeutic (administration of medications, fluids and/or blood products) purposes. There is now a comprehensive range of VADs available which allow for selection based on the device, therapy and the quality-of-life needs of the patient (RCN 2010). Table 14.1 lists the main types of VADs.

Anatomy and physiology

862

Anatomy of veins

Veins consist of three layers.

Tunica intima

The tunica intima is a smooth endothelial lining, which allows the passage of blood cells (Jenkins and Tortora 2013). If it becomes damaged, the lining may become roughened and there is an increased risk of thrombus formation (Hadaway 2010, Scales 2008). Within this layer are thin folds of endothelium called valves (flap-like cusps), which keep blood moving towards the heart by preventing backflow (Jenkins and Tortora 2013). Valves are present in larger vessels and at points of branching and are present as noticeable bulges in the veins (Weinstein and Plumer 2007).

Tunica media

The middle layer of the vein wall is composed of muscular tissue and nerve fibres, both vasoconstrictors and vasodilators, which can stimulate the vein to contract or relax. This layer is not as strong or stiff as in an artery and therefore veins can distend or collapse as the pressure rises or falls (Jenkins and Tortora 2013). Stimulation of this layer by a change in temperature (cold), mechanical or chemical stimulus can produce venous spasm, which can make insertion of a needle more difficult.

Tunica adventitia/externa

The tunica adventitia is the outer layer and consists of connective tissue, which surrounds and supports the vessel (Tortora and Derrickson 2011).

Table 14.1 Vascular access devices

Type of device	Material	Features	Common insertion site (veins)	Recommended indwelling life and common uses
Peripheral cannula	Teflon Vialon	Winged	Cephalic	Removed when clinically indicated for short-term access
		Non-winged	Basilic	
		Non-ported Ported	Dorsal venous network	
Midline catheter	Silicone	Single lumen	Basilic	Used for 1–6 weeks or longer for short- to intermediate-term access
	Polyurethane	Dual lumen	Median cubital Cephalic	
Peripherally inserted central catheter	Polyurethane Silicone	Dual lumen	Antecubital fossa	Used primarily for patients requiring several weeks or months of intravenous access
		Single lumen	Basilic	
		Valved	Cephalic	
			Brachial	
Short-term percutaneous central venous catheter (non-tunnelled)	Polyurethane	Heparin, antibiotic and antiseptic coatings, multiple lumen	Jugular	Intended for days to weeks of intravenous access
	Silicone		Subclavian	
			Femoral	
Skin-tunnelled catheter	Polyurethane	Valved	Jugular	Indefinite. Used for long-term intermittent, continuous or daily intravenous access. May be appropriate for short-term use if reliable access needed
	Silicone	Antimicrobial/ silver cuff	Axillary	
		Multiple lumen	Subclavian	
			Femoral	
Implanted ports	Catheter	Dual ports	Antecubital fossa	Indefinite. Used for long-term access
	Silicone	Peripheral ports	Subclavian	Intermittent, continuous or daily intravenous access
		Valved	Femoral	
		Low profile		
		Computed tomography compatible		
	Port			
	Titanium			
	Plastic			

Anatomy of arteries

By contrast, arteries tend to be placed more deeply than veins and can be distinguished by the thicker walls, which do not collapse, the presence of a pulse and bright red blood. It should be noted that aberrant arteries may be present. These are arteries that are located superficially in an unusual place (Jenkins and Tortora 2013).

There are two main types of arteries – muscular and elastic – and they are composed of three layers:

- the tunica intima has elongated endothelial cells
- the tunica media in the elastic artery is thicker with more elastic and fibrous tissue arranged in circular bands while the muscular artery is a large mass of smooth muscle fibres controlling constriction and relaxation
- the tunica adventitia contains both collagen and elastic fibres, nerve bundles and lymphatic vessels (Tortora and Derrickson 2011).

Veins of the peripheral circulation

The superficial veins of the upper limb are most commonly chosen for cannulation and insertion of midlines and peripherally inserted central catheters (PICCs). These veins are numerous and accessible, ensuring that the procedure can be performed safely and with minimum discomfort (Ernst 2005).

- The cephalic vein. (Figure 14.1a,c)
- The basilic vein. (Figure 14.1a,c)
- The metacarpal veins (used only when the others are not accessible) (Figure 14.1b).

On the lateral aspect of the wrist, the cephalic vein rises from the lateral aspect of the dorsal venous network of the hand and flows upwards along the radial border of the forearm as the median cephalic, crossing the antecubital fossa as the median cubital vein (Jenkins and Tortora 2013). Care must be taken to avoid accidental arterial puncture, as this vein crosses the brachial artery (Jenkins and Tortora 2013). It is also in close proximity to the radial nerve (Dougherty 2008, Masoorli 2007).

The basilic vein begins on the medial aspect of the dorsal venous network of the hand and ascends the forearm and ante-medial surface of the arm (Jenkins and Tortora 2013). It may be prominent but is not well supported by subcutaneous tissue, making it roll easily. Owing to its position, a haematoma may occur if the patient flexes the arm on removal of the needle, as this squeezes blood from the vein into the surrounding tissues (McCall and Tankersley 2012, Weinstein and Plumer 2007). Care must also be taken to avoid accidental puncture of the median nerve and brachial artery (Garza and Becan-McBride 2013).

The metacarpal veins are easily visualized and palpated. However, the use of these veins is contraindicated in the elderly where skin turgor and subcutaneous tissue are diminished (Weinstein and Plumer 2007).

Veins of the central venous circulation

A central vein is one near the centre of the circulation, the heart (Chantler 2009). Those more commonly used for central venous catheterization are the internal jugular, subclavian and femoral veins (Figure 14.2). The internal jugular vein emerges from the skull through the jugular foramen and runs down the neck into the carotid sheath (Farrow et al. 2009, Tortora and Derrickson 2011). The axillary vein is a continuation of the basilic vein. From the lateral edge of the ribs to the sternal edge of the clavicle, the continuation of the axillary becomes the subclavian. It angles upwards as it arches over the first rib and passes under the clavicle, forming a narrow passage for the vein (Galloway and Bodenham 2004, Galloway and Bodenham 2009, Hadaway 2010). Here it joins the internal jugular vein to form the brachiocephalic vein behind the sternoclavicular joint. The left brachiocephalic

Figure 14.1 (a) Superficial veins of the forearm. (b) Superficial veins of the dorsal aspect of the hand. (c) Central veins and veins of the upper arm.

vein is 6 cm in length, twice as long as the right (Hadaway 2010, Jenkins and Tortora 2013).

The superior vena cava (SVC) drains venous blood from the upper half of the body and is formed from the confluence of the two brachiocephalic (innominate) veins (2 cm wide) (Farrow et al. 2009). The SVC is 7 cm long in normal adults and descends vertically to the upper part of the right atrium of the heart (Farrow et al. 2009).

The femoral vein drains the majority of blood from the lower limb and enters the thigh as a continuation of the popliteal vein. It ascends through the thigh and becomes the external iliac vein

and drains into the inferior vena cava. The inferior vena cava drains the lower half of the body and is formed by the two common iliac veins (Jenkins and Tortora 2013).

Evidence-based approaches

Rationale

Indications

- To obtain venous and arterial blood samples.
- To administer fluids, nutrition, medication or blood products.
- To monitor central venous pressure and arterial pressure.

Contraindications

There are no specific contraindications for inserting a vascular access device but there may be contraindications for location of the device and the type of medication that can be administered (very few can be administered via an artery).

Principles of care

Regardless of the type of VAD used, the principles of care for the device remain the same.

- To prevent infection.
- To maintain a 'closed' intravenous system with minimal connections to reduce the risk of contamination.
- To prevent damage to the device and associated intravenous equipment.
- To maintain a patent and correctly positioned device.

Each of these principles will be discussed generally and then in more detail under each type of access device.

Methods for prevention of infection at insertion site

Aseptic technique and compliance with recommendations for equipment and dressing changes are essential if microbial contamination is to be prevented (INS 2011, Loveday et al. 2014,

O'Grady et al. 2011, RCN 2010) (see Chapter 3: Infection prevention and control). Whenever the insertion site is exposed or the intravenous system is broken, aseptic technique should be practised. Where blood or body fluids may be present, gloves should be worn to comply with safe practice (Rowley 2001). It is not necessary to wear sterile gloves when accessing a central venous access device – clean gloves are adequate (Hemsworth et al. 2007).

Cleaning solutions

Most transient flora can be removed from the skin with soap and water using mechanical friction. It is also important to remove dirt as antiseptic solutions are not as effective as they cannot penetrate surface dirt (McGoldrick 2010). Use of a chlorhexidine bath/shower prior to insertion of a central venous catheter has been shown to reduce infection (Lopez 2011, Montecalvo et al. 2012). Chlorhexidine 2% in 70% alcohol has been shown to be the most effective agent for skin cleaning around the VAD insertion site prior to insertion and between dressing changes (Cobbett and LeBlanc 2000, DH 2010, Kim and Lam 2008, Maki et al. 1991, O'Grady et al. 2011, Nishihara et al. 2012, Soothill et al. 2009, Timsit et al. 2012). Seventy percent alcohol acts by denaturing protein and so has excellent properties for destruction of gram-positive and -negative bacteria, as well as being active against fungi and viral organisms. Alcohol concentration between 70% and 92% provides the most rapid and greatest reduction in microbial counts on skin but does not have any residual activity (Larson 1988). This is where chlorhexidine has an advantage over alcohol used alone, as it has excellent residual activity for 4–6 hours after application (Loveday et al. 2014, Nishihara et al. 2012). It is important to be aware of patient sensitivity to chlorhexidine gluconate (Loveday et al. 2014, MHRA 2012), both in cleaning solutions and within coatings of CVADs.

Solutions should be applied with friction in back-and-forth strokes for at least 30 seconds and allowed to air dry for 30–60 seconds (DH 2010, INS 2011, McGoldrick 2010, Scales 2009). It has been found that 1 minute of application with alcohol is as effective as 12 minutes of scrubbing and reduces bacterial counts by 75%. However, a quick wipe fails to reduce bacterial counts prior to peripheral cannulation (INS 2011, Weinstein and Plumer 2007). Allowing any cleaning solution to dry is vital in order for disinfection to be completed and, in the case of alcohol, which is a plasticizer, it ensures that plastic equipment will not 'glue together' (Dougherty 2006).

Inspection of insertion site and cleaning of equipment

Cleaning solutions should be used not only on insertion sites but also to clean junctions and connections, and so on. It is recommended that injection caps should be cleaned vigorously with appropriate cleaning agents such as chlorhexidine 2% in alcohol (Brown et al. 1997, DH 2010, Loveday et al. 2014, NICE 2012, Wright et al. 2013). The frequency of cleaning the insertion site is debatable; peripheral sites are rarely cleaned once the device is sited because the device is *in situ* for such a short period of time. However, central venous access sites, for example PICCs, may be cleaned weekly (at dressing change) and short-term central venous catheters (CVCs) may be cleaned daily or more frequently (being associated with the highest infection risk). The insertion site should be checked regularly for signs of phlebitis (erythema, pain and/or swelling) or infection (DH 2003). Complaints of soreness, unexpected pyrexia and damaged, wet or soiled dressings are reasons for immediate inspection and renewal of the dressing.

Securement and dressings

There are a number of securement devices and dressings available. The aim of a securement device is to secure the device to the skin and prevent movement of the device which in turn will reduce the risk of mechanical phlebitis and infection. They also prevent dislodgement. Types of securement include tape, sutures and self-adhesive anchoring devices applied to the skin, such as Statlocks

(Moureau and Iannucci 2003) and anchor devices that are placed just beneath the skin at the insertion site, e.g. SecurAcath (Egan et al. 2013). Suturing can result in inflammation and bacterial colonization of the exit site (Schears 2005) and is no longer recommended (Maki 2002), particularly with PICCs (Nakazawa 2010b). Statlocks have been shown to result in significantly longer catheter times and fewer total complications (Schears 2005, Yamamoto et al. 2002) but adhesive devices can cause skin surface irritation.

Types of dressings include sterile gauze and transparent dressings. The recommendation for a central venous access device site is an intact dry adherent transparent semi-occlusive dressing (DH 2010, Loveday et al. 2014). These dressings allow observation of the exit site without the need to remove the dressing. They are also moisture permeable, thereby reducing the collection of moisture under the dressing (Casey and Elliott 2010).

Newer products include a chlorhexidine gluconate antimicrobial transparent dressing which contains a chlorhexidine gel pad which is integral to the dressing and has been shown to allow visualization of the site, facilitating absorption of fluid under the dressing (Moureau et al. 2009, Pfaff et al. 2012). It has been shown to prevent the regrowth of microbial skin flora (Maki 2008). This can also be achieved by attaching a hydrophilic polyurethane absorptive foam patch impregnated with CHG under the transparent dressing, which has been shown to reduce the rate of catheter colonization and demonstrated significant reductions in the associated rate of catheter-related bloodstream infection (Ho and Litton 2006, Ruschulte et al. 2009, Timsit et al. 2009). However, the foam patch does not enable insertion site visualization.

Methods for maintaining a closed intravenous system

If equipment becomes accidentally disconnected, air embolism or profuse blood loss may occur, depending on the condition and position of the patient (Perucca 2010). Accidental disconnection poses a greater risk in patients with central venous or arterial access devices than in those with peripheral venous devices. This is because of the amount of air that could be introduced via a CVAD and the speed with which it could enter the pulmonary vessels or the speed of haemorrhage. Luer-Lok provides a more secure connection and all equipment should have these fittings, that is, administration sets, extension sets, injection caps (Dougherty 2006). Needle-free systems provide a closed environment, which further reduces the risk of air entry (Dougherty 2006). Care should be taken to clamp the catheter firmly when changing equipment. Connections must be double checked and precautions taken to prevent the introduction of air into the system when making additions to, or taking blood from, a CVC (Dougherty 2006).

Methods for preventing damage of the VAD and performing a repair

If damage occurs to peripheral devices, they are usually removed and replaced. Catheters are made of non-resealable material so penetration by a needle creates holes and they can rupture if excessive force is exerted (Gorski et al. 2010). Pinch-off syndrome can also result in a transected and potentially embolized catheter segment (Gorski et al. 2010). Temporary and permanent repairs can be performed depending on where the catheter is damaged and the type of catheter (Dougherty 2006). However, prevention of this occurrence is preferred.

Artery forceps or sharp-edged clamps should not be used to clamp the catheter. A smooth clamp should be placed on the reinforced section of the catheter provided for clamping (Dougherty 2006). If a reinforced section is not present, placing a tape tab over part of the catheter can create one. A second alternative is to move the clamp up or down the catheter at regular intervals to reduce the risk of wear and tear in one place (Dougherty 2006).

Use of the correct syringe size in accordance with manufacturer's guidelines will reduce the risk of catheter rupture (INS 2011). However, syringe size alone will not be sufficient to prevent catheter rupture. If resistance is felt and more pressure is

applied to overcome it, catheter fracture could result regardless of the syringe size (Hadaway 1998a, Macklin 1999). The nurse must be familiar with the action to be taken to minimize any risk to patient safety in this event. Immediate clamping of the catheter proximal to the fracture or split is essential to prevent blood loss or air embolism (Gorski et al. 2010). The split area should be cleaned with an alcohol swab and covered with an occlusive transparent dressing until emergency repair equipment has been collected. The procedure must be done using an aseptic technique. The CVAD should be removed and replaced as soon as possible following the repair. The repair should only be undertaken by a healthcare professional who has the necessary knowledge and skills (Dougherty 2006).

Methods for maintaining patency

Patency is defined as the ability to infuse through and aspirate blood from a VAD (Dougherty 2006). It is important for the patency of the device to be maintained at all times. Blockage predisposes to device damage, infection, inconvenience to patients and disruption to drug delivery. Occlusion of the device is usually the result of:

- clot formation (Figure 14.3) due to: (a) an administration set or electronic infusion device being turned off accidentally and left for a prolonged period; or (b) insufficient or incorrect flushing of the device when not in use. Thrombotic occlusions are responsible for 58% of all occlusions (Hadaway 2010)
- precipitate formation due to inadequate flushing between incompatible medications (Dougherty 2006).

Kinking or pinch-off syndrome may also impair patency of the device. Meticulous intravenous technique will prevent the majority of these problems.

Figure 14.3 Clot formations. *Source:* Macklin and Chernecky (2004). Reproduced with permission from Elsevier.

Box 14.1 Advantages and disadvantages of intermittent flushing

The advantages of intermittent flushing compared with a continuous infusion are:

- it reduces the risk of circulatory overload
- it reduces the risk of vascular irritation
- it decreases the risk of bacterial contamination as it eliminates a continuous intravenous pathway
- it increases patient comfort and mobility
- it may reduce the cost of intravenous equipment (Phillips 2005).

One of the disadvantages is the necessity for constant vigilance and regular flushing (Weinstein and Plumer 2007).

Two main types of solutions are used to maintain patency in VADs: heparin and 0.9% sodium chloride. All devices should be flushed with 10–20 mL 0.9% sodium chloride after blood withdrawal followed by the appropriate flushing solution (Dougherty 2006, Dougherty 2008, INS 2011, RCN 2010).

Maintaining patency can be achieved by:

- 866
- a continuous infusion to keep the vein open (KVO), either by the patient being attached to an infusion of 0.9% sodium chloride via a volumetric pump, which reduces comfort and mobility, or by use of an elastomeric device, which is less restrictive and has been able to reduce loss of patency by 50% (Heath and Jones 2001), or
 - intermittent flushing (previously known as a 'heparin lock'). See Box 14.1.

When used for intermittent therapy, the device should be flushed after each use with the appropriate flushing solution. (Guidelines for volumes, concentrations and frequency of flushing are commonly established within individual institutions.) It is now well established that flushing with 0.9% sodium chloride can also adequately maintain the patency of the cannula (Goode et al. 1991, White et al. 2011). This avoids side-effects such as local tissue damage, drug incompatibilities and iatrogenic haemorrhage, which can occur with heparin (Goode et al. 1991). As well as being cost-effective, it appears that daily or twice-daily flushing with a volume of 2–5 mL 0.9% sodium chloride is acceptable (Goode et al. 1991).

There is still no consensus about the solution to use or frequency of flushing in CVADs (Green et al. 2008, Mitchell et al. 2009, Sona et al. 2011) and it also depends on whether the catheter is either valved or non-valved. Heparinized saline is still the accepted solution for maintaining the patency of CVCs for intermittent use or infrequent use (RCN 2010), but due to the risk of errors with heparin, its use must be considered carefully (NPSA 2008a). Use of 0.9% sodium chloride alone is widespread with certain CVADs, e.g. PICCs (INS 2011, Loveday et al. 2014). Flushing regimens, ranging from once daily to once weekly, have been found to be effective. Implanted drug delivery systems such as implanted ports are flushed using a stronger solution of heparin, usually 500 international units heparin in 5 mL 0.9% sodium chloride (Berreth 2013a, Perucca 2010). Recommendations range from monthly (RCN 2010), every 6 weeks (Kefeli et al. 2009) or every 8 weeks (Hoffman 2001) to every 3–4 months when not in use (Kuo et al. 2005, Vescia et al. 2008).

Using the correct techniques to flush the VAD has been highlighted as one of the key issues in maintaining patency (Baranowski 1993, Goodwin and Carlson 1993). There are two stages in flushing.

- 1 Using a pulsated (push-pause) flush to create turbulent flow when administering the solution, regardless of type and volume. This removes debris from the internal catheter wall (Cummings-Winfield and Mushani Kanji 2008, Goodwin and Carlson 1993).

- 2 The procedure is completed using the positive pressure technique. This is accomplished by maintaining pressure on the plunger of the syringe while disconnecting the syringe from the injection cap, which prevents reflux of blood into the tip, reducing the risk of occlusion (Berreth 2013a, Hadaway 2010, INS 2011).

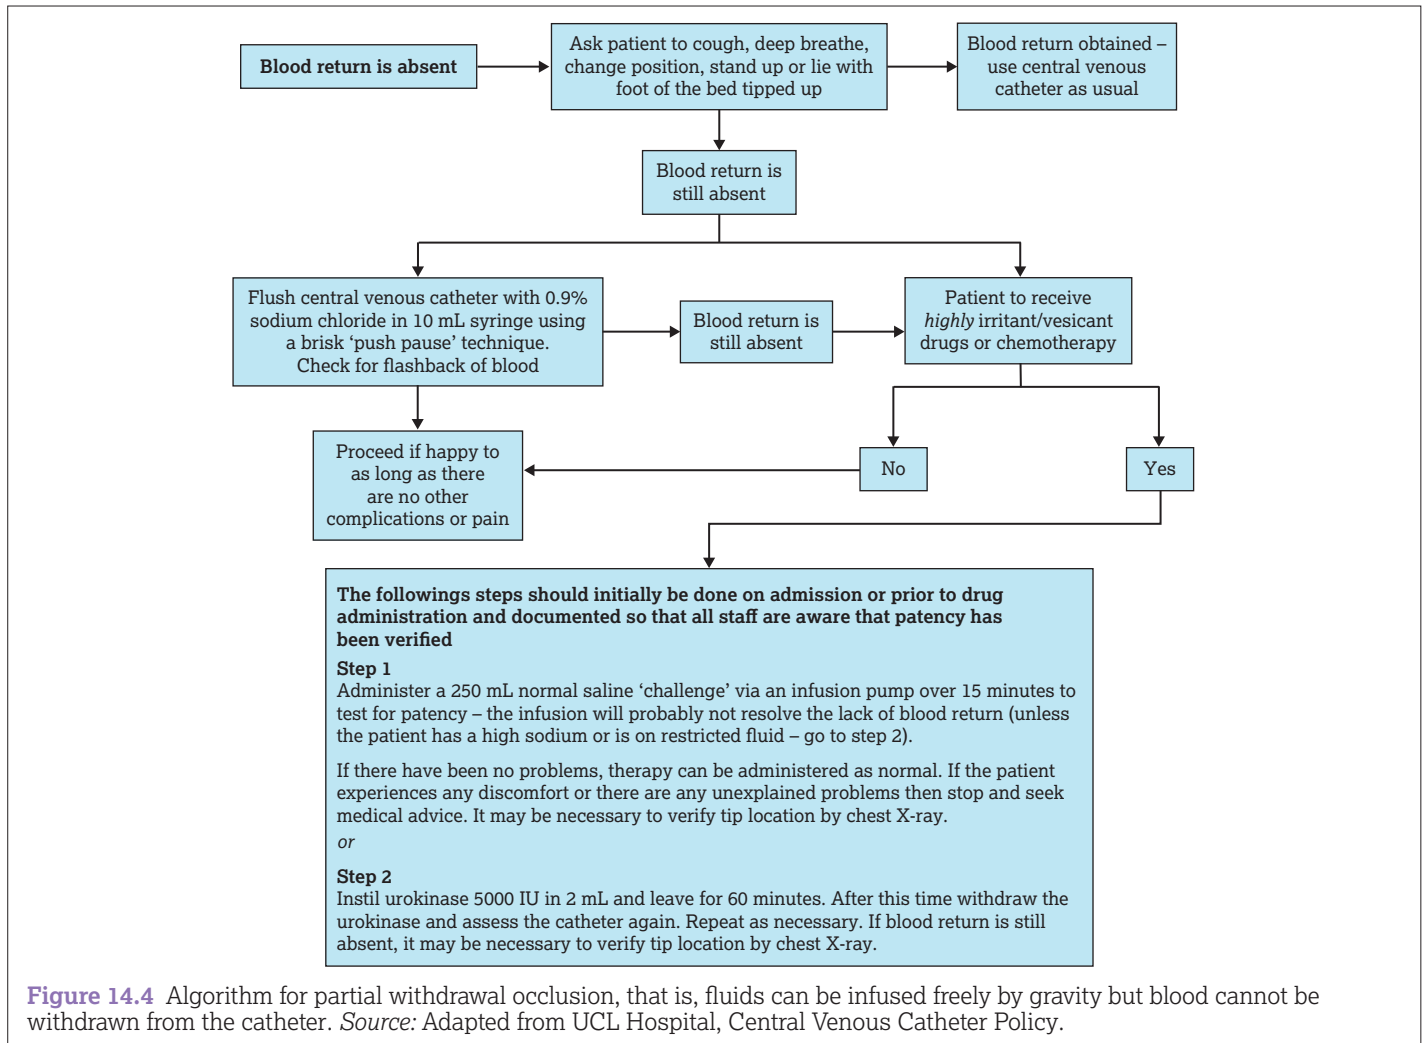

Manufacturers have now produced needleless injection caps which aim to reduce occlusions and infection (Btaiche et al. 2011, Chernecky and Walker 2011, Hadaway 2012, Macklin 2010a). Some enable a positive 'displacement' flush and achieve positive pressure without practitioners being required to actively achieve the positive pressure (Weinstein and Plumer 2007). They have been shown to significantly reduce the incidence of catheter occlusions (Berger 2000, Lenhart 2000, Mayo 2001, Rummel et al. 2001) but there has been controversy about these devices and their associated risk of bloodstream infections, resulting in recommendations to carry out a risk assessment prior to routine use (Hadaway 2010). Negative pressure devices require positive pressure on the syringe. Neutral displacement connectors are not dependent upon flushing technique and can be clamped before or after syringe disconnection (Chernecky et al. 2009).

Excessive force should never be used when flushing devices. When a catheter lumen is totally patent, internal pressure will not increase during flushing (Hadaway 1998b). However, if resistance is felt (due to partial occlusion) and a force is applied to the plunger, particularly with a small-volume syringe, high pressure could result within the catheter, which may then rupture (Conn 1993, Gorski et al. 2010, Hadaway 1998b, Macklin 1999). It is therefore recommended that the device is checked first with a 10 mL or larger syringe containing 0.9% sodium chloride (Hadaway 1998b, Macklin 2010b, RCN 2010). However, smaller syringes should only be used to administer drugs where there is no pressure or occlusion and where it is not possible to further dilute drugs and administer in a large syringe (Hadaway 1998a, Macklin 1999). The composition of the individual device determines the maximum pressure that can be exerted. There are now CVADs available (PICCs and ports) that allow computed tomography (CT) contrast to be administered via a pressure injection pump at 3–5 mL/sec without damaging the device.

If a catheter becomes occluded, the nurse should establish the cause of the clot: occlusion or precipitation (INS 2011). If precipitation occurs, then instillation of hydrochloric acid or ethyl chloride may be required (Doellman 2011, Hadaway 2010). There are two types of thrombotic occlusion.

- *Partial withdrawal occlusion (PWO)* (Figure 14.4): this is usually caused by fibrin sheath formation and identified by absent or sluggish blood return whilst fluids can be infused (Nakazawa 2010). Fibrin sheaths can result in seeding of bacteria and drug extravasation (Mayo 2000, Mayo 2001) and can be resolved by the instillation of a thrombolytic agent such as urokinase or alteplase (Dougherty 2006, Fanikos et al. 2009, Haire and Herbst 2000, Weinstein and Plumer 2007).
- *Total occlusion*: when there is an inability to withdraw blood or infuse fluids or medications. This can be resolved by instillation of a thrombolytic agent (Baskin et al. 2009, Baskin et al. 2012, Deitcher et al. 2002, Ponc et al. 2001, Syner Kinase 2011, Timoney et al. 2002).

If the occlusion is caused by a clot, gentle pressure and aspiration may be sufficient to dislodge it. Silicone catheters expand on pressure and allow fluid to flow around the clot, facilitating its dislodgement. This should only be attempted using a 10 mL or larger syringe. Smaller syringes should never be used as they create a greater pressure (Camp-Sorrell et al. 2004, Gorski et al. 2010) of mmHg or pounds per square inch (psi). This can result in rupture of the catheter, leading to loss of catheter integrity (Gorski et al. 2010). Clearance of a catheter occlusion and instillation of thrombolytic agents should be performed using a three-way

tap and negative pressure (Gabriel 2008, Gallieni et al. 2008, McKnight 2004). The establishment of negative pressure means creating a vacuum by aspiration of the air or dead space within a catheter (Dougherty 2006, Gabriel 2008, Moureau et al. 1999). Another method is use of the percussion technique (Stewart 2001; Johnston 2007). Unblocking a catheter is not a quick procedure and it can take up to 30 minutes or longer to achieve success.

Methods of maintaining a correctly positioned catheter tip

A CVAD is defined as a catheter whose tip terminates in the lower third of the SVC (INS 2011, RCN 2010, Wilkes 2011). However, tip location is a subject of debate although there are some common recommendations (Chantler 2009).

- The vein should be large with a high blood flow (this dilutes drugs and reduces the risk of damage of the vein intima).
- The end of the catheter should be in the long axis of the vein and not abutting the vessel wall (to reduce damage to the intima and inaccurate pressure readings).
- The tip should be beyond the last venous valve.

The tip location of a CVAD will affect the catheter performance – if the tip is too high, it may be sucked against the adjacent wall when aspiration is applied or if the tip is too far within the right atrium (RA) (Vesely 2002, Vesely 2003) and this increases the risk of thrombosis (Gallieni et al. 2008). A catheter tip positioned against a vascular wall may also become a source of persistent

irritation, leading to the possible creation of a potential nidus for thrombus formation (Galloway and Bodenham 2004, Mayo 2001). This is reported more frequently in patients who have left-sided placements (Chantler 2009). The arguments for right atrial tip placement are that the tip is in a large chamber, thus preventing contact with the vein wall, and the rapid blood flow also prevents accumulation of thrombin and minimizes irritation of substances. The disadvantages of this tip position are an increase in cardiac arrhythmias (although this may be associated with the insertion of the guidewire as it is reduced by image guidance) and catheter-induced perforation and cardiac tamponade although this has been reduced by using softer materials and imaging guidance (Chantler 2009, Vesely 2002).

The tip position can also change during its time *in situ*. The final position of a PICC is dependent on the insertion site and the position of the patient's arm and the catheter can move at least 2 cm further into the RA on movement (Forauer and Alonzo 2000). If placed in the left arm, it can move more than if in the right arm and when placed in the basilic more than if in the cephalic vein (Vesely 2003). Anatomical changes occur with subclavian and internal jugular insertion when the patient sits upright following insertion and the catheter tip can move upward. In a skin-tunnelled catheter this can be 2–3 cm, particularly in overweight patients of either sex or female patients with substantial breast tissue. Large-diameter catheters can move more than smaller ones and subclavian more than internal jugular placements.

A correctly placed catheter tip will probably be one that undergoes a range of movement between the SVC and upper RA

Figure 14.5 Chest X-ray showing catheter tip correctly positioned (arrow).

(Dougherty 2006). The direction of the catheter can be tracked with electromagnetic navigation devices and this prevents malposition (Le Greca 2014). Tip position is determined by:

- taking a chest X-ray using the posterior anterior (PA) view (Wise et al. 2001) (Figure 14.5)
- using ECG technology – this has been shown to provide accurate consistent guidance of the tip to the lower third of SVC. It saves time interpreting an X-ray and the cost of the X-ray, reduces patient exposure to radiation and saves time repositioning the tip/catheter (Moureau et al. 2010, Pittiruti et al. 2012) (Figure 14.6).

Anticipated patient outcomes

For the patient to have a functioning vascular access device.

Legal and professional issues

Competencies

The nurse inserting devices and/or providing infusion therapy should be competent in all clinical aspects of infusion therapy and have validated competency in clinical judgement and practice, in accordance with the NMC *Code* to maintain their knowledge and skills (Collins et al. 2006, Hyde 2008, RCN 2010, NMC 2015).

The RCN (2010) recommends that any Registered Nurses undertaking the insertion of VADs or those who manage VADs or administer infusion therapy should have undergone

theoretical and practical training in a number of areas (Box 14.2) (Corrigan 2010, DH 2004, Hyde 2010, Loveday et al. 2014, MDA 2003, NICE 2003, NPSA 2003, NPSA 2007). All staff have a professional obligation to maintain their knowledge and skills (NMC 2015). It is also the responsibility of the organization to support and provide staff with training and education. This may be in the form of study days, practical sessions using a mannequin and a role development workbook or simulation (Andreata et al. 2011, Collins et al. 2006, Kokotis 2014, Phillips et al. 2011).

Consent

Prior to insertion of a peripheral cannula, it is usual to obtain verbal consent from the patient (Hyde 2010). However, prior to

Box 14.2 Required knowledge and skills

Vascular access device insertion

- Anatomy and physiology of the circulatory system, in particular, the anatomy of the location in which the device is placed, including veins, arteries and nerves and the underlying tissue structures.
- Assessment of patients' vascular access needs, nature and duration of therapy and quality of life.
- Improving venous access, for example the use of pharmacological and non-pharmacological methods.
- Selection of veins and problems associated with venous access due to thrombosed, inflamed or fragile veins, the effects of ageing on veins, disease process, previous treatment, lymphoedema or presence of infection.
- Selection of device and other equipment.
- Infection control issues (hand washing, skin preparation).
- Pharmacological issues (use of local anaesthetics, management of anxious patients, management of haematoma, phlebitis).
- Patient's perspective on living with a vascular access device.
- Risk management in order to reduce the risk of blood spills and needlestick injury.
- Professional and legal aspects (consent, professional guidance, knowledge and skill maintenance and documentation).
- Performing the procedure.
- Prevention and management of complications during insertion (nerve injury, haematoma).
- Monitoring and care of the site (flushing, dressing, removal).
- Product evaluation.
- Patient information and education.
- Documentation.
- Specific training for insertion of vascular access devices in certain groups, for example neonates, children and oncology patients.

Administration of IV medication and care of VAD *in situ*

- Legal, professional and ethical issues.
- Anatomy and physiology.
- Fluid balance and blood administration.
- Mathematical calculations related to medications.
- Pharmacology and pharmaceuticals related to reconstitution and administration.
- Local and systemic complications.
- Infection control issues.
- Use of equipment, including infusion equipment.
- Drug administration.
- Risk management/health and safety.
- Care and management of vascular access devices.
- Infusion therapy in specialist areas covered separately (paediatrics, oncology, parenteral nutrition, transfusion therapy).

insertion of a CVAD, written consent should be obtained (unless required in an emergency) following an explanation of the procedure, the benefits, the alternatives and the possible complications and the percentage risk of each (these would include pneumothorax, malposition, haemorrhage, thrombosis and infection). This should be provided verbally and in written form (Hamilton 2009).

Pre-procedural considerations

Equipment

There are many different types of devices available made of a variety of materials and tip endings and specific equipment associated with VADs includes securing devices and dressings. These will be discussed in more detail in each individual section.

Securement (stabilization) of device and dressings

Devices are secured to prevent movement, which reduces the risk of phlebitis, infiltration, infection and migration (INS 2011, McGoldrick 2010, Moureau and Iannucci 2003, Schears 2005, Yamamoto et al. 2002). This can be achieved by suturing, taping or use of securing devices (Figure 14.7). These all require a dressing over them. The stabilization device should be used in a manner that does not interfere with the assessment and monitoring of the access site (McGoldrick 2010).

The choice of dressing is usually based upon what is most suitable for a particular VAD site or type of skin. An intravenous dressing is applied to minimize contamination of the insertion site and provide stability of the device (Dougherty 2006). Therefore the ideal intravenous dressing should:

- provide an effective barrier to bacteria
- allow the catheter to be securely fixed
- be sterile
- be easy to apply and remove
- be waterproof
- adhere well
- be comfortable for the patient (Finlay 2004).

There are two main types of dressing: dry, sterile, low-linting gauze and transparent dressings. A dry, sterile, low-linting dressing secured with the minimum of hypoallergenic tape is most suitable for patients with skin that is prone to allergy or is thin and tears easily, as transparent dressings can damage the skin if not removed correctly (3M Healthcare 2005).

Figure 14.7 SecurA cath securing device. Source: Reproduced with permission from Interrad Medical, Inc.

The benefits of transparent dressings are that they allow inspection of the insertion site while the dressing is *in situ* and therefore do not require removal; they are waterproof and many are also moisture permeable (McGoldrick 2010). This means that the dressing allows moisture vapour transmission, an important factor related to infection as collection of moisture enhances the proliferation of micro-organisms (Loveday et al. 2014, O'Grady et al. 2011).

When transparent dressings have been compared with sterile gauze, it has been shown that there is no significant difference (in peripheral devices) and that infection rates may have been reduced (in CVAD dressings) (DH 2010, Maki and Ringer 1987, RCN 2010). All CVAD dressings must be removed and replaced within 24 hours following insertion of the catheter (Dougherty 2006, RCN 2010, Ryder 2001). This is due to the bacterial colonization, 'biofilm', which occurs 6–18 hours following insertion (Ryder 2002). If gauze is used, it must be replaced when the dressing becomes damp, loosened or soiled or when inspection of the site is necessary (Loveday et al. 2014, RCN 2010). Transparent dressings should be changed every 7 days unless manufacturers recommend otherwise or the integrity is compromised, that is, when damp, loose or soiled (INS 2011, Loveday et al. 2014, RCN 2010). When the dressing is changed, the insertion site should be inspected for inflammation and/or discharge and the condition of the skin documented (DH 2010).

There are also chlorhexidine gluconate (CHG)-impregnated dressings (for example, protective disc impregnated with CHG or CHG gel integrated into the dressing) which may also be considered for placement at the catheter skin junction. This is done to protect the extraluminal pathway and eliminate or reduce the incidence of infection (McGoldrick 2010). Surgical glue (cyanoacrylate) or metallic powder can be applied to the site to reduce bleeding at the insertion site which may enable the dressing to be left in place for at least 7 days following insertion and reduce extraluminal contamination (Scoppettuolo et al. 2013).

Assessment and recording tools

Tools have been developed to facilitate venous assessment and venous access device assessment. For example, the Venous Assessment Tool (VAT) consists of a series of risk factors and characteristics that can be assessed to determine if cannulation will be easy, moderate or hard. The VAT score can then be used in the algorithm 'Deciding on Intravenous Access' or DIVA. This guide helps practitioners bring together the proposed therapy and the type of venous access in order to identify the most suitable VAD (Wells 2008). See Figure 14.8. The Vessel Health Preservation (VHP) system involves assessing for the right patient, the right device at the right time (Moureau et al. 2012, Trick 2011).

Pharmacological support

Solutions to maintain patency

Heparin inhibits the conversion of prothrombin to thrombin and fibrinogen to fibrin, thus inhibiting coagulation, and is therefore used to prevent the build-up of fibrin. The standard strength is 10 international units/mL up to a total of 5 mL (50 international units) for all CVADs with the exception of implanted ports where it is usual for the dose to be 100 international units/mL (500 IU total). Sodium chloride 0.9% is used to clean the internal diameter of the device of blood and drugs (Camp-Sorrell et al. 2004). Urokinase is a fibrinolytic agent indicated for the lysis of blood clots in venous catheters that are occluded by fibrin clots. Usually, 10,000 international units is dissolved in sterile saline and instilled into the catheter every 10 minutes over 30 minutes. The drug and any clots are then aspirated and the process can be repeated if necessary (Syner Kinase 2011).

Specific patient preparation

Education

Patients may be well informed about access devices from the media or via the internet. They may also have gained knowledge

1. Patient characteristics		5. Evidence of previous use		<ul style="list-style-type: none">• For each risk factor score either 0, 1 or 2.• 0 = risk factor not present.• 1 = risk factor present.• 2 = risk factor present and will complicate a cannulation attempt now.• Total points to give VAT score.• Follow action specified below.• Re-evaluate patient score at least every three days.
Needle phobia		Evidence of phlebitis		
Confusion		Evidence of infiltration or extravasation		
2. Limiting the number of available veins		Visible pin prick or needle marks		
Hemiplegia, spasticity of upper limb(s), for example post-cerebrovascular accident		Bruising from vasculature use		
Radical mastectomy		Dark, stained veins		
Arteriovenous fistula		Cord-like, hard veins		
3. Changes in skin integrity		6. Suitability of veins		
Skin graft versus host disease		Flow visible veins		
Tattoos, burns, scars, eczema, over veins		Flow palpable veins		
		Few straight veins		
4. Changes in tissue		Veins are mobile		
Oedema		Only short veins identifiable or multiple valves are palpable		
Obesity		7. History		
Cachexia		Previous peripheral chemotherapy		
Radiotherapy to the upper limb(s)		Previous multiple courses of intravenous (IV) antibiotics		
Dark skin		Previous peripheral vesicant chemotherapy

from friends or family experiences. Therefore, involving the patient in the decision-making process is vital (Dougherty 2006). Patient choice about the device or even the site of insertion, for example use of the non-dominant arm, results in better compliance with care of the device and monitoring of problems (Gabriel 2008). It also enables patients to cope better with the changes to their normal activities (Daniels 1995) and the impact on body image can be reduced by involving the individual in the choice and management of the device (Daniels 1995, Dougherty 2006).

Body image and a patient's lifestyle can be issues when living with a CVAD (Dougherty 2006). This is particularly true with an external catheter, which can be distressing and embarrassing for some patients (Hayden and Goodman 2005). It can result in restrictions to normal daily activities, for example bathing, or involvement in sporting activities such as swimming (Gabriel 2000, Molloy et al. 2008, Robbins et al. 2000); some of these can

be resolved by the use of an implanted device (Chernecky 2001, Johansson et al. 2009).

The following have been listed as ways in which a CVAD can affect body image.

- Physical presence and alteration of body appearance and invasion of body integrity.
- It influences the type of clothes that can be worn.
- It may interfere with physical expressions of closeness and sexuality (Daniels 1995).

The presence of a CVAD could also affect how others view the role function of the individual, particularly if the patient is attached to an infusion pump (Thompson et al. 1989). The psychological impact of an indwelling catheter on body image should not be overlooked, especially when patients are sexually active (Gabriel 2000, Oakley et al. 2000).

Procedure guideline 14.1 Central venous catheter: insertion site dressing change

This can be adapted to changing a peripheral cannula dressing but this is rarely changed and is usually removed along with the cannula.

Essential equipment

- Sterile dressing pack (containing sterile towel and low-linting gauze, sterile gloves)
- Alcohol-based handrub
- Alcohol-based skin cleaning preparation, 2% chlorhexidine in 70% alcohol
- Semi-permeable transparent dressing, sterile low-linting gauze or other appropriate dressing
- Hypoallergenic tape
- Pair of non-sterile gloves
- Apron

Optional equipment

- Securing device
- Bacteriological swab

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid verbal consent (NMC 2013, **C**).

Procedure

- 2 Perform the dressing using an aseptic technique.

To prevent infection (DH 2010, **C**). (For further information on asepsis, see Chapter 3: Infection prevention and control.)

- 3 Screen the bed. Assist the patient into a supine position, if possible.

To allow dust and airborne organisms to settle before the insertion site and the sterile field are exposed. **E**

- 4 Wash hands with bactericidal soap and water or bactericidal alcohol handrub.

To reduce the risk of cross-infection (DH 2010, **C**; Fraise and Bradley 2009, **E**).

- 5 Place all equipment required for the dressing on the bottom shelf of a clean dressing trolley.

To reduce the risk of cross-infection (DH 2010, **C**).

- 6 Take the trolley to the patient's bedside, disturbing the screens as little as possible.

To minimize airborne contamination (DH 2010, **C**).

- 7 Open the sterile dressing pack onto the top of the trolley.

To gain access to equipment. **E**

- 8 Attach an orange clinical waste bag to the side of the trolley below the level of the top shelf.

So that contaminated material is below the level of the sterile field (DH 2010, **C**).

- 9 Open the other sterile packs, tipping their contents gently onto the centre of the sterile field. Pour lotions into gallipots or into an indented plastic tray where required.

To reduce risk of contamination of contents. **E**

- 10 Wash hands with bactericidal alcohol handrub.

Hands may have become contaminated by handling the outer packs, and so on (DH 2010, **C**).

- 11 Place the sterile field under the patient's arm or on the chest.

To create a clean working area. **E**

- 12 Loosen the old dressing gently.

So that the dressing can be lifted off easily. **E**

- 13 Put on clean gloves.

To protect the nurse from any contact with the patient's blood. **E**

- 14 Using gloved hands, remove the old dressing and discard it. Remove tapes or securing device if loose or contaminated or due to be changed.

To remove old dressing without contaminating hands (DH 2010, **C**).

- 15 If the site is red or discharging, take a swab for bacteriological investigation.

For identification of pathogens. To select appropriate treatment (DH 2010, **C**).

- 16 Remove and dispose of gloves, clean hands and put on sterile gloves from pack.

To minimize the risk of introducing infection (DH 2010, **C**).

- 17 Clean the wound with 2% chlorhexidine in 70% alcohol, using back-and-forth strokes with friction. Allow area to dry prior to applying the dressing.

To enable disinfection process to be completed. To prevent skin reaction in response to the application of a transparent dressing to moist skin (Loveday et al. 2014, **C**; NICE 2012, **C**).

- 18 Reapply tapes or securing device if necessary. This may require skin preparation prior to application of securing device.

To secure device and prevent dislodgement and phlebitis (Schears 2005, **R5**).

- 19 Apply appropriate dressing, moulding it into place so that there are no folds or creases.

To minimize skin irritation and reduce risk of dressing peeling or becoming damaged. **E**

To ensure security of device and prevent dislodgement. **E**

- 20 Document date and time on dressing.

To ensure the dressing is changed as required (DH 2010, **C**; NICE 2012, **C**).

Post-procedure

- 21 Remove gloves and dispose into waste bag.

To dispose of waste. **E**

- 22 Fold up the sterile field, place it in the orange clinical waste bag and seal it before moving the trolley. Draw back the curtains. Dispose of waste in appropriate containers.

To prevent environmental contamination (DH 2010, **C**).

- 23 Document date and time of dressing and any relevant changes at the insertion site in the patient's records.

To ensure adequate records and to enable continued care of device and patient (NMC 2010, **C**).

Procedure guideline 14.2 Vascular access devices: maintaining patency*Essential equipment*

- Sterile pack (containing sterile towel and low-linting gauze)
- Chlorhexidine 2% in 70% alcohol

Medicinal products

- Flushing solution ready prepared in a 10 mL syringe in a clinically clean container

*Pre-procedure***Action**

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

- 2 Wash hands thoroughly or use an alcohol-based handrub.

To reduce the risk of contamination (DH 2010, **C**; Fraise and Bradley 2009, **E**).

Procedure

- 3 Open sterile pack and arrange equipment.

To gain access to equipment. **E**

- 4 Clean the needleless injection cap using chlorhexidine 2% in 70% alcohol. Apply with friction, rubbing the cap in a clockwise and anticlockwise manner at least five times and allow to air dry.

To minimize the risk of contamination at the connections (DH 2010, **C**; Loveday et al. 2014, **C**; NICE 2012, **C**).

- 5 Attach the syringe to the needleless injection cap.

To establish connection between cap and syringe. **E**

- 6 Using a push-pause method, inject the contents of the syringe (inject 1 mL at a time).

To create turbulence in order to flush the catheter thoroughly (Goodwin and Carlson 1993, **E**).

- 7 Maintain pressure on the plunger as the syringe is disconnected from the cap then clamp device tubing if necessary.

To maintain positive pressure and prevent backflow of blood into the catheter, and possible clot formation (Berreth 2013a, **E**; Dougherty 2006, **E**).

Post-procedure

- 8 Dispose of equipment safely.

To prevent contamination of others (DH 2010, **C**).

- 9 Record the procedure.

To maintain accurate records (NMC 2010, **C**).

Procedure guideline 14.3 Central venous access devices: unblocking an occlusion*Essential equipment*

- Sterile pack (containing sterile towel and low-linting gauze)
- Bactericidal handrub
- Alcohol-based skin cleaning preparation, 2% chlorhexidine in 70% alcohol
- 10 mL syringes × 3
- Needles
- Three-way tap
- Extension set or needleless injection cap
- Apron
- Clean gloves

Medicinal products

- 0.9% sodium chloride
- Heparin 50 international units in 0.9% sodium chloride
- Fibrinolytic solution if required, for example urokinase

*Pre-procedure***Action**

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

- 2 Perform the procedure using an aseptic technique.

To minimize the risk of infection (DH 2010, **C**; Fraise and Bradley 2009, **E**). (For further information on asepsis see Chapter 3: Infection prevention and control.)

- 3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. Place all equipment required on bottom shelf.

To minimize the risk of cross-infection (DH 2010, **C**).

- 4 Open a sterile pack and empty other equipment onto it.

To create a clean working area (DH 2010, **C**).

Action	Rationale
5 Wash hands with bactericidal alcohol handrub.	Hands may have become contaminated by handling the outer packs, and so on (DH 2010, C).
Procedure	
6 Clean connections thoroughly with chlorhexidine 2% in 70% alcohol before disconnection.	To minimize infection risk at connection site (DH 2010, C).
7 Remove any extension sets or injection caps.	Occlusion may be in extension set/cap and not in catheter. E
8 Draw up and attempt to flush with 0.9% sodium chloride using a 10 mL syringe.	Smaller syringes create excessive pressure which could result in catheter rupture (Conn 1993, E).
9 If there is pressure within the device lumen, attempt to gently instil the 0.9% sodium chloride using a 'to and fro' motion (push-pull) over a few minutes.	To attempt to clear the catheter (Gabriel 2008, E).
10 If nothing can be aspirated:	
(a) if a peripheral device then remove the device and resite as necessary	
(b) if a central venous access device: then determine the cause of the occlusion:	
(i) if blood: discuss with doctors who may prescribe a fibrinolytic agent, for example urokinase (10,000 international units) or alteplase (see Box 14.3)	To break down fibrin (BNF 2014, C ; RCN 2010, C).
(ii) or if precipitation: discuss with pharmacy for best antidote, for example ethyl alcohol or hydrochloric acid.	To break down drug precipitate or fat emulsion (BNF 2014, C).
11 Draw up prescribed solution in a 10 mL syringe.	To prepare appropriate treatment. E
12 Attach a three-way tap and attach an empty 10 mL syringe and the syringe containing prescribed solution (Action figure 12).	To commence the negative pressure technique (Gabriel 2008, E ; McKnight 2004, E).
13 Put on clean gloves.	To minimize the risk of introducing infection (DH 2010, C).
14 Instil via a three-way tap using negative pressure technique (Action figure 14).	To prevent catheter rupture (Conn 1993, E).
15 Attach syringe and inject the priming volume into catheter lumen (see Box 14.3) and 0.5 mL extra.	To allow the drug to come into contact with the fibrin (Syner Kinase 2011, M).
16 Wait 10 minutes.	To allow the drug to come into contact with the fibrin (Syner Kinase 2011, M).
17 Inject another 0.5 mL.	To allow the drug to come into contact with the fibrin (Syner Kinase 2011, M).
18 Wait 10 minutes.	To allow the drug to come into contact with the fibrin (Syner Kinase 2011, M).
19 Inject last 0.5 mL.	To allow the drug to come into contact with the fibrin (Syner Kinase 2011, M).
20 Attach an empty syringe to catheter and attempt to aspirate any clots and solution.	To unblock catheter and ensure no clots are administered into the patient (Gabriel 2008, E).
21 If blood returns, withdraw at least 10 mL and discard.	To ensure no clots are flushed into the patient (Gabriel 2008, E).
22 Flush catheter with 10 mL 0.9% sodium chloride using a pulsatile flush and then flush with heparinized saline.	To ensure the catheter is flushed and patent (RCN 2010, C).
Post-procedure	
23 Remove gloves and dispose of waste.	To prevent contamination of others (DH 2010, C).
24 If still unable to aspirate, discuss the use of a second instillation of fibrinolytic agent or use an infusion. It may be necessary to remove the catheter if a single lumen or if multilumen, to refrain from using the occluded lumen and label not for use.	To maintain some venous access for the patient. If occlusion cannot be removed the catheter is no longer patent. In multilumen catheters there may be another patent lumen for use (Gabriel 2008, E).
25 Document in patient's records.	To ensure adequate records and to enable continued care of device and patient (NMC 2010, C).

Action Figure 14 Unblocking an occluded catheter. (a) Aspirate on an empty syringe, which creates a negative pressure. (b) Turn tap to close off the empty syringe and open to the pre-filled syringe. The medication will automatically be aspirated into the catheter. Repeat as necessary. *Source:* Adapted from Becton Dickinson First PICC Clinical Education Manual D11 952B 5/98.

Post-procedural considerations

Immediate care

This will depend on the type of VAD that has been inserted (see each individual VAD).

Ongoing care

Discharging patients home with a VAD *in situ*

Patients may be discharged home with a VAD *in situ* which will allow them to receive treatment at home (e.g. continuous chemotherapy or intermittent antibiotics) or allow for easier access on each admission (e.g. via implanted ports). An early referral to the community nurses is crucial to ensure adequate support for the patient once at home (Kayley 2012).

Patients may now receive daily treatment over a 3–5-day period with an indwelling peripheral cannula (Shotkin and Lombardo 1996). The degree of care is minimal compared with a CVC, but patients should receive adequate information about the early signs of phlebitis, such as pain, redness and swelling, and what to do in the case of accidental dislodgement or removal of the cannula.

The dressing of choice for PICC and skin-tunnelled (when required) insertion sites is one that is moisture permeable and transparent (Loveday et al. 2014, NICE 2003), which usually requires changing once a week, following the initial change within the first 24 hours (RCN 2010, Ryder 2001). This type of

dressing may make it difficult for the patient to change the dressing themselves and so a carer or community nurse will need to be involved. At the dressing change, the site should be inspected and any signs of erythema or inflammation should be reported to the hospital at once in order for appropriate treatment to be prescribed (DH 2010). The area should be cleaned using an aseptic technique with a 2% chlorhexidine-based solution (DH 2010, Loveday et al. 2014, NICE 2003).

If a patient wishes to be self-caring, the nurse should observe them carrying out the flushing procedure, either in hospital or in the home setting, until competent to do so without supervision of a nurse (Dougherty 2006, INS 2011). However, some patients

Box 14.3 Volumes for instillation of urokinase

Priming volumes

PICC = 0.5 mL

Skin tunnelled catheter = 1 mL

Port = 3 mL

Reconstitute Syner Kinase 10000 units with the priming volume of the CVAD plus an additional 1.5 mL of 0.9% sodium chloride

prefer the community nurse to take responsibility for maintaining patency. Sufficient equipment (Box 14.4, Box 14.5) must be supplied to enable the patient or nurse to care for the CVD from the time of discharge until the patient's next admission (Kayley 2012).

Education of patient and relevant others

Patients with long-term CVDs *in situ*, such as PICCs or skin-tunnelled catheters, will require instruction and supervision to ensure adequate understanding of the care and maintenance of their devices (Dougherty 2006, Kayley 2012). This must start early within the discharge planning process along with an assessment of the home environment, the patient's manual dexterity, physical and medical condition (Kayley 2012). Patient education is one of the most important aspects of care but, to make teaching effective, it is essential to recognize each patient's needs and limitations. It is also vital to acknowledge each patient's past experiences and readiness to learn (Czaplewski 2010, Kayley 2012). Education of the patient should encompass care and maintenance of the device as well as signs and symptoms of complications (Kayley 2012, RCN 2010). Educational packages should be prepared in the form of practical demonstrations and clear, succinct handouts (INS 2011, Kayley 2012, NICE 2012) (Figure 14.9). It is also important to recognize the need to prepare patients carefully to participate in their own self-care and therapy (Czaplewski 2010). The patient, relative and/or carers should understand the following.

- The frequency of changing the dressing and how to care for the site.
- How to maintain patency.
- How to inspect for signs of infection or other complications.
- How to solve problems and where to seek help (RCN 2010).

Patients should be taught what early signs and symptoms to look out for, must know what to do if the catheter becomes occluded or damaged and be told when and who to contact along with a contact name and number in order to be able to seek professional advice. This will help to alleviate any anxiety (Dougherty et al. 1998). Most problems can be managed at home with the involvement of the community nurses and general practitioner (Kayley 2012).

The most common complications associated with CVDs are infection and thrombosis (Dougherty 2006, Kayley 2008, RCN 2010). The patient should be told to report signs of redness and tracking at the exit site, along the skin tunnel or up the arm, any oozing at the exit site and fevers or rigors. Patients are no longer routinely prescribed prophylactic warfarin as this has been shown to have no apparent benefit in the prevention of thrombosis (Couban et al. 2005, Young et al. 2005). Therefore it should be stressed to the patient that any of the following signs or symptoms should be reported immediately: breathlessness, pain and/or swelling over the shoulder, across the chest and into the neck and arm. Early reporting may enable effective treatment and avoid removal of the device (Bishop 2009).

Box 14.4 CVD flushing kit

A CVD flushing kit should contain the following when a patient has a skin-tunnelled catheter or PICC *in situ*.

- Needleless injection caps
- Ampoules of heparinized saline (50 units heparin in 5 mL 0.9% sodium chloride) or prefilled syringes
- Chlorhexidine 2% in 70% alcohol wipes
- Sterile 10 mL Luer-Lok syringes
- 21 and 23 G needles
- Instruction leaflet to provide both the community nurse and patient with a point of reference, for example a patient information leaflet on central venous access devices
- Sharps container

Box 14.5 Contents of pack to take home for patients with PICC

For PICC dressings, a pack containing the following should be sent home with the patient.

- Dressing packs (contains gloves)
- Securing device (where required)
- Gauze
- Transparent dressings
- Chlorhexidine 2% in 70% alcohol sponges
- Bandages

Complications

The complications associated with vascular access devices can be found in Box 14.6. Each complication will be discussed in more detail under each device.

Peripheral cannulas

Definition

A cannula is a flexible tube containing a needle (stylet) which may be inserted into a blood vessel (Dougherty 2008, RCN 2010). Cannulas are usually placed in the peripheral veins in the lower arm but may also be placed in the veins of the foot (an area used particularly in paediatric care) (Weinstein and Plumer 2007). However, veins of the lower extremities should not be routinely used in adults due to the risk of embolism and thrombophlebitis (INS 2011, RCN 2010).

Anatomy and physiology

Choice of vein

The main factors to consider prior to inserting a peripheral cannula are the location for siting, condition of the vein, purpose of

Figure 14.9 Patient information booklet on central venous access devices.

the infusion (that is, the rate of flow required and the solution to be infused) and the duration of therapy (Dougherty 2008, Phillips 2005).

A suitable vein should always be determined prior to selection of the device. The vein should feel bouncy, refill when depressed, should be straight and free of valves to ensure easy advancement of the cannula. Valves can be felt as small lumps in the vein; some may be visualized at bifurcations, some may be visible to the naked eye in certain vessels. It is best to avoid siting a cannula over a joint as this increases the risk of mechanical phlebitis and an infusion that will infuse intermittently due to the patient's movement (Dougherty 2008, INS 2011, RCN 2010, Witt 2010). It can also be very awkward for the patient and may restrict their ability to carry out activities (Macklin and Chernecky 2004, Marsigliese 2000).

The veins of choice are either the cephalic or basilic veins, followed by the dorsal venous network (see Figure 14.1). The practitioner should choose distal veins and then cannulate at proximal points (INS 2011, Perucca 2010). The best vein should always be used (Weinstein and Plumer 2007).

The cephalic vein

The size and position of the cephalic vein make it an excellent vessel for administration of transfusions. It readily accommodates a large-gauge cannula and, by virtue of its position on the forearm, provides a natural splint (Weinstein and Plumer 2007). However, its position at a joint may increase complications such as mechanical phlebitis and even general discomfort. The tendons controlling the thumb obscure the vein during insertion (Hadaway 2010), and care must be taken not to touch the radial nerve (Dougherty 2008).

The basilic vein

The basilic vein is a large vessel, which is often overlooked due to its inconspicuous position on the ulnar border of the hand and forearm. It is found on palpation when the patient's arm is placed across the chest, with the practitioner opposite the patient (Hadaway 2010). Cannulation can be awkward because of its position, mobility and tendency to have many valves (Dougherty 2008, Hadaway 2010).

Dorsal venous network

Using the veins of the dorsal venous network of the hand will allow for cannulation proximally along the veins when resiting

the device (Weinstein and Plumer 2007). They can usually be visualized and palpated easily (Hadaway 2010).

- The digital veins are small and may be prominent enough to accommodate a small-gauge needle as a last resort for fluid administration. With adequate taping, the fingers can be immobilized, making it more comfortable as well as preventing the cannula from piercing the posterior wall of the vein (leading to bruising or infiltration) (Springhouse 2002).
- The metacarpal veins are accessible, and easily visualized and palpated. They are well suited for cannulation as the cannula lies flat and the metacarpal veins provide a natural splint (Weinstein and Plumer 2007). The veins tend to be smaller than those in the forearm and therefore may prove difficult to access in infants because they have higher amounts of subcutaneous fat than older children and adults. The use of these veins is contraindicated in the elderly as there is diminished skin turgor and loss of subcutaneous tissue, making the vein difficult to stabilize. They are also more fragile and venous distension is slower (Fabian 2010, Hadaway 2010, Springhouse 2002). Metacarpal veins are a better option for short-term or outpatient intravenous therapy.

Evidence-based approaches

Rationale

The advantages of using a peripheral cannula are that they are usually easy to insert and have few associated complications; however, they are associated with phlebitis (either mechanical or chemical) and require constant resiting (Dougherty 2008, INS 2011, RCN 2010).

Indications

- Short-term therapy of less than a week.
- Bolus injections or short infusions in the outpatient/day unit setting (Hadaway 2010, RCN 2010).

Contraindications

- Long-term intravenous therapy.
- Longer or continuous infusions of medications that are vesicant or those that have a pH >9 (Hadaway 2010).

Methods of improving venous access

Difficult peripheral access is traumatic for the patient. Application of a tourniquet, taping and stroking of veins, vigorous swabbing, clenching the hand to pump up veins, hanging the forearm downwards and application of local warmth are all commonly used aids for cannulation (Berreth 2013b, Dougherty 2008).

The application of the tourniquet promotes venous distension. The tourniquet should be tight enough to impede venous return while not affecting arterial flow (Garza and Becan McBride 2013, Perucca 2010, RCN 2010). Reusable tourniquets are recommended (El Hassan and Dixon 2012). It should be applied around the upper forearm about 6–8 inches above the venepuncture site (McCall and Tankersley 2012) to promote dilation of the veins and time should be allowed for the veins to fill. However, too tight application (particularly in the older patient) can result in petechiae at the site of the tourniquet, haematoma, general bruising or venous high-pressure backflow of blood, resulting in vein 'blows' (Moureau 2008). To help reduce this, the tourniquet should be applied over clothing wherever possible (Hoeltke 2013, Toth 2002, Weinstein and Plumer 2007) or using a blood pressure cuff upside down and inflating just below diastolic pressure for effective compression. It may also be possible in some patients to avoid a tourniquet altogether by compressing a superficial vein with a finger above the insertion site (Dougherty 2013). Light tapping of the vein may be useful as this releases histamines beneath the skin and causes dilation (Phillips 2005), but it can be

painful and may result in the formation of a haematoma; again, older patients and those with fragile veins are most at risk (Garza and Becan McBride 2013, Witt 2010). Other methods used to improve venous distension include lowering the extremity below the level of the heart and opening and closing the fist (the action of the muscles forces blood into the veins, causing them to distend) (Phillips 2005).

When these methods fail, applying a warm compress in the form of a heat pack, warmed towels or electric heating blanket or immersing the limb in a bowl of warm water for 10–15 minutes helps to increase vasodilation and promote venous filling (Chen 2002, Fink et al. 2009, Weinstein and Plumer 2007). Ointments or patches containing small amounts of glycerol trinitrate have been used to improve vasodilation (Gunwardene and Davenport 1990) as well as reducing the incidence of chemical phlebitis and increasing site survival time (Hecker 1988).

Vein locating devices

These are optional but useful portable devices that make it easier to locate veins that are difficult to visualize or palpate (Berreth 2013b). They are called transillumination devices and they enable visualization of veins by passing light, e.g. LED or infrared light, through the walls and subcutaneous tissues to highlight the vessels. The haemoglobin in the blood absorbs the light, causing the vein to stand out as a dark line (Berreth 2013b, McCall and Tankersley 2012) (Figure 14.10). Ultrasound can also be used (Lamperti et al. 2012, Walker 2009).

Methods of insertion

Skin stabilization is one of the most important elements for successful cannulation (Dougherty 2008, Perucca 2010) (Figure 14.11). Superficial veins tend to roll; to prevent this, the vein must

Figure 14.10 Vein visualization device.

Figure 14.11 Anchoring the vein with the thumb. *Source:* Dougherty (2008). Reproduced with permission from John Wiley & Sons.

be stabilized by applying traction to the side of the insertion site or below it, using the practitioner's non-dominant hand. This also facilitates a smoother needle entry. Various methods are used (Dougherty 2008).

- The thumb can be used to stretch the skin downwards.
- The hand of the practitioner can be placed under the patient's arm and traction applied with the thumb and forefinger on either side, creating an even traction.
- The vein can be stretched between forefinger and thumb.

Stabilization of the vein must be maintained throughout the procedure until the needle or cannula is successfully sited. If the tension is released halfway through the procedure, the needle may penetrate the opposite wall of the vein, resulting in a haematoma formation (Dougherty 2008, de Verteuil 2010).

It is important that the needle enters the skin with the bevel up, as this results in a smooth venepuncture as the sharpest part of the needle will penetrate the skin first, and this also reduces the risk of piercing the posterior wall of the vein (Weinstein and Plumer 2007). The angle at which the needle enters the skin varies with the type of device used and the depth of the vein in the subcutaneous tissue, from 10° to 45° (Dougherty 2008, Perucca 2010, Weinstein and Plumer 2007). Once the device is in the vein, the angle should always be reduced in order to prevent puncturing the posterior wall of the vein (Perucca 2010).

There are two main methods for approaching the vein.

- The *direct method* is when the device enters through the skin and immediately enters the vein. However, with smaller veins this method may result in puncture of the posterior wall (Dougherty 2008).
- The *indirect method* is when the device is inserted through the skin and then the vein is relocated and the device advanced into the vessel. This method enables a more gentle entry and may be useful in veins which are palpable and visible for only a short section (Dougherty 2008, Perucca 2010, Weinstein and Plumer 2007).

When blood appears in the chamber of a cannula, this is known as ‘flashback’ and it indicates that the initial entry into the vein has been successful. This may be accompanied by a ‘giving way’ sensation felt by the practitioner, which occurs because resistance from the vein wall decreases as the device enters the lumen of the vein. This usually occurs with thicker-walled cannulas (de Verteuil 2010, Weinstein and Plumer 2007). If the device punctures the posterior wall, the flashback will stop. However, the flashback may be slow with small-gauge cannulas or hypotensive patients.

The cannula should be advanced gently and smoothly into the vein and a number of techniques are used by practitioners. One method which provides the least risk of through puncture, but which is more difficult to learn initially, is the one-handed technique (de Verteuil 2010, Perucca 2010). The same hand that performs cannulation also withdraws the stylet and advances the cannula into the vein. This allows skin traction to be maintained while the device is advanced and in the older patient it also allows the practitioner to draw loose thick skin downward from underneath by using the hand in a ‘C clamp’ position (Rosenthal 2005). If one hand is not used to apply traction then on cannula advancement, there may be unnecessary damage to the endothelium, resulting in phlebitis (Hadaway 2010).

This technique is also more suited to the older patient (Hadaway 2000, Perucca 2010, Weinstein and Plumer 2007) because the connective tissue that anchors superficial veins is reduced with ageing and this makes veins more likely to roll so it is important to firmly anchor older adult veins (Rosenthal 2005).

The one-step technique is when the cannula has entered the vein and the practitioner can slide the cannula off the stylet in one movement. The disadvantage with this method is that the stylet must remain completely still in order to prevent damage to the vein. It is best accomplished on a straight vein and when the cannula has a small finger guard which can be used to ‘push’ the cannula off (Dougherty 2008).

The two-handed technique is where the practitioner performs the cannulation with one hand but releases the skin traction in order to advance the cannula off the stylet. This method prevents blood spill, but as it necessitates the release of skin traction, it can often lead to puncturing of the vein wall (Dougherty 2008).

If the cannulation is unsuccessful, the stylet should not be reintroduced as this could result in catheter fragmentation and embolism (Perucca 2010). A practitioner should not have more than two attempts at cannulation before passing the patient on to a more experienced colleague (Dougherty 2008, INS 2011, Perucca 2010).

Anticipated patient outcomes

The outcome of cannulation is to ensure the patient can receive their intravenous therapy and has a cannula placed that is comfortable and in a convenient position, enabling them to continue daily activities, and finally is secured and dressed to prevent any complications.

Legal and professional issues

Competencies

Pre-registration nurse education does not normally cover cannulation, necessitating post-registration training (Phillips et al. 2011). Post-registration nurses must follow professional guidelines and local policy prior to taking up these skills as it is classified as expanded practice. Nurses must be taught both theory and practical skills in cannulation (RCN 2010). Competencies would include knowledge and skills in anatomy and physiology of the veins, selection of the vein and equipment, ability to improve venous access and prevention and management of complications. One way of achieving these skills is using a structured learning programme (Collins et al. 2006) which provides supervised self-assessment using objective structured clinical examinations (OSCE) (Phillips et al. 2011).

Skilled practitioners who undertake cannulation on a regular basis, for example those in intravenous therapy teams, can reduce pain and discomfort for patients and reduce local complications such as phlebitis (Dougherty 1994). Patients usually give verbal consent for cannulation (Hyde 2010).

Pre-procedural considerations

Equipment

Sizing

A number of different types of peripheral cannula are available. It has been shown that the incidence of vascular complications increases as the ratio of the external diameter of the cannula to vessel lumen increases. Therefore most of the literature recommends the smallest, shortest gauge cannula in any given situation (Macklin and Chernecky 2004, RCN 2010). The measurement used for needles and cannulas is standard wire gauge (swg), which measures the internal diameter; the smaller the gauge size, the larger the diameter. Standard wire gauge measurement is determined by how many cannulas fit into a tube with an inner diameter of 1 inch (25.4 mm) and uses consecutive numbers from 13 to 24. The diameter, for example 1.2 mm, may be expressed as a gauge, for example 18 G (Nauth-Misir 1998). Needles are odd numbers, for example 19 G, 21 G, while cannulas are even numbers, for example 18 G, 20 G (Weinstein and Plumer 2007).

The walls of the device should therefore be thin to provide the largest internal diameter without increasing the external diameter. This is to ensure that maximum flow rates may be achieved while reducing complications such as mechanical irritation. Flow rates vary with equipment from different manufacturers. Flow rate through a cannula is related to its internal diameter and is inversely proportional to its length (Table 14.2). However, as the length of the cannula increases, so does the likelihood of vascular complications. For example, a large-gauge device of longer length (1.6–2.0 cm) will fill the vessel, preventing blood flow around it, which could result in mechanical trauma to the vessel and encourage the development of phlebitis (Dougherty 2008, Tagalakakis et al. 2002).

Materials

The most suitable material is one that is non-irritant and does not predispose to thrombus formation (Dougherty 2008). The material should also be radiopaque or contain a stripe of radiopaque material for radiographic visualization in the event of catheter embolus (Dougherty 2008, Perucca 2010). Types of material include

Table 14.2 Gauge sizes and average flow rates (using water)

Gauge (G)	Flow rate (mL/min)	General uses
14	350	Used in theatres or emergency for rapid transfusion of blood or viscous fluids
16	215	As 14 G
18	104	Blood transfusions, parenteral nutrition, stem cell harvesting and cell separation, large volumes of fluids
20	62	Blood transfusions, large volumes of fluids
22	35	Blood transfusions, most medications and fluids
24	24	Medications, short-term infusions, fragile veins, children

polyvinylchloride, Teflon, Vialon and various polyurethane and elastomeric hydrogel materials (Dojcinovska 2010). Studies have compared the different types of material available to ascertain which is most likely to be associated with the lowest potential risk of phlebitis (Karadag and Gorgulu 2000). When considering the results of these studies, however, it must be noted that investigators often use different phlebitis scales and calculations for creating a total score for each device. Other inconsistencies relate to the differences in catheter size, skin preparation, the use of dressings and the type of solution being infused. This makes research comparing catheter materials difficult.

Types of cannula

The 'over the needle' type of cannula is the most commonly used device for peripheral venous access and is available in various gauge sizes, lengths, composition and design features (Dougherty 2008). The cannula is mounted on the needle (known as the stylet) and once the device is pushed off the needle into the vein, the stylet is removed. A sharp-tipped stylet facilitates penetration into the vein and the type of graduation from the cannula to the needle can affect the degree of trauma to the vessel and the cannula tip (Dougherty 2008). A thin smooth-walled cannula tapering to a scalloped end causes less damage than one that is abruptly cut off (Dougherty 2008, Macklin and Chernecky 2004).

Some peripheral cannulas have wings which help with the securing of the device to the skin in order to prevent a piston-like movement within the vein and accidental removal (Dougherty 2008). Some devices may have small ports on the top (these are favoured more in Europe than in the USA) (Figure 14.12). The advantage of a ported device is the ability to administer drugs without interfering with a continuous infusion. However, the caps are often not replaced correctly, which leaves the system exposed to contamination and the possible risk of air entering, so where ported devices are used they should be capped off using a needle-free injection connector (Easterlow et al. 2010). It has also been found that the ports cannot be adequately sterilized with a swab, as there is no flat surface. The use of ports may encourage the practitioner not to remove the dressing and inspect the site but merely to administer the drug via the port (Dougherty 2008).

Safety cannulas are now available and have either active or passive mechanisms. In the active devices the practitioner has to push a button in order to activate the safety feature, whilst in the passive devices, the stylet has a blunting or shielding facility which is automatically activated on removal from the cannula (Dojcinovska 2010, Dougherty 2008, HSE 2013, RCN 2010) (Figure 14.13).

Assessment and recording tools

Using a care bundle for insertion helps to promote best practice and includes hand hygiene, ensuring the practitioner has the

Figure 14.13 Safety non-port cannula.

appropriate equipment, e.g. gloves, tourniquet, skin preparation, cannulae, dressings and sharps bins (Burnett et al. 2010). The Visual Infusion Phlebitis Scale (VIP) (Figure 14.14) was developed by Jackson (1998) and measures the signs and symptoms of phlebitis, matching them to the appropriate management. Each stage has a numbered score and this is recorded by nursing staff at regular intervals and, where necessary, the corresponding action is taken (Groll et al. 2010, Morris 2011). However, there is now debate as to the efficacy of these phlebitis assessment scales (Ray-Barruel et al. 2013).

Pharmacological support

The use of local anaesthetic prior to insertion of peripheral cannulas has been advocated to reduce pain and anxiety in children and specific adults (Scales 2005). It is recommended:

- if the cannula is larger than 18 G
- for use at a sensitive site, for example inner aspect of wrist
- at the patient's request (Dougherty 2008, Moureau and Zonderman 2000).

When required, the agent that is the least invasive and/or carries the least risk for allergic reaction should be considered first (RCN 2010).

Local anaesthetic may be applied in a cream/gel, given as an intradermal injection (Anderson et al. 2010, Ganter-Ritz et al. 2012), administered by iontophoresis: a painless dry electrode pushing the local anaesthetic into the skin within 7–10 minutes to a depth of 10 mm (Dougherty 2011).

The most commonly used local anaesthetic creams are EMLA (eutectic mixture of local anaesthetics: lidocaine and prilocaine) and Ametop (topical amethocaine). These are applied to the skin 30–60 minutes prior to cannulation and covered with an occlusive dressing. A meta-analysis showed that EMLA cream significantly decreased the pain of intravenous cannulation in 85% of adults and children (Fetzer 2002). However, it causes vasoconstriction, making cannulation more difficult. Ametop has been shown to be more effective than EMLA and to cause significantly less vasoconstriction (Browne et al. 1999). However, it can result in an erythematous rash if left *in situ* longer than the recommended time (BNF 2014).

Ethyl chloride is a fast-acting vapo-coolant spray that provides rapid, transient, topical local analgesia for minor invasive procedures such as cannulation. It has no anaesthetic properties but the sprayed liquid makes the skin cold and less sensitive as it evaporates, causing instant numbing. The effect lasts about 30–45 seconds (IS Pharma 2009).

Intradermal lidocaine 1% can be slowly injected around the vein to be cannulated after skin sterilization to minimize the discomfort of the procedure. Intradermal injection of lidocaine has been shown to reduce the pain of intravenous cannulation and

Figure 14.12 Ported cannula.

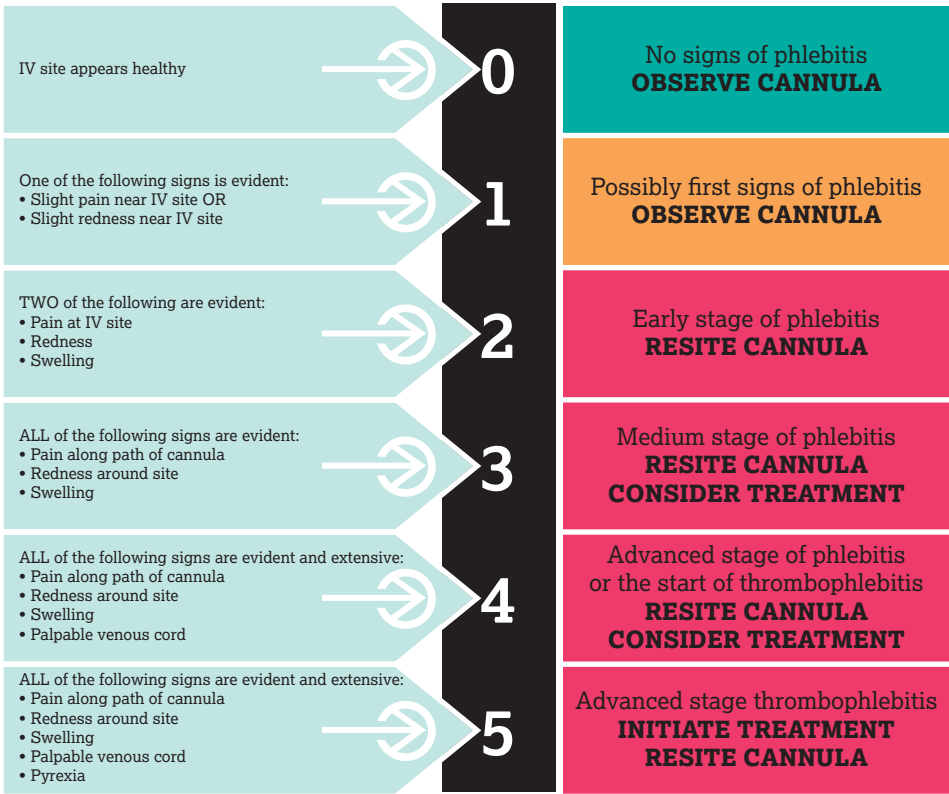

Figure 14.14 Vein Infusion Phlebitis (VIP) Scale. Source: Jackson (1998). Reproduced with permission from EMAP Publishing Ltd.

be less painful than placement of the cannula itself (Brown and Larson 1999, Ganter-Ritz et al. 2012). However, it should be used with caution because of the potential to cause an allergic reaction, tissue damage and inadvertent injection of the drug into the vascular system, and it can even obliterate the vein (Dougherty 2011, INS 2011). It is not recommended for routine use (INS 2011, RCN 2010).

Iontophoresis uses a painless electrical current to facilitate the movement of solute ions across the skin. It has been used to administer lidocaine prior to intravenous cannulation without the need for intradermal injection and has been shown to be as effective as EMLA (Dougherty 2011, Galinkin et al. 2002).

Although local anaesthetic reduces the pain of intravenous cannulation, it is not without complications. Irrespective of the method of anaesthesia, there is a risk that the symptoms of extravasation may be obscured or it may even influence the risk of injury occurring (Stanley 2002).

Non-pharmacological support

There are a number of methods for relieving pain using a non-pharmacological approach (MacKereth et al. 2012), including distraction, such as the cough trick (Usichenko et al. 2004), massage (Wendler 2003), transcutaneous electrical nerve stimulation (TENS) (Coyne et al. 1995) and visualization (Andrews and Shaw 2010).

Specific patient preparation

Skin preparation

As the most common cause of VAD infection is the patient’s own skin flora, it is important to clean the skin adequately prior to cannulation (Figure 14.15). The patient’s skin should be washed with soap and water if visibly dirty which will remove most transient flora (Perucca 2010). Then an antiseptic solution such as 2% chlorhexidine solution or 70% alcohol should be applied with

repeated back-and-forth strokes with friction for 30–60 seconds for an area of 4–5 cm (DH 2010, Perucca 2010). A quick wipe fails to reduce bacterial count (Weinstein and Plumer 2007). It should be allowed to air dry for up to 1 minute to ensure coagulation of the organism and to prevent stinging as the needle pierces the skin (INS 2011, RCN 2010, Weinstein and Plumer 2007). Fanning, blowing or blotting the prepared area is contraindicated (Perucca 2010). Once the skin has been cleaned, it must not be touched or repalpated (Dougherty 2008). If it is necessary to repalpate, then the cleaning regimen should be repeated.

Shaving the skin prior to cannulation is not recommended (INS 2011, RCN 2010, Weinstein and Plumer 2007) as the need

Figure 14.15 Cleaning the skin.

to remove hair has not been substantiated by scientific evidence (Weinstein and Plumer 2007). Shaving with a razor should not be performed because of the potential for causing microabrasions, which increase the risk of infection (INS 2011, Perucca 2010, RCN 2010). Depilatories should not be used because of the potential for allergic reaction or irritation (Perucca 2010, RCN 2010). If hair removal is necessary then this can be accomplished by clipping with scissors or clippers (Perucca 2010, RCN 2010). These should be cleaned between patients or only used once to prevent cross-infection (RCN 2010).

Psychological preparation

The influence of a bad experience can be overwhelming for a patient and any practitioner performing venepuncture or cannulation must never underestimate either the impact for the patient of undergoing the procedure or how they may view these procedures in the future (Dougherty 2011). Twenty percent of adults experience mild to intense fear of injections and blood, with 10% having a profound fear of needles; this is expressed as feelings of anxiety, experiencing a vasovagal episode with symptoms of

bradycardia and hypotension (Dougherty 2008). Anxiety can be caused by previous bad experiences, a degree of needle phobia or dislike of needle procedures (Andrews 2011, Andrews and Shaw 2010, Lavery and Ingram 2005). Many patients will be apprehensive and this anxiety may cause vasoconstriction, making cannulation more difficult as well as more painful for the patient. How nurses approach the patient, their manner and attitude, may have a direct bearing on the patient's response to the procedure (Dougherty 2011).

If the patient's history includes complications associated with any procedure, venepuncture or cannulation may be very difficult (Weinstein and Plumer 2007). However, when the procedures are performed by an experienced practitioner and it is a positive experience for the patient, they may feel more comfortable and relaxed. The nurse should ask patients about their past experiences and acknowledge their feelings and fears (Dougherty 2011). Provision of clear and comprehensive information on the procedure should reduce the patient's anxiety and pain (Dougherty 2011, Lüker and Stahlheber-Dilg 2003, Weinstein and Plumer 2007).

Procedure guideline 14.4 Peripheral cannula insertion

Essential equipment

- Sterile pack
- Various gauge sizes of cannula
- Alcohol-based hand scrub
- Alcohol-based skin preparation, 2% chlorhexidine in 70% alcohol
- Extension set
- Needleless injection cap
- Non-sterile well-fitting gloves
- Hypoallergenic tape
- Bandage, for example light crepe

- 5 mL syringe
- 21 G needle
- Tourniquet
- Sharps container

Optional equipment

- Securing device, for example Statlock
- Topical local anaesthetic

Medicinal products

- 0.9% sodium chloride 5 mL

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 If they require topical local anaesthetic, then apply it to the chosen venepuncture sites for 30–60 minutes prior to cannulation.	In order to give adequate time for local anaesthetic to be effective (BNF 2014, C).
3 Assemble all the equipment necessary for cannulation.	To ensure that time is not wasted and that the procedure goes smoothly without unnecessary interruptions. E
4 Check all packaging before opening and preparing the equipment to be used.	To ensure all equipment is in date and not contaminated. E

Procedure

5 Carefully wash your hands using bactericidal soap and water or bactericidal alcohol handrub and dry.	To minimize the risk of infection (DH 2010, C ; Fraise and Bradley 2009, E).
6 Check your hands for any visibly broken skin, and cover with a waterproof dressing.	To minimize the risk of contamination of the nurse by the patient's blood (Loveday et al. 2014, C).
7 In both inpatient and outpatient situations, the correct lighting, ventilation, privacy and position of the patient must be found.	To ensure that the operator and patient are comfortable and that adequate light is available to illuminate the procedure. E
8 Support the chosen limb on a pillow.	To ensure the patient's comfort and ease of access. P, E
9 Apply the tourniquet to the chosen limb.	To dilate the veins by obstructing the venous return. If necessary, use other methods to encourage venous access (Dougherty 2008, E).
10 Assess and select the vein (Action figure 10).	To select a vein (Dougherty 2008, E).

(continued)

Procedure guideline 14.4 Peripheral cannula insertion (*continued*)

Action	Rationale
11 Release the tourniquet.	To ensure that the patient does not feel discomfort while the device is selected and equipment prepared (Dougherty 2008, E).
12 Select the device based on the vein size.	To reduce damage or trauma to the vein. To reduce the risk of phlebitis (Dougherty 2008, E ; RCN 2010, C).
13 Wash hands using bactericidal soap and water or bactericidal alcohol handrub.	To minimize risk of infection (DH 2010, C ; Fraise and Bradley 2009, E).
14 Open a pack, empty all equipment onto the pack and place a sterile dressing towel under the patient's arm (Action figure 14).	To create a clean working area. E
15 Prime the extension set with a syringe of 0.9% sodium chloride (unless taking blood samples immediately after cannulation).	To remove air from the set prior to connection. If taking blood then the sodium chloride will contaminate the sample (Dougherty 2008, E).
16 Reapply the tourniquet.	To promote venous filling (Dougherty 2008, E).
17 Clean the patient's skin and the selected vein for at least 30 seconds using 2% chlorhexidine using back-and-forth strokes with friction and allow to dry (see Figure 14.15). Do not repalpate the vein or touch the skin.	To maintain asepsis and remove skin flora (DH 2010, C ; Dougherty 2008, E ; RCN 2010, C).
18 Put on gloves.	To prevent contamination of the nurse from any blood spill (DH 2010, C).
19 Remove needle guard and inspect the device for any faults (Action figure 19).	To detect faulty equipment, for example bent or barbed needles. If these are present, do not use and report to company as faulty equipment (MHRA 2005, C ; RCN 2010, C).
20 Anchor the vein with the non-dominant hand by applying manual traction on the skin a few centimetres below the proposed site of insertion.	To immobilize the vein. To provide countertension, which will facilitate a smooth needle entry (Dougherty 2008, E).
21 Holding the cannula in the dominant hand, ensure that it is in the bevel-up position and place the device directly over the vein; insert the cannula through the skin at the selected angle according to the depth of the vein (Action figure 21).	To ensure a successful, pain-free cannulation (Dougherty 2008, E).
22 Wait for the first flashback of blood in the flashback chamber of the stylet (see Action figure 21).	To indicate that the needle has entered the vein (Dougherty 2008, E).
23 Level the device by decreasing the angle between the cannula and the skin. Advance the cannula slightly to ensure entry into the lumen of the vein.	To avoid advancing too far and causing damage to the vein wall. To stabilize the device (Dougherty 2008, E).
24 Withdraw the stylet slightly with the dominant hand and a second flashback of blood will be seen along the shaft of the cannula (Action figure 24).	To ensure that the cannula is still in a patent vein. This is called the hooded technique (Dougherty 2008, E).
25 Maintaining skin traction with the non-dominant hand and using the dominant hand, slowly advance the cannula off the stylet and into the vein.	To ensure the vein remains immobilized, thus reducing the risk of a 'through puncture' (Dougherty 2008, E).
26 Release the tourniquet.	To decrease the pressure within the vein. E
27 Apply digital pressure to the vein above the cannula tip and remove the stylet (Action figure 27).	To prevent blood spillage. E
28 Immediately dispose of the stylet into an appropriate sharps container (Action figure 28).	To reduce the risk of accidental needlestick injury (NHS Employers 2007, C).
29 Attach a primed extension set, needleless injection cap or administration set (Action figure 29).	To enable flushing of cannula (Dougherty 2008, E).
30 Tape/secure the cannula using, for example, the method illustrated in Action figure 30 .	To ensure the device will remain stable and secure (Dougherty 2008, E).
31 Aspirate to check for blood flashback then flush the cannula with 0.9% sodium chloride using a pulsatile flush ending with positive pressure.	To ascertain and maintain patency (Goode et al. 1991, R1b).
32 Observe the site for signs of swelling or leakage and ask the patient if they are experiencing any discomfort or pain.	To check that the device is positioned correctly and is stable and secure (Dougherty 2008, E).

Action

- 33 Cover with low-linting swabs or appropriate dressing and bandage firmly.

Rationale

To ensure patient comfort and security of device (Dougherty 1994, **R5**).

Post-procedure

- 34 Remove gloves and discard waste, making sure it is placed in appropriate containers.
- 35 Document date and time of insertion, site and size of cannula, number of attempts and sign in patient's notes or care plan.

To ensure safe disposal in the correct containers and avoid laceration or injury of other staff. To prevent reuse of equipment (NHS Employers 2007, **C**).

To ensure adequate records and to enable continued care of device and patient (DH 2011, **C**; NMC 2010, **C**).

Problem-solving table 14.1 Prevention and resolution (Procedure guideline 14.4)

Problem	Cause	Prevention	Action
Anxious patient.	Previous traumatic experiences. Fear of needles or blood. Ignorance about what the procedure involves.	Approach the patient in a calm and confident manner. Listen to the patient's previous experiences and involve them in site selection. Offer a local anaesthetic (by gel or injection). Explain what the procedure involves and show them the equipment if appropriate. Offer the patient the opportunity to lie down or recline during the procedure. Use all methods of improving venous dilation to ensure success on the first attempt.	Refer the patient for psychological support if anxiety and fear are of phobic proportions. It usually takes a few weeks to help a patient manage needle phobia.
Difficulty in locating a suitable vein.	Excessive previous use. Shock or dehydration. Anxiety. Fragile, thready veins, for example in the elderly or in patients on anticoagulant therapy. Thrombosed veins as a result of treatment, for example cytotoxic therapy.	Alternate sites wherever possible to avoid overuse of certain veins. Use the methods described above to reduce anxiety.	Reassure the patient. Use all methods of improving venous access before attempting the procedure, for example use warm water/GTN to encourage venous dilation or vein illumination/ultrasound devices. Assess patient using an assessment tool to ascertain degree of difficulty and refer for CVAD if necessary. Do not attempt the procedure unless experienced.
Missing the vein on insertion of the cannula.	Inadequate anchoring. Collapse of the vein. Incorrect position of practitioner or patient. Inadequate palpation. Poor vein choice. Lack of concentration. Failure to penetrate the vein properly due to incorrect insertion angle.	Ensure good position and lighting. Better preparation and concentration. Use correct technique and accurate vein selection.	Withdraw the needle and manoeuvre gently to realign it and correct the angle of insertion. Check during manoeuvring that the patient is not feeling any pain. If the patient complains of pain, remove the needle. If unsuccessful then remove the needle. Where necessary, pass to a colleague with more experience.
Blood flashback seen and then stops.	Venospasm. Bevel of needle up against a valve. Penetration of the posterior vein wall by the device. Possible vein collapse.	Try to locate valves prior to insertion and insert the device just above the valve. Carefully level off once in the vein to prevent penetration of posterior wall. Use a good angle of approach to the vein to prevent through puncture.	Release and tighten the tourniquet. Gently stroke the vein above the needle to relieve venous spasm. Withdraw the needle slightly to move the bevel away from the valve. If the vein wall is penetrated, remove the device.
Difficulty in advancing the cannula.	Releasing the tourniquet too soon, causing the vein to collapse. Removing the stylet too far and being unable to advance the cannula which is now no longer rigid enough to be advanced. Encountering a valve. Not releasing the cannula from the needle prior to insertion according to manufacturer's instructions. Poor anchoring or stretching of the skin.	Ensure the tourniquet remains sufficiently tight until insertion is completed. Ensure the cannula is released from the stylet prior to insertion, to allow for smooth advancement. Ensure that a sufficient length of the cannula is inserted into the vein before stylet withdrawal. Use good technique. Assess the vein accurately, observing for valves, and avoid them where possible.	In the event of early stylet removal or encountering a valve, connect a syringe of sodium chloride 0.9%, flush the cannula and advance at the same time in an effort to 'float' the device into the vein. Tighten the tourniquet and wait for vein to refill.

(continued)

Problem-solving table 14.1 Prevention and resolution (Procedure guideline 14.4) (continued)

Problem	Cause	Prevention	Action
Difficulty in flushing once the cannula is <i>in situ</i> .	Sometimes, the cannula has been successfully inserted, but on checking patency by flushing, the practitioner has difficulty because: <ul style="list-style-type: none">• the cannula tip is up against the valve• the cannula has pierced the posterior wall of the vein• the cannula tip is resting on the wall of the vein• there is an occlusion.	Avoid areas along the vein where there may be valves. Ensure careful insertion to prevent puncturing the posterior wall of the vein.	Withdraw the cannula slightly to move it away from the vein wall or valve and attempt to flush. If the vein wall is pierced and any swelling is observed, remove the cannula. Attempt to withdraw the clot and clear the occlusion.

Post-procedural considerations

Immediate care

Once sited, the peripheral cannula should be flushed using a pulsatile flush, ending with positive pressure (Dougherty 2008, RCN 2010, Weinstein and Plumer 2007). The cannula should be secured using clean tape or a securing device (Figure 14.16). Non-sterile tape should not cover the insertion site and taping should enable the site to remain visible and the cannula stable (Figure 14.17). The procedure shown in Procedure guideline 14.4: Peripheral cannula insertion, **Action figure 30** is recommended (Dougherty 2008, Hadaway 2000). Securement devices are now available and reduce the risk of dislodgement and other complications (Bausone-Gazda et al. 2010, Moureau and Iannucci 2003). A dressing should be applied: this can be either a transparent dressing or low-linting gauze (Perucca 2010). Once the gauze is in

886

Figure 14.17 Cannula *in situ*.

place, a bandage may be applied. However, transparent dressings, particularly moisture-permeable dressings, should not be bandaged as the visibility and moisture permeability are obscured.

Ongoing care

A peripheral cannula should be flushed before and after each use to check for patency prior to administration of a medication, and at least daily if not in use, using 0.9% sodium chloride. The dressing should be changed as required (if transparent) or each time the device is manipulated (gauze). The site should be monitored daily or when the device is used. The site should be inspected for signs of infiltration, extravasation and leakage and using a scale such as the VIP Scale for signs of phlebitis (DH 2010).

Removal

It has been recommended that peripheral devices should be resited every 48–72 hours (Barker et al. 2004, DH 2012) but some literature supports dwell times (length of time cannula *in situ*) of up to 96 hours with no significant complications providing that non-irritants are administered (Homer and Holmes 1998, McGoldrick 2010, Palese et al. 2011). Other studies have found that drug irritation is the most significant predictor of phlebitis and infiltration, rather than dwell time, and that extending the dwell time up to 144 hours could be considered under certain circumstances (Bregenzer et al. 1998, Catney et al. 2001).

The Rickard et al. (2012) study of over 5000 peripheral cannulas found no difference in phlebitis, infection or failure rates

Figure 14.16 Peripheral cannula secured with Statlock.

Need No:

Peripheral Cannula

- ## INSERTION OF A PERIPHERAL CANNULA

- ◆ Patient will verbalize an understanding of the insertion of a peripheral cannula and the possible side-effects, complications
- ◆ Patient will have a peripheral cannula which is correctly positioned and inserted with minimum of discomfort to the patient and trauma to the vein

A Patient Assessment

- ◆ Assess the patient's anxiety about the insertion of a peripheral cannula and agree any measures that are to be taken e.g. local anaesthetic cream and the type of peripheral cannula
- ◆ Assess the patient and carer's knowledge and understanding of: the site for the insertion of a peripheral cannula; the potential duration of the peripheral cannula; the care of the peripheral cannula by the nurse and/or the patient; and the need to report any side effects to the nurse
- ◆ Check that the patient/carer demonstrates an understanding of the intended peripheral cannula
- ◆ Assess ability to manage a peripheral cannula at home and arrange Community Nurse support if required

B Insertion

- ◆ Check with the patient for details of any previous ill effect from vascular access device insertion
 - ◆ Insert a peripheral cannula according to hospital procedure and manage any complications effectively
- Possible complications: pain, bruising, haematoma, missed vein, vasovagal reaction**

Use for 1st cannulation and then any subsequent resites during the patient's admission (and on subsequent admission)
(shaded area to be completed by nurse who cannulates)

Treatment * BT-blood transfusion CT-chemotherapy AB-antibiotics FL-fluids Other-please state

Phlebitis **Grade 1 – red OR painful Grade 2 – red and painful OR red and swollen OR swollen and painful Grade 3 – painful, swollen AND red

[illegible]

- ◆ Date and sign care plan when initiated, enter need number
- ◆ Individualise as appropriate. Date/time/sign any additional entries/interventions
- ◆ If need/outcome/interventions are stopped/changed or not applicable – DELETE by drawing a line through the entry, date/time/sign this deletion

Figure 14.18 Care plan related to the insertion of a peripheral cannula.

Patient Care Need: To maintain patient safety related to the management of a Peripheral Cannula**ONGOING ASSESSMENT & CARE****Anticipated Outcome:**

- ♦ Patient will have a peripheral cannula which is patent, correctly secured and free from signs of phlebitis, infiltration, extravasation and/or infection (and where these complications do occur that they are managed effectively)

Nursing Interventions:**C Maintaining a patent device**

- ♦ Flush all devices with 0.9% sodium chloride at start of drug administration, in between drugs and after drug administration
- ♦ Flush all devices using a turbulent flush and ending with positive pressure
- ♦ When not in constant use – flush the peripheral cannula once a day with 5 ml 0.9% Sodium Chloride

D Preventing infection

- ♦ Use an aseptic technique whenever the device is manipulated. Use clean non-sterile tape, sterile gauze and a peha crepe bandage – change gauze at each manipulation, and change tape when soiled.

E Prevent movement or dislodgement of device

- ♦ Tape peripheral cannula to secure (as per method in RMH Manual of Clinical Procedures)
- ♦ Tape administration/extension set to prevent the tubing from pulling on peripheral cannula

F Monitor site for signs of local complications

- ♦ Observe site for erythema, oedema, blanching and ask the patient if any pain or discomfort experienced
- ♦ If signs or symptoms indicate phlebitis or infiltration, remove cannula
- ♦ If extravasation indicated – follow extravasation policy
- ♦ If signs of infection, swab insertion site, remove cannula, send tip to microbiology, inform doctor

G Inform doctor of any complications during administration of treatment via peripheral cannula**REMOVAL OF A PERIPHERAL CANNULA****Anticipated Outcome:**

- ♦ Patient will have a peripheral cannula which is removed safely with minimal discomfort and no bruising

Nursing Interventions:**H Removal of a peripheral cannula**

- ♦ Remove and apply sterile dressing – check the bleeding has stopped before leaving the patient to ensure no bruising
- ♦ If further treatment, discuss type of vascular access device required
- ♦ Record reason for re-siting the cannula (*see page 1*)

Patient/Carer Education:**I Inform and discuss with the patient/carers:**

- ♦ the insertion procedures and the hazards, instructing the patient about the importance of positioning during insertion, and advise the patient to report if during insertion of peripheral cannula the following occurs: pain on insertion, feeling faint, light-headed or dizzy
- ♦ the function, potential side effects and implication of the peripheral cannula including: potential occlusion, pain/redness at peripheral cannula site and advise the patient how to mobilize and care for the peripheral cannula in situ e.g. during showering
- ♦ advise the patient of the importance in reporting to the nurse/doctor if they have any symptoms e.g. pain, and that a record is kept for future therapy

J Give the patient the peripheral cannula information leaflet, together with gauze and bandages if required for those patients who have daily outpatient treatment via a peripheral cannula**Additional Interventions:**

between replacing cannulas every 3 days compared with leaving *in situ* and replacing when clinically indicated. They concluded that peripheral devices need only be removed as clinically indicated and that this would save millions of unnecessary resites, associated discomfort and a reduction in cost of both equipment and staff time. This is supported by van Donk et al. (2009) and Webster et al. (2008) who recommend resiting cannulas based on clinical indication instead of time *in situ*. Lee et al. (2009) also state that this approach does not increase infection rate but they do recommend that insertion is done by highly skilled IV teams or rates could increase. Finally, Epic3 now recommend that peripheral cannulas should only be resited when clinically indicated and not routinely (Loveday et al. 2014).

Removal of the intravenous device or cannula should be an aseptic procedure. The device should be removed carefully using a slow, steady movement and pressure should be applied until haemostasis is achieved. This pressure should be firm and not involve any rubbing movement. A haematoma will occur if the device is carelessly removed, causing discomfort and a focus for infection (Perucca 2010). The site should be inspected to ensure bleeding has stopped and should then be covered with a sterile dressing (INS 2011). The cannula integrity should be checked to ensure the complete device has been removed (Dougherty 2008, INS 2011, RCN 2010).

Documentation

On insertion, the practitioner should document the date and time, the site and size of the cannula, the number of attempts and sign their name. This can be as part of a specific cannula care plan or by use of a sticker in the notes (Figure 14.18) (DH 2010). If a tool is

used to monitor the site, for example VIP score, then this should be recorded on a regular basis (e.g. every shift change or at least once a day) (Loveday et al. 2014). The date, time and reason for removal of the cannula must also be documented in the patient's notes (DH 2011, Dougherty 2008, RCN 2010). This documentation ensures adequate records for the continued care of the device and patient as well as enabling audit and gathering of statistics on rates of phlebitis and infiltration and so on.

Education of patient and relevant others

See 'Discharging patients home with a VAD *in situ*'.

Complications

On insertion

Pain

Pain can be caused by the following:

- tentative stop-start insertion (often associated with hesitant or new practitioners)
- hitting an artery, nerve or valve
- poor technique – inadequate anchoring causes skin to gather as the needle is inserted
- alcohol is not allowed to dry adequately before insertion, resulting in stinging pain
- using a frequently punctured, recently used or bruised vein
- anxious patient, may have low pain threshold
- use of large-gauge device
- use of veins in sensitive areas (Dougherty 2008).

Pain can be prevented by using methods to relax and relieve anxiety, for example massage, distraction or the use of local anaesthetic creams or injections. The practitioner should avoid the use of bruised, used or sensitive areas. If the patient complains of pain, depending on the cause (e.g. nerve or artery), it may be necessary to remove the device immediately. Reassure the patient and explain, especially in the case of nerve pain, that it may last for a few hours, provide the patient with an information leaflet (containing instructions of what to do if it gets worse or there is no improvement) and document the incident (Dougherty 2008).

Haematoma

This is leakage of blood into the tissues indicated by rapid swelling which occurs during the insertion procedure or after removal (McCall and Tankersley 2012, Perucca 2010). It can be caused by:

- penetration of the posterior vein wall
- incorrect choice of needle to vein size
- fragile veins
- patients receiving anticoagulant therapy
- excessive or blind probing to locate the vein
- spontaneous rupture of the vessel on application of the tourniquet or cleaning of the skin
- inadequate pressure on venepuncture site following removal of the cannula (Dougherty 2008, McCall and Tankersley 2012, Moini 2013).

Prevention includes good vein and device selection and using a careful technique. The practitioner should always be aware of patients with fragile veins or those on anticoagulant therapy and inexperienced individuals should not attempt cannulation in these individuals (Perucca 2010). A tourniquet should not be applied to a limb where recent venepuncture has occurred and the tourniquet should not be left in place for any longer than necessary.

On removal of the cannula, adequate pressure should be applied to the site. Alcohol pads inhibit clotting and should not be used (Perucca 2010). In the event of a haematoma occurring, the needle should be removed immediately and pressure applied to the site for a few minutes (Garza and Becan McBride 2013,

McCall and Tankersley 2013). Elevate the extremity if appropriate and reassure the patient and explain the reason for the bruise. Apply a pressure dressing if required and an ice pack if bruising is extensive (Moini 2013). Hirudoid or arnica ointment can help to reduce bruising and discomfort. Arnica is made of dried roots or flower of the arnica plant which stimulates activity of the white blood cells which process congested blood and reduce the bruise (<http://emc.medicines.org.uk/medicine/19031/SPC>). Hirudoid is a substance similar to heparin which acts by dissolving blood clots and improving blood supply to the skin (<http://emc.medicines.org.uk/medicine/5001/SPC/Hirudoid+Cream/>). They are both applied directly to the affected arm (BNF 2014). The incident should be documented and the patient given an information sheet with advice about when and who to contact if the haematoma gets worse or they develop any numbness in the limb (Dougherty 2008, Moini 2013, Morris 2011, Perucca 2010).

Inadvertent arterial puncture

This is characterized by pain and bright red blood caused by accidental puncture of an artery (Dougherty 2008, McCall and Tankersley 2012, Moini 2013). It can be prevented by adequate assessment and recognition of arteries prior to performing the procedure. It is rare when proper procedures are followed and can be associated with deep or blind probing (McCall and Tankersley 2012). However, should it occur, the device should be removed immediately and pressure applied to the puncture site for up to 5 minutes or until the bleeding has stopped (McCall and Tankersley 2012, Moini 2013). Reassure the patient but do not reapply the tourniquet to the affected limb. If an inadvertent arterial puncture goes undetected, accumulation of blood can result in compression injury and damage nearby nerves. The incident must be documented and the patient given an information sheet with advice about when and who to contact if they develop numbness or tingling in the limb (Dougherty 2008).

Nerve injury

If a nerve is accidentally hit on insertion of the needle into the vein, this will result in pain – described as severe shooting pain (Masoorli 2003, Yuan and Cohen 1985), painful burning sensation (Moini 2013) or a sharp electric tingling sensation that radiates down the nerve (McCall and Tankersley 2012). It can occur due to poor vein selection, inserting the needle too deeply or quickly or blind probing and can lead to injury and possibly permanent damage (McCall and Tankersley 2012). Prevention is achieved by ensuring that the location of superficial nerves is known; for example, a common place to hit a nerve is the cephalic vein and this can be avoided by placing three fingers at the wrist and inserting the needle above this (the nerve runs deeper at that point and therefore the practitioner will be less likely to touch it) (Boeson et al. 2000, Masoorli 2007). In the event of touching a nerve, release the tourniquet and remove the needle immediately (Garza and Becan McBride 2013). Reassure the patient and explain that the pain may last for a few hours and the area may feel numb. Explain that the pain can sometimes last for a few days and that, if it continues or gets worse, medical advice should be sought. Give the patient an information sheet with advice about when and who to contact and document the incident (Dougherty 2008, Garza and Becan McBride 2013).

Once in situ

Phlebitis

This is inflammation of the intima of the vein (Perucca 2010, Washington and Barrett 2012). It is characterized by pain and tenderness along the cannulated vein, erythema, warmth and streak formation with/without a palpable cord (Mermel et al. 2001).

There are three main types.

- *Mechanical* is related to irritation and damage to a vein by large-gauge cannulas, sited where there is movement, for example antecubital fossa, not secured adequately or increased dwell time.

- *Chemical* is related to chemical irritation from drugs such as antibiotics and chemotherapy.
- *Bacterial* is when the site becomes infected due to poor hand-washing or aseptic technique (Lamb and Dougherty 2008, Morris 2011).

Influencing factors that increase the risk of phlebitis include being female, dwell time, large-gauge cannulas, higher number of doses of irritating medications such as antibiotics; factors that reduce risk include choice of vein (forearm), smaller gauge cannulas and use of IV teams (da Silva et al. 2010, Mestre et al. 2013, Wallis et al. 2014, Washington and Barrett 2012). Prevention is key and includes appropriate device and vein selection, dilution of drugs and pharmacological methods, for example application of glyceryl trinitrate (GTN) patches (Dougherty 2008). Treatment includes discontinuing the infusion at the first signs of phlebitis (grade 1). Warm or cold compresses can be applied to the affected site. The patient should be referred to the doctor if the phlebitis rating is over 3. If bacterial phlebitis is suspected then the insertion site should be cultured and the cannula tip sent to microbiology (Dougherty 2008, Morris 2011).

Infiltration and extravasation

See Chapter 12: Medicines management.

Midline catheters

Definition

A midline catheter can be defined as one that is between 7.5 and 20 cm in length (Cummings et al. 2011, Dougherty 2008, RCN 2010). It provides vascular access in a larger peripheral vein without entering the central venous circulation. It is inserted into an antecubital vein and the tip is extended into the vein of the upper arm for about 20 cm, but it is not extended past the axilla (Hada-way 2010, RCN 2010).

Anatomy and physiology

Choice of vein

The basilic vein is the vein of choice due to its larger size, straighter course for catheter advancement and improved haemodilution capability (Perucca 2010, Weinstein and Plumer 2007). The cephalic and median cubital veins would be the second and third choices (INS 2011).

Evidence-based approaches

Rationale

The midline catheter offers an alternative to peripheral and central venous access. Where patients present with poor peripheral venous access and when the use of a CVC is contraindicated, the midline catheter provides venous accessibility along with easy, less hazardous insertion at the antecubital fossa (Goetz et al. 1998, Weinstein and Plumer 2007). Because the tip of the catheter does not extend beyond the extremities in which it is placed, radiographic confirmation of tip placement is optional and recommended only when there is difficulty in insertion or flushing (Gorski and Czaplewski 2004, Weinstein and Plumer 2007). Benefits to the patient include less frequent resiting of the catheter and a subsequent reduction in associated venous trauma (Gorski and Czaplewski 2004, Weinstein and Plumer 2007).

Indications

Midline catheters are indicated in the following circumstances.

- When patients do not have accessible peripheral veins in the lower arm.

- When patients will be undergoing therapy for 1–4 weeks (Carlson 1999), in order to preserve the integrity of the veins and increase patient comfort by removing the need for resites, for example antibiotics.
- Patient preference (Cummings et al. 2011, Dougherty 2008, Hadaway 2010, Perucca 2010).

Contraindications

The following should not be used for administration via a midline catheter: vesicant medications, especially by continuous infusion; parenteral nutrition, solutions and/or medications with pH less than 5 or greater than 9 and those with osmolarity greater than 600 mOsm/L (Banton and Leahy-Gross 1998, Gorski and Czaplewski 2004, Hadaway 2010, INS 2011).

Methods of insertion

The insertion is performed via an introducer or using a modified Seldinger technique (i.e. when venous access is established with a needle, a guidewire is threaded through the needle, the needle is removed and the catheter is threaded over the guidewire) (Hadaway 2010, Weinstein and Plumer 2007). Adequate assess-

ment of the patient's veins is vital and, given the choice, the non-dominant arm should be used.

Legal and professional issues

The procedure should only be performed by trained and competent nurses who have achieved a high standard of cannulation (Weinstein and Plumer 2007). Competencies would include knowledge of the anatomy and physiology of the veins of the upper arm, ability to select veins and equipment, and prevent and manage complications.

Pre-procedural considerations

Equipment

Silicone and polyurethane are the materials most frequently used in the manufacture of midline catheters (Hadaway 2010, Kupensky 1998). Catheters are available as single and double lumen in lengths of up to 20 cm, which can be cut to the desired length following measurement of the arm from the selected vein towards the axilla. They are available in various sizes from 2 to 5 Fr (Dougherty 2008, Hadaway 2010).

Procedure guideline 14.5 Midline catheter insertion

891

Essential equipment

- Sterile minor operation pack (contains sterile drapes and scissors)
- Sterile gloves
- Alcohol-based hand scrub
- Alcohol-based skin cleaning preparation, such as 2% chlorhexidine in 70% alcohol
- Extension set and needleless injection cap
- Midline catheter
- Introducer
- Transparent dressing
- Securing device and sterile tapes
- 10 mL syringes
- 21 G needle
- Tape measure
- Apron
- Tourniquet
- An assistant to open the pack

Medicinal products

- 0.9% sodium chloride
- Topical local anaesthetic

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient.	To ensure that the patient understands the procedure and gives their valid verbal consent (NMC 2013, C).
2 Apply tourniquet to the arm. Assess venous access in both arms and locate veins by sight and palpation, then release the tourniquet.	To ensure the patient has adequate venous access and to select the vein for catheterization (RCN 2010, C).
3 Apply local anaesthetic cream/gel to the chosen venepuncture site and leave for allotted time.	To minimize the pain of insertion (BNF 2014, C).
4 Apply apron, draw screens and position patient in a comfortable position.	To ensure privacy. To aid insertion and correct placement. E
5 Measure using the tape measure from the selected venepuncture site up the arm, to just below the axilla.	To enable selection of the most suitable catheter length and to know how far to advance the catheter in order for its tip to be located in the correct position. E
6 Take equipment required to patient's bedside. Open outer pack.	To gain access to equipment. E

Procedure

7 Carefully wash hands using bactericidal soap and water.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
8 Put on sterile gloves; open sterile pack, arranging the contents as required. Draw up the syringe with 0.9% sodium chloride (from assistant).	To prevent contamination. E
9 Remove the cap from the extension set and attach the syringe of 0.9% sodium chloride; gently flush with 2 mL and leave syringe attached.	To check that the catheter is patent and to enable easy removal of guidewire. E

(continued)

Procedure guideline 14.5 Midline catheter insertion (*continued*)

Action	Rationale
Procedure	
10 Using the graduated markings along the catheter, select the marking required and pull back guidewire 1 cm from desired new tip, and using sterile scissors trim the catheter. Never trim the guidewire!	To ensure the catheter will be the correct length for placement and to prevent damage to the vein if the guidewire is damaged. E
11 Place sterile towel under patient's arm.	To provide a sterile field to work on. E
12 Clean the skin at the selected site with an appropriate disinfectant, for example 2% chlorhexidine in 70% alcohol, using back-and-forth strokes with friction, and prepare an area of 15–25 cm.	To ensure skin flora is destroyed and to minimize the risk of infection (Fraise and Bradley 2009, E ; RCN 2010, C).
13 Allow the solution to dry thoroughly.	To ensure coagulation of bacteria and completion of disinfection process (Loveday et al. 2014, C).
14 Drape the patient with a fenestrated towel.	To provide a sterile field (Loveday et al. 2014, C).
15 Draw up and inject local anaesthetic intradermally, if required, using a 25 G needle and wait for a few minutes for it to take effect.	To provide adequate anaesthesia (BNF 2014, C).
16 Reapply tourniquet.	To aid venous distension (Dougherty 2008, E).
17 Perform venepuncture with introducer by entering the skin, 1 cm from desired point of entry, at a 15–30° angle. Advance 0.5–1.0 cm once flashback is seen.	To gain venous access (Dougherty 2008, E).
18 Release tourniquet.	To prevent blood loss and 'through puncture' and enable advancement of catheter (Dougherty 2008, E).
19 Position fingers in a V, with index finger on wings and middle finger above sheath tip, and gently remove stylet. Apply pressure.	To contain flashback, prevent contamination of the area with blood and minimize the amount of blood loss from patient (Dougherty 2008, E).
20 Grip catheter 1 cm from the tip and thread through the introducer sheath.	To ensure tip is not contaminated (Dougherty 2008, E).
21 Continue slow advancement of the catheter to the desired length.	To minimize damage to intima of vein (Dougherty 2008, E).
22 Apply pressure above introducer and carefully withdraw the introducer and peel apart.	To ensure there is no movement of the catheter. To remove peel-away introducer (Dougherty 2008, E).
23 Aspirate for blood return and flush catheter with 0.9% sodium chloride.	To check patency of device and ensure continued patency (Dougherty 2008, E).
24 Apply gentle pressure on catheter and slowly withdraw the guidewire.	To ensure there is no withdrawal of catheter (Dougherty 2008, E).
25 Attach needleless injection cap and flush as per local policy.	To ensure patency of the device (Dougherty 2008, E).
26 Secure the catheter with sterile tape or other securing device and a small pressure dressing over the insertion site. Apply a transparent dressing. Apply gauze and a bandage.	To ensure stability of device and protection of the site (Dougherty 2008, E).
Post-procedure	
27 Remove gloves and dispose of equipment appropriately. Dispose of sharps and clinical waste.	To reduce risk of sharps injury (NHS Employers 2007, C).
28 Document the procedure in the patient's notes: type, length and gauge of catheter, where it was inserted, any problem, how it was secured.	To ensure adequate records and enable continued care of device and patient (NMC 2010, C).

Problem-solving table 14.2 Prevention and resolution (Procedure guideline 14.5)

Problem	Cause	Prevention	Action
Missed vein (see 'Cannulation').			
Unable to advance catheter.	Valves. Choice of vein, for example cephalic narrows above antecubital fossa.	Select a vein with fewer valves or one with large lumen.	Flush and attempt to advance the catheter. Depending on the length advanced, it may be acceptable to leave it and use for short period of time.

Post-procedural considerations

Immediate care

It is not usually appropriate to suture these devices *in situ*, as they can be adequately secured with Steri-Strips or catheter securement devices such as a Statlock (Perucca 2010). The insertion site can then be covered with a moisture-permeable transparent dressing and changed according to the manufacturer's recommendations, for example once a week. The device should be flushed with 0.9% sodium chloride after each use and then with a heparinized solution according to the manufacturer's recommendations, for example weekly.

Ongoing care

Midline catheters can be left *in situ* for extended periods of time; the optimal time interval for removal of a midline catheter is unknown (Hadaway 2010). Therefore it is recommended that maximum dwell times should be limited to 2–4 weeks (INS 2011). Longer dwell times should be decided on site assessment, length of maintaining therapy and patient condition (INS 2011, Kupensky 1998). Once *in situ*, the catheter should be managed exactly as a CVC. If patient goes home with a midline then they should receive information, equipment and support (see 'Discharging patients home with a VAD *in situ*').

Removal

Removal requires gentle firm traction and the catheter will slide out from the insertion site. Pressure should be applied for at least 3–4 minutes and the site inspected prior to applying a dressing to ensure bleeding has stopped. The catheter integrity should be checked and its length measured to ensure that a complete device has been removed (RCN 2010).

Complications

Mechanical phlebitis is a common side-effect. Close observation and appropriate management such as the application of heat are indicated (see 'Peripheral cannulas, Complications' for more details on management).

Peripherally inserted central catheters

Definition

A peripherally inserted central catheter (PICC) is a catheter that is inserted percutaneously via the veins in the arm and advanced into the central veins, with the tip located in the SVC (usually the lower third) (Hadaway 2010, INS 2011, Nakazawa 2010a, NAVAN 1998, RCN 2010). It is not to be confused with a midclavicular catheter (often referred to as a 'long line') where the tip is located in a central vein leading to the SVC such as the subclavian or proximal axillary vein (Carlson 1999, Dougherty 2006). Because of the increasing evidence that midclavicular catheters are associated with a high incidence of thrombotic complications (up to 60%), midclavicular placement should only be considered if there are anatomical or pathophysiological reasons, for example SVC syndrome (Carlson 1999, Gallieni et al. 2008).

Anatomy and physiology

Choice of vein

Careful evaluation and adequate assessment of the patient prior to attempting catheter placement go a long way to ensuring success. Examine both arms using ultrasound with a tourniquet in place and preferably on the non-dominant arm (Figure 14.19). It has been shown that ultrasonography can increase the chance of successful cannulation of the vein on the first attempt (Lamperti et al. 2012, LaRue 2000) compared with using the traditional landmark method (using surface anatomical landmarks and knowing the expected anatomical relationship of the vein to its palpable

Figure 14.19 Applying the ultrasound probe to the arm to locate veins.

companion artery) (Dougherty 2006, NICE 2002). By using ultrasound, the nurse can position the transducer to obtain a transverse (cross-sectional) or horizontal view of the vein which may aid in the identification of arterial vessels as well as facilitating visualization of solid material, such as a thrombus, in the lumen of the vessel (Hadaway 2010, Weinstein and Plumer 2007) (Figure 14.20, Figure 14.21). The size of the vessels can be improved by use of a blood pressure cuff (Mahler et al. 2011). Choice of vein and vein diameter is vital to avoid thrombosis (Meyer 2011). Dawson (2011) found that thrombosis rates were 57% in cephalic veins, 14% in basilic veins and 10% in brachial veins.

The basilic and brachial veins

The upper basilic vein is the vein of choice for PICC insertions owing to its larger size, straighter course for catheter advancement and improved haemodilution capability (Bullock-Corkhill 2010, NAVAN 1998, RCN 2010) (Figure 14.22).

The basilic vein begins in the ulnar (inner aspect) part of the forearm, runs along the posterior, medial surface (back of the

Figure 14.20 Ultrasound image of veins on screen.

Figure 14.21 Ultrasound cross-sectional image of the right internal jugular vein (IJV) without compression through the probe. Image orientation as seen from the head of the patient. CA, carotid artery; T, thyroid; TA, thyroid artery. Depth of field of image is only 2.8 cm, so all structures are very superficial. *Source:* Hamilton (2009). Reproduced with permission from John Wiley & Sons.

Figure 14.22 Anterior view of superficial veins.

Figure 14.23 Anteromedial view of superficial veins of arm and forearm. *Source:* Tortora and Derrickson (2011). Reproduced with permission from John Wiley & Sons.

arm) and then curves towards the antecubital region, where it is joined by the median cubital vein. It then progresses straight up the upper arm for approximately 5–8 cm and enters the deep tissues. It ascends medially to form the axillary vein (Dougherty 2006, Hadaway 2010). Brachial veins (Figure 14.23) are located deep in the arm alongside the brachial artery and nerve and are slightly smaller than the basilic (Hadaway 2010). Its proximity to the brachial artery means that there is a greater chance of arterial puncture and touching a nerve.

The median cubital vein

The median cubital vein (see Figure 14.23) ascends from just below the middle of the antecubital region and commonly divides into two vessels, one of which joins the basilic and the other the cephalic vein. The median cubital vein is commonly used for blood sampling owing to its size and ease of needle entry. If a practitioner is having difficulty locating and/or cannulating the basilic vein, then the median cubital vein may be used as an alternative insertion route (Sansivero 1998). The catheter will then advance into the basilic (or cephalic) vein.

The cephalic vein

The cephalic vein begins in the radial side (thumb side) of the hand and ascends laterally (along the outer region of the forearm) into the antecubital region, where it forms a junction with the axillary vein. This vein is usually more accessible than the basilic but its size and the sharp angle where it anastomoses with the subclavian make it more difficult to advance the catheter (Dougherty 2006) and therefore it presents a greater potential for catheter tip malposition (Dougherty 2006, Weinstein and Plumer 2007).

Evidence-based approaches

Rationale

The PICC has many advantages over the other central venous access devices. Firstly, it eliminates the mechanical complications associated with CVC placement, particularly pneumothorax (Dougherty 2006, Gallieni et al. 2008). Secondly, PICCs have been shown to be associated with a reduction in catheter sepsis. This may be related to the temperature of the skin and it has been reported that peripheral sites rarely have more than 50–100 colony-forming units (cfu) of bacteria per 10 cm² of skin compared with 1000–10,000 cfu/cm² on the neck and chest (Carlson 1999, Moureau and Gabriel 2009, Philpot and Griffiths 2003). Thirdly, it is easy to use for both staff and patients (Dougherty 2006) as well as helping to preserve peripheral veins (Gabriel 2000, Oakley et al. 2000, Philpot and Griffiths 2003). It has been shown to reduce patient discomfort and provide a reliable form of access (Costa and Ferguson 2002, Oakley et al. 2000) and to be cost-effective when compared with other long-term and short-term catheters and can be inserted at the bedside (Mussa 2014, Snelling et al. 2001, Wilkes 2011).

Disadvantages include an increase in self-care, blood withdrawal is not always easy with the smaller gauges and they may occlude (Dougherty 2006, Molloy et al. 2008). Over time, multiple insertions can cause venous scarring and decrease the ability to reuse the site (Wilkes 2011). It has also been found that compared with skin-tunnelled catheters in patients with gastrointestinal cancers, the advantages of a PICC decrease significantly if treatment lasts more than 120 days (Snelling et al. 2001). PICCs should not be considered as a last resort, but introduced early in treatment (Springhouse 2002).

Indications

- Lack of peripheral access.
- Infusions of vesicant, irritant, parenteral nutrition or hyperosmolar solutions.
- Intermediate to long-term venous access.
- Patient preference.
- Patients with needle phobia, to prevent repeated cannulation.
- Clinician preference if patients are at risk of complications associated with CVAD insertion, for example haemorrhage or pneumothorax, or if other types of devices are contraindicated (Dougherty 2006, Lin et al. 2010, Moureau and Gabriel 2009, Philpot and Griffiths 2003, Yamada et al. 2010).

Contraindications

- Anatomical distortions from surgery, injury or trauma, for example scarring from mastectomy, lymphoedema or burns, which may prevent advancement of the catheter to the desired tip location (Dougherty 2006, Philpot and Griffiths 2003).
- Cardiac pacemaker *in situ*.
- Enlarged axillary/supraclavicular lymph nodes.
- Tumour mass.
- Previous history of thrombosis.
- History of fractured clavicle (may be necessary to avoid that side of patient's body).

Methods of insertion

Venous assessment and selection play key roles in the successful insertion of a PICC, along with the correct positioning of the patient and careful measurement of the patient and the device. To obtain the correct measurement of the length of catheter to be inserted based on anatomical landmarks, using a tape measure, with the arm at 90°, measure from the selected point for venepuncture to the axilla, and then measure total distance of the clavicle and down to the intercostal space. Lum (2004) has since developed a formula-based measurement guide based on a patient's height which provides a more accurate assessment to achieve optimal tip placement (Dougherty 2006) (Box 14.7). Arm

Box 14.7 Formula to calculate measurement for length of PICC (with PICC located 2.5 cm below the antecubital fossa)

Right PICC	Height in cm $\times 3 \div 10$
Left PICC	Height in cm $\times 3 \div 10 + 4$ cm

Source: Adapted from Lum (2004).

adduction and bending can also influence PICC depth and movement (Connolly et al. 2006).

Legal and professional issues

Nurses who wish to undertake this role must be competent in cannulation and receive additional training in theory and practical hands-on instruction at the bedside (Bullock-Corkhill 2010).

Competencies would include:

- knowledge and skills in anatomy and physiology of the veins of the upper arm and central veins
- selection of the vein and equipment
- use of ultrasound and local anaesthetic
- prevention and management of complications.

A number of hospitals and companies now provide PICC training days that may also include the use of ultrasound.

Consent

The benefits (the ability to withdraw blood and infuse medications for long-term access) and risks (bleeding, thrombosis, infection, malposition) must be explained to the patient prior to insertion. Written consent must be obtained. An example of the PICC consent form is shown in Figure 14.24.

Pre-procedural considerations

Equipment

Peripherally inserted central catheters are available as single, double and triple lumen, non-valved or valved (may reduce occlusions) (Bartock 2010, Johnston et al. 2012) and may be made of silicone or polyurethane (Dougherty 2006). They are also available as power injectable devices that can tolerate up to 300 psi (de Lutio 2014, Wilkes 2011). Catheters usually measure 55 cm long, with a diameter of 2–7 Fr (Figure 14.25). PICCs can be cut to the required length, except for those with valves in the tip (Dougherty 2006). A guidewire within a silicone catheter adds firmness, enhancing its advancement. Guidewires are not usually required with a polyurethane catheter (Perucca 2010). The catheter is inserted using a modified Seldinger technique with a microintroducer which reduces the trauma to the vein and risk of arterial or nerve damage (Bullock-Corkhill 2010). It can also be used to facilitate placement in a smaller difficult vein, as well as upper arm placement (Bullock-Corkhill 2010, Sansivero 1998). A cannula is inserted and, once the stylet has been removed, a guidewire is advanced, the cannula is removed and a scalpel is used to enlarge the skin puncture site. Then an introducer is passed over the wire, the wire is removed and the catheter is then advanced via the introducer into the vein (Dougherty 2006, Gabriel 2008, Sansivero 1998).

Pharmacological support

The use of local anaesthetic by injection reduces the pain associated with the initial venepuncture and ensures that the area where the incision is made or deeper tissues are anaesthetized to reduce pain and discomfort (Hartley Jones 2009). Injectable local anaesthetic such as 1% lidocaine is commonly used and it has been found that intradermal lidocaine is superior to EMLA prior to insertion of PICCs (Fry and Aholt 2001).

Consent Form 1

THE ROYAL MARSDEN
NHS FOUNDATION TRUST

Patient's surname/family name:

Patient's first names:

Date of birth:

Responsible health professional:

Job title:

Insertion of a peripherally
inserted central catheter
(PICC)

NHS number (or other identifier):

☐ Male

☐ Female

Patient Agreement to
Investigation or Treatment

Special requirements
(e.g. other language/other communication method)

Name of proposed procedure or course of treatment
(include brief explanation if medical term not clear)

Insertion of a peripherally inserted central catheter (PICC)

The PICC is inserted into a vein in your upper arm and threaded up into the main vein to your heart called the superior vena cava. Before insertion, local anaesthetic will be administered (usually as an injection) around the vein to minimise the chance of pain during the procedure. The procedure takes about 30 minutes, and we will use a tracking device to ensure correct placement however you may still need to have a chest x-ray to confirm the final position of the PICC tip.

Statement of health professional (to be filled in by health professional with appropriate knowledge of proposed procedure, as specified in consent policy)

I have explained the procedure to the patient. In particular, I have explained:

The intended benefits:

☐ This catheter will provide a reliable way to administer your therapy to your vein

.....
.....
.....

To be retained in patient's notes

Title Version Published: Date Published
..... Number

Significant, unavoidable or frequently occurring risks:

☐ There are some risks during insertion – firstly that the needle could cause a bruise or swelling.

☐ The PICC may not thread into the correct position and the tip may not be in the correct vein. This is unlikely now with use of a tracking device during the procedure.

☐ Once the PICC is in place there is a risk of infection. The risk is usually less than 3 in 100 but can be higher depending on many other factors, such as your diagnosis or treatment. Your doctor or nurse will be able to explain the risk to you. You may be able to have antibiotics to treat the infection if it is local around the PICC site. If not the PICC may need to be removed.

☐ Once the PICC is in place there is a risk of a clot (thrombosis) forming around the PICC. This occurs in less than 3 of every 100 patients depending on your diagnosis, treatment or if you have had a clot before. Your doctor or nurse will be able to explain the risk to you. You may need to take anticoagulants (blood thinning) medication and the PICC may need to be removed if the blood clot does not respond to the medication.

Other problems that may arise when the PICC is in place include:

☐ The PICC may become blocked. This can usually be unblocked by the nursing staff but if not the PICC will have to be removed, or

☐ The PICC may split or become damaged and will have to be removed, or

☐ The PICC may become dislodged and if no longer in the correct position it will need to be removed.

Any other risks:

.....
.....
.....

Any extra procedures which may become necessary during the procedure

blood transfusion

other procedure (please specify)

.....
.....
.....

I have also discussed what the procedure is likely to involve, the benefits and risks of any available alternative treatments (including no treatment) and any particular concerns of this patient.

To be retained in patient's notes

Title Version Published: Date Published
..... Number

Figure 14.24 PICC consent form.

Figure 14.25 PICC types.

Procedure guideline 14.6 PICC insertion using modified Seldinger technique with ultrasound

Essential equipment

- Sterile pack containing sterile gown, mask with visor, sterile drapes and scissors
- One pair of sterile gloves
- Alcohol-based hand scrub
- Alcohol-based skin cleaning preparation, such as 2% chlorhexidine in 70% alcohol
- 10 mL syringes
- Needleless injection cap
- MST kit (contains 22 G cannula, wire, 5 mL syringe, introducer/dilator, safety scalpel, needle)
- PICC
- Transparent dressing
- Securing device and sterile tapes
- 23 and 25 G needles
- Tape measure
- Tourniquet
- Sharps container
- Ultrasound machine, gel and sterile probe cover
- ECG leads, electrodes and monitor

Medicinal products

- Pre-filled 10 mL syringes of 0.9% sodium chloride
- Heparinized saline (if necessary)
- 1% lidocaine

Pre-procedure

Action

- 1 Assess patient's medical and intravenous device history.
- 2 Explain and discuss the procedure with the patient. Gain written consent.
- 3 Apply tourniquet and assess venous access using ultrasound, assessing both extremities. Locate and select most suitable vein.
- 4 Where required, apply local anaesthetic cream/gel to chosen venepuncture site and leave for allotted time.
- 5 Draw screens and position patient in a supine position, with patient's arm at a 90° angle.

Rationale

- To ensure the patient has no underlying medical problems such as taking anticoagulants or previous surgery to arm or chest and so is suitable to undergo the procedure (Hamilton 2009, **E**).
- To ensure that the patient understands the procedure and gives their valid written consent (NMC 2013, **C**).
- To ensure the patient has adequate venous access and to select the vein for catheterization (Gabriel 2008, **E**).
- To minimize the pain of insertion (BNF 2014, **C**).
- To ensure privacy. To aid insertion of introducer and then advancement of catheter (Gabriel 2008, **E**).

(continued)

Procedure guideline 14.6 PICC insertion using modified Seldinger technique with ultrasound (*continued*)

Action	Rationale
6 Ascertain the length of the catheter by using the height of the patient as part of the formula (Lum 2004) (see Box 14.7) or by measurement. Measure from the selected venepuncture site to the axilla, then measure total distance of clavicle, and down to the 3rd intercostal space. If using ECG tip confirmation then additional cms will need to be added depending if right or left arm used.	To enable selection of the most suitable catheter length and to establish how far to advance the catheter in order for its tip to be located in the correct position, that is, the SVC (Lum 1999, E ; Lum 2004, R5).
7 Attach ECG leads to electrodes and monitor and apply to patient – black lead to right shoulder and red lead to left thigh.	To ensure an ECG tracing can be obtained and used as a comparison once PICC inserted. E
8 Take equipment required to patient's bedside. Open outer pack.	To ensure appropriate equipment is available for procedure. E
9 Apply facemask with visor.	To protect practitioner from blood splash contamination. E
Procedure	
10 Carefully wash hands using bactericidal soap and water. Dry hands using sterile paper towels in pack.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
11 Put on sterile gown and sterile gloves; open inner pack, arranging the contents as required. If not using pre-filled syringes then draw up 0.9% sodium chloride into a 10 mL syringe (from an assistant). Draw up 1% lidocaine into a 5 mL syringe and attach a 25 G needle.	To prevent contamination (Elliott 1993, E ; Loveday et al. 2014, C). To have medications prepared for use. E
12 Remove the cap from the extension set and attach syringe of 0.9% sodium chloride; gently flush to the end of each lumen and leave syringe attached.	To check that the catheter is patent and to enable easy removal of guidewire (manufacturer's guidelines, C).
13 Place sterile towel under patient's arm.	To provide a sterile field to work on. E
14 Clean the skin at the selected site with 2% chlorhexidine in 70% alcohol, with friction, for 30 seconds, and prepare an area of 15–25 cm.	To ensure the removal of skin flora and to minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
15 Allow the solution to dry thoroughly.	To ensure coagulation of bacteria and disinfection (Loveday et al. 2014, C).
16 Drape the patient with a full body sterile fenestrated drape.	To provide a sterile field (Loveday et al. 2014, C).
17 Ask assistant to add gel to the ultrasound probe. Then apply the sterile ultrasound probe cover over the probe head and pull down along the cable.	To ensure all equipment that is in contact with the patient is sterile (Loveday et al. 2014, C).
18 Retighten the tourniquet.	To aid venous distension (Dougherty 2008, E).
19 Apply gel to skin and scan for vein.	To identify most suitable vein. E
20 <i>Keeping probe in position</i> , inject local anaesthetic intradermally using a 25 G needle and wait for it to take effect.	To provide adequate anaesthesia (BNF 2014, C).
21 <i>Visualizing the vein under ultrasound</i> , perform venepuncture with cannula. When flashback is seen, advance cannula into vein.	To gain venous access (Gabriel 2008, E). To prevent blood loss and 'through puncture' and enable advancement of catheter (Gabriel 2008, E).
22 Release tourniquet and remove the probe.	To contain flashback, prevent contamination of the area with blood and minimize the amount of blood loss from the patient (Gabriel 2008, E).
23 Remove stylet and advance guidewire through cannula until there is 10–15 cm of wire in vein (Action figure 23).	To maintain venous access. E
24 Remove cannula and advance introducer over the wire up to puncture site.	To prepare for insertion. E
25 Infiltrate over the puncture site with 1% lidocaine (intradermally) until a small bleb is observed (Action figure 25).	To achieve anaesthesia and minimize patient discomfort. E
26 Check the patient has no sharp sensations at puncture site and then make a small incision by sliding the tip of the scalpel blade along the top of the wire (Action figure 26).	To ensure area is anaesthetized before proceeding. E

27 Grip the introducer firmly and advance through puncture site (Action figure 27).	To enable advancement of dilator. E
28 Measure from the antecubital fossa to the insertion site to ascertain final measurement.	To ensure correct length of catheter. E
29 If the catheter tip can be trimmed, using the graduated markings along the catheter, select the marking required and pull back guidewire 1 cm from desired new tip, using sterile scissors trim the catheter. Never trim the guidewire!	To ensure the catheter will be the correct length for SVC tip placement and to prevent damage to the vein if the guidewire is damaged (manufacturer's guidelines, C).
30 Remove the wire and then the dilator and grip catheter 1 cm from the tip and thread through introducer sheath.	To enable catheter insertion. E
31 Continue slow advancement of the catheter and aspirate and flush to check for blood return or resistance.	To minimize damage to intima of vein (Gabriel 2008, E). To check there is no obstruction and that it advances into the correct location. E
32 Turn the patient's head towards the arm of insertion and place their chin on the shoulder if possible.	To prevent the catheter entering the jugular vein and to ensure correct advancement of catheter downwards to the SVC (Gabriel 2008, E).
33 Ask patient if they have any aural (behind the ear) sensations on side of catheter insertion.	This could indicate that the catheter has advanced along the internal jugular vein and needs to be withdrawn and readvanced (Dougherty 2006, E).
34 Continue slow advancement of the catheter till unable to advance any further.	To minimize damage to intima of the vein (Gabriel 2008, E).
35 Apply pressure above introducer and carefully withdraw the introducer and peel apart.	To ensure there is no movement of the catheter. To remove peel-away introducer (Gabriel 2008, E).
36 Advance catheter to the hub and do a final check for any aural sensations.	To check for any malposition. E
37 Aspirate for blood return and flush catheter with 0.9% sodium chloride.	To check patency of device and ensure continued patency (Gabriel 2008, E ; Loveday et al. 2014, C).
38 Gently pull back catheter and observe ECG trace for change in P wave. When highest peak in P wave seen, the tip is in correct position.	To ensure tip is located in correct position (Moureau et al. 2010, R5).
39 Apply gentle pressure on catheter and slowly withdraw the guidewire.	To ensure there is no withdrawal of catheter (Gabriel 2008, E).
40 Attach a needleless injection cap and flush as per local policy.	To ensure patency of the device (Gabriel 2008, E ; Loveday et al. 2014, C).
41 Secure the catheter with a securing device such as a Statlock or SecurAcath (fold the device and then slide the prongs down the side of the venotomy and release) (Action figure 41). Apply a small pad of low-linting gauze directly over the insertion site and secure with sterile tape.	To ensure stability of device and to minimize blood leakage at the site which occurs following insertion (Gabriel 2008, E ; Moureau and Iannucci 2003, E ; RCN 2010, C).
42 Apply a transparent dressing. Apply low-linting gauze over the lumens, then bandage.	To ensure protection of the site. To prevent the tubing pressing into the patient's skin (Gabriel 2008, E ; RCN 2010, C).

Post-procedure

43 Dispose of sharps and clinical waste. Remove gloves and dispose of equipment appropriately.	To prevent sharps injury (NHS Employers 2007, C).
44 Send patient for chest X-ray as necessary. Position of catheter to be assessed and documented by the appropriate healthcare professional (see Figure 14.5).	To allow position of tip to be assessed. To ensure correct tip location (Wise et al. 2001, E).
45 Document the procedure in the patient's notes: <ul style="list-style-type: none"> • type, length and gauge of catheter • where it was inserted • tip confirmation by ECG and/or CXR • batch number of catheter and lot number of sterile packs • ECG trace • any problems • how it was secured and • patient education given. 	To ensure adequate records and enable continued care of device and patient (NMC 2010, C). To trace any faulty equipment back to manufacturers (MHRA 2004, C).

Problem-solving table 14.3 Prevention and resolution (Procedure guidelines 14.5 and 14.6)

Problem	Cause	Prevention	Action
Difficulty when advancing catheter (this may be indicated by resistance when advancing the catheter with or without blood return).	Valves. Chosen vein, for example cephalic (size or problems when at junction of axillary vein into subclavian). Muscle spasm in neck.	Select a vein with fewer valves or one with large lumen.	Flush and attempt to advance the catheter. Ask patient to turn head back to normal position and allow neck muscles to relax.
Aural sensations when flushing.	Catheter has advanced into the jugular vein.	Get patient to turn their head to side of insertion and tuck chin down on clavicle to help prevent tip malposition.	Withdraw catheter until sensation has disappeared, turn patient's head and attempt to readvance, checking for sensations. If it continues, it may be necessary to abandon placement in that vein.
Malposition (coiled in vessels, advanced into jugular or accessory veins).	Patient has deviant anatomy. Patient not correctly positioned. Catheter deflected by valves.	Check previous history in case has had previous problems in that vein. Position patient correctly. Advance catheter slowly.	Sit patient upright. Withdraw wire a few cm to allow tip to be more flexible and flush vigorously.

901

Post-procedural considerations

Immediate care

Most PICCs are designed with suture wings, so the PICC can be sutured to the patient's skin. However, patients have reported long-term suturing to be uncomfortable; scarring when the device is removed (Gabriel 2000, Gabriel 2001) and inflammation and bacterial colonization of the exit site (Schears 2005). Therefore suturing is no longer recommended (Maki 2002). PICCs can be adequately secured using Steri-Strips or securement devices such as self-adhesive anchoring devices applied to the skin (such as Statlocks) or SecurAcath (Figure 14.26). These have been shown to result in significantly longer catheter dwell times and fewer total complications (Gabriel 2001, Maki 2002, Schears 2005, Yamamoto et al. 2002). Bleeding occurs in the first 24 hours so a fold of sterile gauze should be placed over the site under the dressing (Philpot and Griffiths 2003). The insertion site is then covered with a moisture-permeable transparent dressing.

Tip location technology is available that enables tracking of the PICC during insertion to identify malposition, e.g. Sherlock or Navigator (Naylor 2007). The position of the tip of the PICC

should be verified immediately after insertion before any infusion. This can be done by a chest X-ray or ECG. Ascertaining correct placement is the major reason for ordering a chest X-ray, but a chest X-ray also rules out malposition and confirms acceptable tip location for the type of medication being administered (Dougherty 2006, INS 2011, RCN 2010, Royer 2001, Wise et al. 2001). If using the ECG method to ascertain tip location, the printout and relevant information must also be documented.

Ongoing care

The initial dressing should be changed at 24 hours and then according to dressing manufacturer's recommendations, for example once a week, to minimize the potential for infection and catheter migration (Loveday et al. 2014, NICE 2003, RCN 2010).

Flushing solution and frequency are usually dependent on the type of catheter and so manufacturer's recommendations should be followed. For example, valved catheters are usually flushed once a week with 0.9% sodium chloride, while non-valved catheters may require flushing with a heparinized solution (Loveday et al. 2014, RCN 2010). Care should be taken when using devices such as power injectors for administering intravenous contrast agents via a PICC as the pressure created may lead to catheter rupture. The likelihood of rupture will depend on the gauge and manufacturer of the catheter (Williamson and McKinney 2001) as most manufacturers now provide CT-compatible PICCs, made specifically to withstand the pressure created during CT scanning. The Medicines and Healthcare Products Regulatory Agency (MHRA 2004) recommends that CT contrast using a pressure injector should not be performed via any CVAD that is not CT rated.

Documentation

The following should be documented on insertion (Moureau and Gabriel 2009).

- Vein used.
- Insertion date and time.
- Length of catheter inserted and external length.
- Size of catheter, manufacturer and batch number.
- Number of cannulation attempts, the veins used and problems encountered.
- Flushing solution used.
- Securement method and dressing.
- Signature of practitioner inserting PICC.
- ECG/X-ray confirmation and tip location.

Figure 14.26 PICC with adhesive securing device.

- Type of local anaesthetic used.
- Type of cleaning solutions.

Education of patients and relevant others
See 'Discharging patients home with a VAD *in situ*'.

Complications

On insertion

Haematoma/arterial puncture/hitting a nerve

See 'Cannulation'.

Once in situ

Mechanical phlebitis

See 'Cannulation'.

Thrombosis

A thrombosis is a clot of blood that can be present at the tip of a catheter or can surround the catheter, for example a thrombosis in the upper arm caused by the presence of a PICC. A SVC thrombus occurs when a catheter chronically rubs against the wall of the SVC, provoking a thrombosis at the site, and is often associated with a fibrin sheath. In order for a thrombosis to develop, three factors are required, known as Virchow's triad:

- 1 stasis
- 2 endothelial damage
- 3 hypercoagulable state, caused by the following conditions: diabetes, malnutrition, dehydration, pregnancy, osteomyelitis, smoking, chronic renal failure, cirrhosis, cancer, obesity, sickle cell, surgery, congestive heart failure, oestrogen therapies (Gorski et al. 2010, Qinming 2012, Wilkes 2011).

Incidence can be 1–5% (Qinming 2012), with rates in PICCs 4–5% (Aw et al. 2012, Lobo et al. 2009). There is an increased risk in suboptimal tip position, with the risk decreasing using the subclavian approach, small-bore catheters, basilic rather than cephalic vein and secure fixation (Bodenham and Simcock 2009). It may initially present as PWO or inability for resistance to flushing (Bodenham and Simcock 2009). Symptoms can be very acute or vague. The patient will usually complain of pain in the area such as the arm or neck, oedema of neck, chest and upper extremity, periorbital oedema, facial tenderness, tachycardia, shortness of breath and sometimes a cough, signs of a collateral circulation over the chest area, jugular venous distension and discoloration of the limb (Bodenham and Simcock 2009, Qinming 2012).

Thrombosis can be prevented by correct placement of the tip in the SVC, IVC or RA (Bodenham and Simcock 2009), monitoring of catheter function and flushing with pulsatile positive pressure flush (Mayo 2000). The use of prophylactic anticoagulants such as low-dose warfarin has been shown to be of no apparent benefit (Couban et al. 2005, Young et al. 2005). Full anticoagulation

may be necessary if the patient has had previous thromboembolic events (Bishop 2009).

If a thrombosis is suspected then the patient should have a venogram and ultrasound (Dougherty 2006). Treatment can be either catheter removal or leave the CVAD *in situ* and commence anticoagulation as thrombolytic therapy has proved successful in extreme cases and is often dependent on the size of the clot and area of impaired circulation (Bodenham and Simcock 2009, Gorski et al. 2010). If the catheter is to be removed, patients will be prescribed injectable low molecular weight heparin (LMWH) and this may continue for 6 weeks to 6 months and up to 3 months following removal (Gorski et al. 2010).

Sepsis

Infection is one of the greatest complications associated with a central venous catheter (Dougherty 2006). The catheter provides the ideal opportunity for micro-organisms to either track along the outside of the catheter or be administered via the hub internally into the central venous system. Infections can occur locally on the skin at the insertion site, in the skin tunnel/port pocket or systemically (Wilkes 2011). Signs of infection at the insertion site include erythema, oedema, tracking along the length of the catheter, tenderness at the site, exudate such as pus and offensive smell (Wilkes 2011).

Septicaemia is a systemic infection which is usually characterized by pyrexia, flushing, sweating and rigors (rigors occur particularly when the catheter is flushed) (Wilkes 2011). Prevention is good aseptic non-touch technique and the use of evidence-based guidelines, for example CVC care bundle (DH 2010, Loveday et al. 2014, Wilkes 2011) as well as the use of catheters with antiseptic properties, e.g. impregnated, bonded or coated with antibiotics or chlorhexidine or the addition of chlorhexidine in an impregnated patch or integrated into a gel dressing (DH 2007, Wilkes 2011). If the patient develops symptoms of an infection then site swabs should be taken along with blood cultures (from the device and peripheral veins). The needle should be removed from a port if there is a skin infection and the port should not be reaccessed until the infection has cleared (Wilkes 2011). Depending on the clinical condition of the patient, the CVAD may be removed and/or intravenous antibiotics may be commenced (Gorski et al. 2010).

Removal of peripherally inserted central catheters

Pre-procedural considerations

Removal requires gentle firm traction and the catheter will slide out from the insertion site. A PICC may resist removal because of venous spasm, vasoconstriction, phlebitis, valve inflammation, thrombophlebitis or when a fibrin sheath is present (Gorski et al. 2010). Difficulty may occur in 1% of removals (Drewett 2000). Gentle traction and a warm moist compress can be applied to alleviate venous spasm, resulting in easier removal of the catheter (Gorski et al. 2010, Marx 1995). If there is difficulty with removal then wait 20–30 minutes and try again or leave for 12–24 hours (Dougherty 2006). Other interventions to aid removal include smooth muscle relaxants, hand and arm exercises or relaxation techniques (Gorski et al. 2010, Marx 1995).

Procedure guideline 14.7 PICC removal

Essential equipment

- Dressing pack containing gauze and sterile gloves
- Apron
- Pair of clean gloves
- Cleaning solution
- Occlusive dressing

- Tape
- Bactericidal handrub

Optional equipment

- Sterile scissors
- Specimen container

Pre-procedure**Action**

- 1 Explain the procedure to the patient.
- 2 Place the patient supine if possible.

Rationale

To ensure that the patient understands the procedure and gives their valid written consent (NMC 2013, **C**).

To prevent the risk of air embolism (Scales 2008, **E**).

Procedure

- 3 Wash hands using a bactericidal handrub and gather equipment required. Apply apron and clean gloves.

To minimize the risk of infection (DH 2010, **C**; Fraise and Bradley 2009, **E**).

- 4 Remove transparent dressing and gently remove adhesive securing devices and/or sterile tapes as necessary.

To prepare for catheter removal. **E**

- 5 Apply sterile gloves and clean the insertion site. If there is a SecurAcath *in situ*, remove top of device.

To prevent contamination of the site. **E**

To facilitate the removal of the catheter. **E**

- 6 Using a steady and constant motion, gently pull catheter until it is completely removed from exit site.

To remove the catheter and prevent vein damage. **E**

- 7 Apply pressure with a finger (digital pressure) on a gauze square over exit site for about 2–3 minutes or until bleeding stops.

To minimize blood loss and bruising. **E**

- 8 Cut down the centre of the SecurAcath and remove the device (see **Action figure 8**).

To facilitate the removal of the device. **E**

- 9 Apply dressing.

To provide protection of the entry site. **E**

Post-procedure

- 10 Check marking of length removed and ensure it is the same as length inserted.

To ensure that complete catheter has been removed (RCN 2010, **C**).

- 11 If the catheter is removed because of infection, carefully cut off the tip (approximately 5 cm) of the catheter using sterile scissors and place it in a sterile container for microbiological investigation.

To detect any infection related to the catheter and thus provide necessary treatment (DH 2010, **C**).

- 12 Remove gloves and dispose of waste.

To ensure safe disposal in the correct containers and avoid laceration or injury of other staff. To prevent reuse of equipment (NHS Employers 2007, **C**).

- 13 Document length of catheter removed and reason for removal in care plan.

To ensure adequate records and to enable continued care of device and patient (DH 2011, **C**; NMC 2010, **C**).

Action Figure 8 Removing the SecurAcath device. Source: Reproduced with permission from Interrad Medical, Inc.

Post-procedural considerations

Following removal of the PICC, pressure should be applied for at least 2–3 minutes and the site inspected prior to applying a sterile transparent dressing to ensure bleeding has stopped. The catheter integrity should be checked and its length measured to ensure an intact device has been removed (Dougherty 2006).

Documentation

On removal, the following should be documented: catheter length and integrity, site appearance, dressing applied, reason for removal (Gorski et al. 2010).

Short-term percutaneous central venous catheters (non-tunnelled)

Definition

A short-term non-tunnelled percutaneous CVC is a device that enters through the skin directly into a central vein (Dougherty 2006, Hamilton 2009).

904 Evidence-based approaches

Rationale

Percutaneous non-tunnelled CVCs are commonly used for patients in acute settings and insertion may be in response to an emergency or planned event (Hamilton 2009, Wilkes 2011). Their multilumen configuration allows administration of several solutions at once and they are easy to remove (Dougherty 2006, Ives 2009). However, these catheters are associated with an increased risk of complications such as pneumothorax and infection (Chantler 2009) and the catheter material results in irritation of the inner lumen of the vessel and is more thrombogenic than softer silicone catheters (Dougherty 2006, Springhouse 2002).

Indications

- Short-term therapy (a few days up to several weeks).
- CVP readings.
- Emergency use, for example fluid replacement.
- Absence of peripheral veins (Dougherty 2006).

Contraindications

There are few absolute contraindications as these catheters are often placed in an emergency, but where possible they should be avoided in the following situations.

- Patients who have an existing infection.
- Patients with an existing pneumothorax or poor respiratory function.
- Patients with radiation burns to the insertion site, fractured clavicle or malignant lesion at base of neck or apex of lungs (Dougherty 2006, Scales 2008), SVC syndrome or a history of central placement problems (Hamilton 2009).

Methods of insertion

Choice of vein

These catheters are usually placed in the jugular, subclavian or femoral veins. The shortest catheter and the most direct route are required to create a rapid blood flow around the catheter, which reduces irritation and obstructions and the risk of complications, and increases the dwell time of the catheter (O'Grady et al. 2011, Weinstein and Plumer 2007). The preferred vein for most CVCs is the subclavian (Weinstein and Plumer 2007). This route has the lowest risk of infection (Chantler 2009, Mermel et al. 2001), allows greatest patient mobility after insertion and provides a flatter

surface to maintain a dressing (Hadaway 2010). Disadvantages are an increased risk of pneumothorax and difficulty controlling bleeding (Chantler 2009).

The jugular vein approach can be via the internal or external jugular vein. The anatomical location of the internal jugular vein makes it easier to catheterize than the subclavian vein and there is less risk of pneumothorax (Chantler 2009, Hadaway 2010). The external jugular vein is observable and easily entered and insertion complications are rare (Weinstein and Plumer 2007). Disadvantages include catheter occlusion and venous irritation as a result of head movement, difficulty in maintaining an intact dressing, and the position of the catheters being disturbing for patient and family (Chantler 2009, Dougherty 2006, Weinstein and Plumer 2007). The femoral veins are primarily used for short-term access when other sites are not suitable (O'Grady et al. 2011). This route is associated with an increased risk of infection and thrombosis, difficulty in maintaining an intact dressing and inhibiting the patient's mobility (Chantler 2009, Dougherty 2006, Hadaway 2010).

Central venous catheter insertion is a sterile procedure and the insertion should be performed following the central venous catheter care bundle which includes the use of a mask, sterile gloves, a gown and sterile full body drapes (DH 2011, INS 2011, Loveday et al. 2014, O'Grady et al. 2011, RCN 2010). These catheters can be inserted at the patient's bedside, but it is recommended that the procedure is performed in a controlled environment to reduce the risk of contamination (Dougherty 2006). This procedure is usually performed by doctors although more nurses are expanding their roles to include it (Alexandrou et al. 2010a, Alexandrou et al. 2010b, Hamilton 2009).

Insertion can be aided by the use of ultrasound (Bodenham 2009). Ultrasound guidance should be used routinely when a CVC is being inserted via the jugular or femoral vein whether in an elective or emergency situation (NICE 2002, Wigmore et al. 2007). Ultrasound has been shown to decrease failure by 83% and reduce complications by 57% (NICE 2002).

Methods for the Valsalva manoeuvre and Trendelenburg position

Placing the patient in the Trendelenburg position facilitates entry to the vein by distending the vein, increasing CVP and venous blood supply, making veins more visible and accessible (Farrow et al. 2009). It also reduces the chance of air embolism because the venous pressure is higher than atmospheric pressure. This is especially important when the catheter is placed using the subclavian approach (Dougherty 2006). A rolled towel may be placed under the back along the spinal cord and between the shoulders to hyperextend the neck and clavicle (Weinstein and Plumer 2007). The Valsalva manoeuvre can be performed by conscious patients to aid insertion of the catheter and also to prevent air embolism (Dougherty 2006, Verghese et al. 2002, Weinstein and Plumer 2007). The patient is asked to breathe in and then try to force the air out with the mouth and nose closed (i.e. against a closed glottis). This increases the intrathoracic pressure so that the return of blood to the heart is reduced momentarily and the veins in the neck region become engorged (Dougherty 2006).

Legal and professional issues

Nurses who wish to undertake this role must receive additional training in theory and practical hands-on instruction at the bedside in insertion techniques and ultrasound (Bullock-Corkhill 2010). Competencies would include knowledge of anatomy and physiology of the vasculature of the neck and the chest, selection of the vein and equipment, use of ultrasound and local anaesthetic, and prevention, recognition and management of complications (Leung 2011, Paolucci et al. 2011, Wilbeck 2011). It is also recommended that nurses have had previous training in critical care or theatre or have Advanced Life Support skills so they can

Figure 14.27 Non-tunnelled multilumen central venous catheter.

respond appropriately in the event of an emergency during insertion (Hamilton 2009).

Pre-procedural considerations

Equipment

Catheters

Most catheters are made of polyurethane and may be single- or multi- (up to five) lumen devices (Figure 14.27). There are a variety of lumen gauges and the catheters vary in length. They are usually open-ended but lumens can exit at staggered points along the catheter (Figure 14.28) (Dougherty 2006, Ives 2009). Multilumen catheters carry a high risk of infection, which has resulted in the manufacture of coated and impregnated catheters, which may have antimicrobial agents such as chlorhexidine, silver sulphadiazine or antibiotics bonded onto the surface (Hill et al. 2010, Monzillo et al. 2012). It has been shown that this can reduce the incidence of catheter-related bloodstream infections and their use is strongly recommended by the Department of Health (Bassetti et al. 2001, Loveday et al. 2014, RCN 2010, Sampath et al. 2001). Care must be taken as patients have been known to develop sensitivity to chlorhexidine (MHRA 2012) or the medications impregnated on the catheter (Lai et al. 2013).

Figure 14.28 Types of catheter tips. (a) Open-ended catheter (single and double lumen). (b) Staggered exit open-ended catheter.

Pharmacological support

Since these devices are usually in constant use, 0.9% sodium chloride is the flushing solution of choice to reduce the risk of occlusion (Loveday et al. 2014). It may be appropriate to use continuous infusions to keep the vein open. 1% Lidocaine is often used to provide anaesthesia prior to cannulation and advancement of the introducer.

Specific patient preparation

When inserting the catheter, the following aspects should be assessed prior to insertion (Hamilton 2009).

- Allergies.
- Physical examination, for example physique, weight (obesity, cachexic), physical features (bull neck, lymphoedema, tracheostomy).
- Vascular assessment.
- Assessment of respiratory, cardiovascular and neurological function.
- Fractures and arthritis, shape of sternum.
- Infection issues.
- Radiological assessment/thrombosis.
- Laboratory assessment, for example biochemistry, coagulation, platelets.

In general, the nurse's responsibilities when assisting another practitioner include the following.

- To ensure, where possible, that the patient understands and has been given a full explanation of the procedure and had the opportunity to discuss any aspects.
- To explain any specific pre- and post-procedure instructions and the appearance and function of the catheter.
- To teach the patient techniques that may be required during insertion, the Valsalva manoeuvre and being placed in the Trendelenburg position (where the patient lies flat with the head lower than the feet; knees may be bent) (Dougherty 2006, Weinstein and Plumer 2007) (Figure 14.29).
- To assemble the equipment requested.
- To prepare local anaesthesia and dressing materials.
- To ensure the correct positioning of the patient during insertion, that is, in the supine or Trendelenburg position.
- To attend to the physical and psychological comfort of the patient during and immediately following the procedure.
- To ensure that no fluid or medication is infused before the correct position of the catheter is confirmed on X-ray by an appropriate clinician and the tip location is documented in the patient's notes.

Figure 14.29 Ways of achieving the Trendelenburg position.

Procedure guideline 14.8 Short-term central venous catheter (non-cuffed/tunnelled) insertion into the internal jugular vein

Essential equipment

- Sterile pack containing sterile gown and drapes
- One pair of sterile gloves
- Alcohol-based hand scrub
- Alcohol-based skin cleaning preparation, such as 2% chlorhexidine in 70% alcohol
- 10 mL syringes
- 5 mL syringes
- Needleless injection cap
- Introducer
- Central venous catheter and kit
- Transparent dressing
- Sutures/Securing device
- 21 G needle
- Cannulas 22 G
- 23 G needle
- 25 G needle
- Labels
- Ultrasound machine
- Ultrasound gel
- Ultrasound probe cover

Optional equipment

- Securing device

Medicinal products

- 0.9% sodium chloride
- 1% plain lidocaine 10 mL

Preprocedure

Action	Rationale
1 Gain consent from doctor to carry out procedure and assess patient's medical and intravenous device history.	To ensure the patient has no underlying medical problems and is suitable to undergo the procedure. E
2 Explain and discuss the procedure with the patient and obtain written consent.	To ensure that the patient understands the procedure and gives their valid written consent (NMC 2013, C).
3 Draw screens and position patient in a supine position.	To ensure privacy. To aid insertion of introducer and then advancement of catheter (Gabriel 2008, E).
4 Wash hands using a bactericidal handrub.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
5 Take equipment required to patient's bedside. Open outer pack.	To ensure appropriate equipment is available for procedure. E

Procedure

6 Wash hands using a bactericidal handrub.	To minimize the risk of infection (Fraise and Bradley 2009, E ; Loveday et al. 2014, C).
7 Put on sterile gown and powder-free sterile gloves; open sterile tray, arranging and preparing the contents as required.	To prevent contamination. Powder on gloves can increase the risk of mechanical phlebitis (Elliott 1993, E ; Loveday et al. 2014, C).
8 Pre-fill the syringe with 0.9% sodium chloride and flush each lumen of the catheter and then slide clamp across lumen.	To prevent blood loss and risk of air entry. To ascertain that all lumens are patent. E
9 Place sterile towel under patient's selected site.	To provide a sterile field to work on. E
10 Clean the skin at the selected site with 2% chlorhexidine in 70% alcohol, with friction, and prepare an area of 15–25 cm.	To ensure the removal of skin flora and to minimize the risk of infection (Loveday et al. 2014, C).
11 Allow the solution to dry thoroughly.	To ensure coagulation of bacteria and disinfection (Loveday et al. 2014, C).
12 Drape the patient with a sterile full body fenestrated towel.	To provide a sterile field (Loveday et al. 2014, C).
13 Ask assistant to tip the patient head down into the Trendelenburg position.	To encourage venous filling and reduce risk of air embolism (Farrow et al. 2009, E).
14 Ask assistant to apply ultrasound gel to head of probe. Then apply sterile ultrasound probe cover.	To improve conductivity. E To maintain sterility during procedure. E
15 Apply ultrasound gel to neck and scan the side of the neck from below the ear lobe to the clavicle to locate the internal jugular vein and other vessels.	To identify and select suitable vein and vessels to avoid, for example thrombosed vessels or arteries. E
16 Inject local anaesthetic intradermally using a 25 G needle to the area over the selected vessel and wait for it to take effect.	To ensure that the area is anaesthetized and reduce patient discomfort. E
17 Attach an empty 5 mL syringe to the cannula.	To prepare equipment. E

18 Whilst visualizing the vein on the ultrasound machine, insert the cannula directly into the vein at a downward angle of 30–50° (or steeper, up to 60–70° to get clear visualization on the screen), maintaining gentle suction with the syringe plunger.	To gain venous access (Gabriel 2008, E), reduce risk of arterial puncture and to know when the cannula is in the vein – apposition of the anterior and posterior walls of the vein can occur so blood is often only aspirated on withdrawal rather than insertion (Farrow et al. 2009, E).
19 When blood is observed in the syringe, advance the cannula off the stylet and into the vein. Check that the blood is dark and non-pulsatile.	To ensure the cannula is in the vein and not the artery as it would then be bright red and pulsatile although the most reliable method of checking is to perform a blood–gas analysis (Farrow et al. 2009, E).
20 Remove stylet, apply a digit over the entry and thread the guidewire through cannula until selected depth is reached (this will depend on side used and anatomy of patient). Keep hold of the guidewire at all times.	To prevent air entry and to prevent contamination of the area with blood and minimize the amount of blood loss from the patient (Gabriel 2008, E). If placed too deeply, patient will have arrhythmias (Farrow et al. 2009, E).
21 Remove cannula and advance dilator over the wire up to the puncture site.	To prepare for advancement of dilator. E
22 Make a small incision in the skin at the puncture site.	To aid the advancement of the dilator through the skin. E
23 Advance the dilator using a gentle corkscrew motion to dilate the soft tissues. Advance to about same depth as cannulation and then remove.	To facilitate the passage of the catheter (Farrow et al. 2009, E).
24 Remove the catheter from the plastic cover and advance over the wire and into vein via the puncture site.	To maintain sterility until required. To commence insertion of catheter. E
25 As the catheter is advanced along the wire, keep hold of wire from the end of the lumen and ensure it moves freely.	To ensure that the wire is not kinked or stuck within the vessels (Farrow et al. 2009, E).
26 Continue slow advancement of the catheter to the desired length (15 cm on right and 17 cm on left) then remove wire.	To minimize damage to intima of vein (Gabriel 2008, E). To check there is no obstruction and that it advances into the correct location (Farrow et al. 2009, E).
27 Aspirate and flush all lumens with 0.9% sodium chloride.	To check for blood return or resistance. To check the patency of the device and ensure continued patency (Gabriel 2008, E ; Loveday et al. 2014, C).
28 Return the patient to a supine position.	To aid patient comfort. E
29 Attach needlefree caps.	To ensure a closed system. E
30 Clean the insertion site and attach the wings of the catheter to the securing device.	To ensure protection of the site. To prevent the tubing pressing into the patient's skin (Gabriel 2008, E ; RCN 2010, C).
31 Suture to the skin or attach to a securing device. Cover with a transparent dressing.	To ensure stability of the device (Gabriel 2008, E ; RCN 2010, C).

Post-procedure

32 Remove gloves and dispose of equipment appropriately. Dispose of sharps and clinical waste.	To prevent sharps injury (NHS Employers 2007, C).
33 Send patient for chest X-ray. Position of catheter to be assessed and documented by the doctor. The X-ray should also be checked to ensure there is no pneumothorax.	To allow position of tip to be assessed. To ensure correct tip location and that there is no pneumothorax (Wise et al. 2001, E).
34 Document the procedure in the patient's notes: <ul style="list-style-type: none"> • type of catheter (number of lumens) • number of passes (times needle inserted) • length and gauge of cannula • vein used • any problems • ability to aspirate blood • how it was secured • tip confirmation • patient education • serial number of catheter and ultrasound machine used. 	To ensure adequate records and enable continued care of device and patient (NMC 2010, C).

Problem-solving table 14.4 Prevention and resolution (Procedure guideline 14.8)

Problem	Cause	Prevention	Action
Unable to advance wire, dilator or catheter.	Anatomical deviation. Valves.	Use of ultrasound prior to insertion. Good history taking and physical examination prior to commencing procedure.	Do not force the wire, dilator or catheter as it may rupture a vessel. Remove and reposition patient. If still having problems, remove the wire/catheter and change site or contact a more experienced colleague.
Unable to achieve blood flashback.	Vein may be transfixied. Vein missed.	Use of ultrasound to visualize vein.	Blood may only be aspirated on withdrawal rather than insertion. Withdraw the needle slowly, aspirating gently until flashback seen.
Arterial blood aspirated.	Arterial puncture.	Accurate use of ultrasound and steep needle insertion to avoid past pointing.	Withdraw needle and press on site firmly for at least 5 minutes to prevent major haematoma formation.
Occurrence of arrhythmias on inserting the wire.	Wire inserted too far.	Assess likely distance to heart prior to insertion.	Withdraw wire 2–3 cm.
Air aspirated from needle.	Pleural space entered during insertion.	Accurate use of ultrasound.	Abandon procedure. Contact medical team urgently to request insertion of chest drain.
Pneumothorax on post-procedure CXR.	Pleural space entered during insertion.	Accurate use of ultrasound.	Contact medical team urgently to request insertion of chest drain.

Post-procedural considerations

Immediate care

The catheter may be sutured in place but this is no longer recommended due to the risk of infection and the need to reduce use of sharps (Crnich and Maki 2002, HSE 2013, Maki 2005). The use of other securement devices is recommended such as a Statlock (Figure 14.30).

Figure 14.30 Statlock securement device.

Ongoing care

Flushing is recommended after each use of the catheter. The types of dressings used at the insertion site may vary according to the type of patient and unit. Staff in some critical care units do not dress the site but clean it every 4 hours whilst other units may use a moisture-permeable dressing which is changed as necessary, for example weekly (Scales 2008). This enables the staff to observe the site regularly for any signs of infection. Repeated changes of dressing, for example at the jugular site, may increase the risk of infection (Timsit et al. 2012). It is recommended that these types of catheter remain in for 10–14 days. They can then be removed or the site rotated (Timsit 2000) or they can be replaced over a guidewire (Cook et al. 1997).

Complications

Air embolism

Air embolism can occur in conjunction with any entry into the vascular system but commonly occurs at insertion and removal of central venous catheters (Cook 2013). For air to enter the vascular system, a pressure gradient between the vascular space and atmospheric air must exist, giving a direct line of access to the blood vessel (Cook 2013). The severity of the embolism depends on:

- *the volume of air that enters the vessel:* there is not an exact volume of air that is significant but usually any air greater than 50 mL is considered potentially lethal
- *the rate of entry:* rapid bolus injection may cause cardiovascular collapse whereas gradual accumulations (of microbubbles) may go unnoticed
- *the patient's position at time of entry:* patients sitting upright during removal are at greater risk (passive air entry). Active air entry may occur when using pressure bags or if tubing has not been primed correctly or syringes are not purged of air (Cook 2013).

Incidence is considered low but the true frequency is unknown, estimated at 1:47 to 1:3000 (Cook 2013). For prevention see Box 14.8. Signs and symptoms are sudden dyspnoea, light-headedness, shoulder and chest pain, tachypnoea, tachycardia and hypotension (Cook 2013). Management includes turning the patient onto the left side and in the Trendelenburg position.

Box 14.8 Prevention of air embolism

During insertion and removal	Position supine or Trendelenburg
	Get patient to perform Valsalva manoeuvre
	Use air occlusive dressing for 24 hours
During use and maintenance	Expel air from all IV systems before attaching to the patient
	Use Luer-Lok connections to prevent accidental disconnection of tubing
	Examine equipment for cracks or leaks which may allow ingress of air
	Use infusion devices that have air in line alarms
	Don't allow collapsible IV fluid bags to run dry

This is the optimal position as it decreases the gradient between atmospheric air and the vessels and holds the entrapped air in the apex of the right atrium to prevent occlusion of the pulmonary artery (Cook 2013). Monitor vital signs and administer 100% oxygen via a mask.

Pneumothorax

Pneumothorax means presence of air in the pleural space between the lungs and the chest wall (Bodenham and Simcock 2009, Scales 2008). It can occur for a number of reasons but is the most common complication with central venous catheterization. It results when a needle, guidewire, dilator or catheter inadvertently punctures the lungs during insertion of a central venous catheter. Incidence is 1–4% depending on the experience of the operator, site or technique (Biffi 2012a). It is more common with the subclavian approach due to its anatomical proximity to the lung. It is characterized by shortness of breath and sudden onset of chest pain but it may be clinically silent (Bodenham and Simcock 2009) and only be discovered on the chest X-ray performed following the

procedure. Pneumothorax may also be diagnosed by ultrasound (Lichenstein et al. 2005, Volpicelli 2011). Other symptoms include tachycardia, persistent cough and diaphoresis (Dougherty 2006).

Prevention is based on the skill level of the inserting practitioner (Wigmore et al. 2007) as well as the use of ultrasound (NICE 2003). If symptoms are noted during insertion, the practitioner should stop the procedure. The patient's colour, respirations and pulse should be monitored and oxygen should be administered. In the case of a small pneumothorax, the patient may feel slightly breathless but no intervention is required and the pneumothorax will heal spontaneously (Bodenham and Simcock 2009). However, a large pneumothorax will necessitate the insertion of a chest drain (Biffi 2012a, Scales 2008).

Haemorrhage

This results from damage to the vein and/or artery during or following insertion of a CVAD. It is not usually a serious problem unless the carotid artery is punctured (Bodenham and Simcock 2009, Scales 2008). Incidence is 0–15% (Qinming 2012). The use of ultrasound can help to reduce the risk of arterial puncture as the artery can be visualized during insertion (Bodenham and Simcock 2009, Qinming 2012). It is important to ensure that the patient is not compromised by having a high international normalized ratio (INR) or a low platelet count, or receiving anticoagulant therapy (Bodenham and Simcock 2009). These should all be corrected prior to CVAD insertion by administration of platelets and vitamin K, stopping medication a few days prior to insertion, or changing the patient from warfarin to subcutaneous LMWH, for example tinzaparin (Bodenham and Simcock 2009, Dougherty 2006). If symptoms are noted at the time of insertion and the artery can be located then pressure should be applied for at least 5 minutes (longer if the patient has a bleeding disorder). Pressure is not always possible as the ability to apply pressure depends on the location of the artery (Bodenham and Simcock 2009, Qinming 2012). If symptoms are not recognized immediately then the patient may develop a mediastinal haematoma, which can then lead to tracheal compression and respiratory distress and require surgical intervention (Bodenham and Simcock 2009).

Removal of short-term percutaneous central venous catheters (non-tunnelled)

Central venous catheters should not be removed and replaced routinely to prevent catheter-related infection (Loveday et al. 2014).

Procedure guideline 14.9 Short-term central venous catheter (non-cuffed/tunnelled): removal**Essential equipment**

- Sterile dressing pack (containing gloves)
- Alcohol-based handrub
- Occlusive dressing or other appropriate dressing
- Hypoallergenic tape
- Sterile scissors
- Small sterile specimen container

- Stitch cutter
- Additional sterile low-linting gauze swab

Medicinal products

- Alcohol-based skin cleaning preparation, for example 2% chlorhexidine in 70% alcohol

Pre-procedure**Action**

- 1 Explain and discuss the procedure with the patient.
- 2 Screen the bed.

Rationale

To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).

To allow dust and airborne organisms to settle before the insertion site and the sterile field are exposed. **E**

Procedure

- 3 Wash hands with bactericidal soap and water or bactericidal alcohol handrub. Place all equipment required for the dressing on the bottom shelf of a clean dressing trolley.

To reduce the risk of cross-infection (DH 2010, **C**; Fraise and Bradley 2009, **E**).

(continued)

Procedure guideline 14.9 Short-term central venous catheter (non-cuffed/tunnelled): removal (*continued*)

Action	Rationale
Procedure	
4 Take the trolley to the patient's bedside, disturbing the screens as little as possible.	To minimize airborne contamination (DH 2010, C).
5 Open the sterile dressing pack.	To gain access to sterile field. E
6 Attach an orange clinical waste bag to the side of the trolley below the level of the top shelf.	So that contaminated material is below the level of the sterile field (DH 2010, C).
7 Open the other sterile packs, tipping their contents gently onto the centre of the sterile field. Pour lotions into gallipots or an indented plastic tray where required.	To reduce risk of contamination of contents. E
8 Discontinue the infusion, if in progress, and disconnect the infusion system from the catheter. Clamp the catheter.	To prevent entry of air or leakage of blood when the catheter is disconnected. E
9 Assist the patient into the Trendelenburg position, that is, head slightly lower than feet.	To prevent air entering vein on catheter removal (Drewett 2009, E).
10 Wash hands with bactericidal alcohol handwash.	To reduce risk of cross-contamination (Fraise and Bradley 2009, E).
11 Loosen the old dressing gently.	So that the dressing can be lifted off easily. E
12 Put on clean gloves.	To protect the nurse from any contact with the patient's blood. E
13 Using gloved hands, remove the old dressing and discard it. Remove tapes or securing device.	To remove old dressing without contaminating hands (DH 2010, C).
14 Remove gloves, clean hands and put on sterile gloves from pack.	To minimize the risk of introducing infection (DH 2010, C ; Fraise and Bradley 2009, E).
15 Clean the wound with 2% chlorhexidine in 70% alcohol using back-and-forth strokes, with friction.	To prevent contamination of the catheter on removal, and a false-positive culture result (DH 2010, C).
16 Cut and remove any skin suture securing the catheter.	To facilitate removal. E
17 Cover the insertion site with low-linting gauze.	Swabs are used to discourage the entry of organisms into the insertion site and to absorb any leakage of blood. E
18 Ask the patient to perform the Valsalva manoeuvre.	To reduce the risk of air embolus (Drewett 2009, E).
19 Hold the catheter with one hand near the point of insertion and pull firmly and gently. As the catheter begins to move, press firmly down on the site with the swabs. Maintain pressure on the swabs for about 5 minutes after the catheter has been removed.	Pressure is applied to prevent haemorrhage and to encourage resealing of the vein wall. It also prevents the entry of air into the vein. E Continued pressure is necessary to allow time for the puncture in the vein to close. E
20 Remove the catheter and check the tip is intact.	To ensure that all of the catheter has been removed. E
21 If the catheter is removed because of infection, carefully cut off the tip (approximately 5 cm) of the catheter using sterile scissors and place it in a sterile container for microbiological investigation.	To detect any infection related to the catheter, and thus provide necessary treatment (DH 2010, C).
Post-procedure	
22 When bleeding has stopped (approximately 5 minutes), cover site with a small gauze pad and a transparent dressing.	To detect any infection at exit site. To prevent air entering the vein via the site (Scales 2008, E).
23 Fold up the sterile field, place it in the orange clinical waste bag and seal it before moving the trolley. Dispose of the equipment in the appropriate containers.	To reduce the risk of environmental contamination (DH 2010, C).
24 Make the patient comfortable.	To ensure patient comfort. E
25 Document date and time and reason for removal in patient's notes or care plan.	To ensure adequate records and to enable continued care of device and patient (NMC 2010, C).

Post-procedural considerations**Immediate care**

Major vessels usually heal quickly, but direct pressure must be applied to the site to help this process until cessation of bleeding (Dougherty 2006, INS 2011). A sterile transparent occlusive dressing should be applied (RCN 2010, Scales 2008). Patients should remain flat for a short time after catheter removal to maintain

positive intrathoracic pressure and allow the tissue tract time to seal (Drewett 2009).

Ongoing care

The site is assessed daily until it has epithelialized (INS 2011), usually within 72 hours. The integrity of the catheter should be ascertained, and the date, time and reason for removal must be documented (NMC 2010, RCN 2010).

Skin-tunnelled catheters

Definition

A skin-tunnelled catheter is a long-term catheter that lies in a subcutaneous tunnel before entering a central vein (usually subclavian) (Hadaway 2010). The tunnel commonly exits between the sternum and the nipple. The tip lies at the junction of the SVC and right atrium or within the lower portion of the SVC or the upper right atrium (Dougherty 2006, Galloway and Bodenham 2004) (Figure 14.31).

Evidence-based approaches

Rationale

Tunnelled silicone catheters were first described by Broviac in Seattle in 1973 and were modified by Hickman and his colleagues, who created a larger lumen of 1.6 mm internal diameter (Bjeletich and Hickman 1980). The special features added included an inert antithrombogenic flexible material and a subcutaneous Dacron cuff attached to the catheter (Ives 2009). The cuff has two functions – to secure the catheter and prevent infection.

Indications

A skin-tunnelled catheter is used when safe and reliable long-term venous access is required or if peripheral vascular access is problematic (Dougherty 2006, Wilkes 2011).

Contraindications

As for other CVADs.

Methods of insertion

The insertion of a skin-tunnelled catheter is a surgical procedure usually carried out in an operating theatre or designated area, under aseptic conditions, using fluoroscopy and monitoring of the patient by pulse oximetry and electrocardiogram (ECG) to detect arrhythmias (Benton and Marsden 2002, Dougherty 2006, Galloway and Bodenham 2004, Weinstein and Plumer 2007). The procedure is now also performed by nurse specialists at the bedside and within radiology departments (Benton and Marsden 2002, Boland et al. 2003, Fitzsimmons et al. 1997, Hamilton et al. 1995). The procedure is usually performed under sedation along with the use of local anaesthesia (Dougherty 2006). In some patients, for example children, this procedure would be carried out under general anaesthesia.

The aim of the insertion is to place the catheter tip in the right atrium via the subclavian vein and SVC (Galloway and Bodenham 2004). When there is an SVC obstruction from thrombosis or compression, the femoral vein can be used to access the inferior vena cava. Selection of vessels is as for non-tunnelled CVC. Access may be gained percutaneously using a needle and guide-wire or via an open surgical cutdown procedure.

The catheter can be inserted percutaneously when the venepuncture site is near the subclavian or internal jugular. The tunnelling rod is then passed under the skin and exits at a predetermined point on the chest. The catheter is then attached to the tunnelling rod and drawn through the subcutaneous tunnel. The catheter is then passed into the vein via a peel-away sheath introducer (Davidson and Al Mufti 1997, Galloway and Bodenham 2004, Hadaway 2010). Position is confirmed by the easy aspiration of blood from each lumen and these are then flushed with heparin until correct tip placement has been confirmed. A chest X-ray should be performed after insertion to check for correct placement and rule out pneumothorax (Davidson and Al Mufti 1997, Stacey et al. 1991).

Methods for removal

Removal techniques for skin-tunnelled catheters vary. Removal should only be performed by specially trained nurses or doctors. It is recommended that the patient is placed supine and that aseptic technique is used throughout. There are two methods for removal.

Surgical excision

This method involves locating the cuff and performing a minor surgical excision under local anaesthetic. A small incision is made over the site of the cuff and blunt dissection, that is, using forceps, is carried out to prise the tissues apart (Galloway and Bodenham 2004); this causes less damage to the tissues than using a scalpel. The cuff and the catheter are freed from the surrounding fibrous tissue (Dougherty 2006). The proximal section of the catheter is then removed, cut and then the distal end is removed via the exit site. Once the catheter has been removed, the wound is sutured using interrupted sutures, which can be removed after 7 days (Drewett 2009, Galloway and Bodenham 2004).

Traction method

With the traction method, there is a greater risk of the catheter breaking, which could result in a catheter embolism. It should only be used if the catheter has been in less than 3–4 weeks, healing is delayed or the site is heavily infected as in all of these situations the cuff may not be fixed and is easier to pull out. If movable, the cuff will pull out with a series of tugs, if it passes

through the tissues. If immovable, proceed to surgical removal to avoid breaking the catheter (Drewett 2009).

Legal and professional issues

Nurses who wish to undertake this role must receive additional training in theory and practical hands-on instruction at the bedside in the removal technique and suturing (Bullock-Corkhill 2010). Competencies would include using local anaesthetic, making an incision/use of scalpel, suturing, and prevention and management of complications.

Pre-procedural considerations

Equipment

Polyurethane or silicone skin-tunnelled catheters are available as single, double or triple lumen with a Dacron cuff (Wilkes 2011). The cuff is used to secure the catheter as fibrous tissue grows around it and obliterates part of the subcutaneous tunnel within 1–2 weeks of insertion. As it becomes overgrown with epithelial cells, this also serves to prevent easy passage of micro-organisms from the skin along the catheter into the vein (Wilkes 2011). The cuff is about 1 cm wide (Hadaway 2010) and is usually located about 3–5 cm from the exit site (Stacey et al. 1991, Weinstein and Plumer 2007). Knowledge of the distance of the cuff from the bifurcation may assist the practitioner in locating the cuff during removal of the catheter, although it will vary according to the brand of catheter.

The tip of the catheter may be valved or non-valved (Dougherty 2006, Ives 2009). The disadvantage of a non-valved catheter is the problem of blood reflux, resulting in occlusion. Valved catheters can have the valves in a round closed tip, such as the Groshong catheter, or in the hub. The valve is usually a two-way valve that remains closed at normal vena caval pressure. Application of a vacuum in order to withdraw blood enables the valve to open inwards; positive pressure into the catheter forces the valve to open outwards (Figure 14.32) (Dougherty 2006). The valve opens with minimal positive pressure for infusion but requires four times as much negative pressure for aspiration (Weinstein and Plumer 2007). This feature reduces the risk of air embolism or bleeding resulting from accidental disconnection, elimination of the need for catheter clamping and the need for heparin and

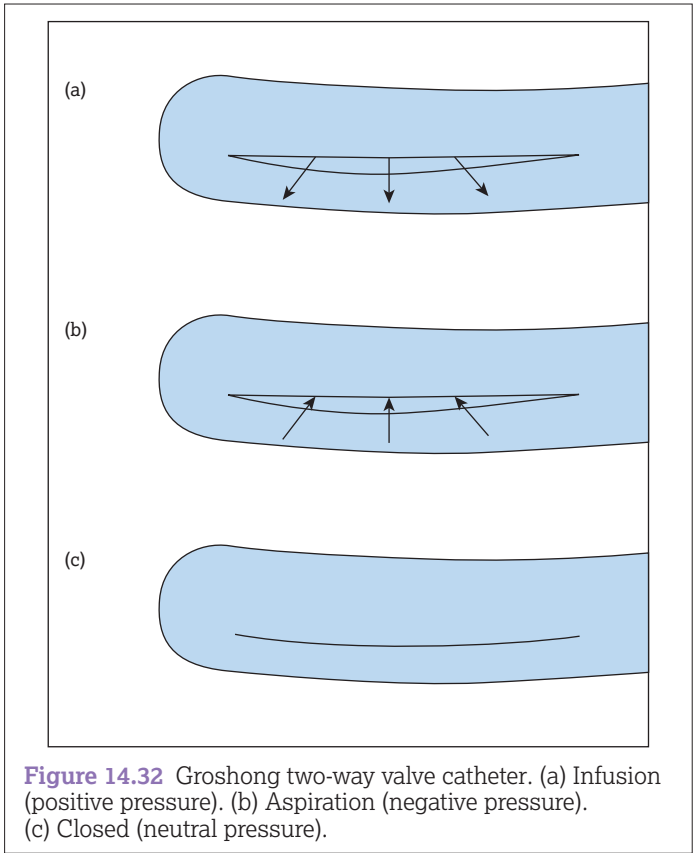

Figure 14.32 Groshong two-way valve catheter. (a) Infusion (positive pressure). (b) Aspiration (negative pressure). (c) Closed (neutral pressure).

the frequency of flushing (Ives 2009). When a valve is incorporated within the hub and not the tip it may reduce the risk of reflux even during periods of raised CVP (Weinstein and Plumer 2007). However, if a thrombus forms around the tip, it can result in malfunction and loss of valve competence (Dougherty 2006).

Procedure guideline 14.10 Central venous catheter (skin-tunnelled): surgical removal	
<p>Essential equipment</p> <ul style="list-style-type: none">• Plastic apron• Sterile gloves• Minor operations set• 10 mL Luer-Lok syringe• 25 G needle• 21 G needle• 10 × 10 cm low-linting gauze swabs × 5• 3/0 Mersilk suture on a curved needle• Transparent dressing	<p>Optional equipment</p> <ul style="list-style-type: none">• Steri-Strips (to be used if necessary)• Specimen container <p>Medicinal products</p> <ul style="list-style-type: none">• 10 mL plain lidocaine 1%• Chlorhexidine 2% in 70% alcohol
<p>Pre-procedure</p>	
<p>Action</p> <ol style="list-style-type: none">1 Check the patient's full blood count and clotting profile for that day.2 Explain and discuss the procedure with the patient.3 Screen the bed and ask patient to remove clothing down to the waist.	<p>Rationale</p> <p>To ensure that the patient is not at risk of bleeding or infection from this invasive procedure. The platelets should be above $100 \times 10^9/L$, the white blood count >2 and the INR <1.3 (Dougherty 2006, E). In haematology patients the platelets should be >50 and the INR <1.5.</p> <p>To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).</p> <p>To ensure ease of access to the patient's chest. E</p>

- 4 Ask patient to lie as flat as possible with their arms by their sides.

To minimize the risk of bleeding from gravitational pressure and to dissuade the patient from touching the sterile field (Dougherty 2006, **E**).

Procedure

- 5 Palpate and identify the position of the cuff in the patient. This can be done by gently pulling on the catheter and observing for skin pucker.

To locate the area for the incision (Drewett 2009, **E**; Galloway and Bodenham 2004, **E**).

- 6 If the cuff cannot easily be felt, measure up from the bifurcation or hub at the end of the catheter distal to the patient, dependent on the type of catheter *in situ*, then palpate again. If it still cannot be felt, ask for assistance from a more experienced colleague.

The cuff will be positioned differently depending on the type of catheter. To locate the probable site of the cuff. To guard against misplaced incisions (Dougherty 2006, **E**).

- 7 Open the outer bag of the minor operation pack.

To gain access to contents. **E**

- 8 Put on plastic apron and wash hands, then dry hands on sterile towel provided in the pack.

To reduce risk of infection (DH 2010, **C**; Fraise and Bradley 2009, **E**).

- 9 Put on sterile gloves and assemble all necessary equipment on the sterile pack.

To maintain asepsis and to prepare for the procedure and maximize efficiency (DH 2010, **C**).

- 10 Advise the patient that you will explain each step of the procedure as you go along if the patient wishes.

This should take into account the patient's individual wish for information. **E**

- 11 Clean the area directly over the cuff with 2% chlorhexidine in 70% alcohol, using back-and-forth strokes, working out from the centre directly over the cuff. Allow the area to dry.

To reduce the risk of infection. To enable disinfection process to be completed. To prevent stinging on insertion of the needle (Dougherty 2006, **E**).

- 12 Apply a fenestrated drape.

To create a sterile field to operate within and therefore reduce the risk of infection (Dougherty 2006, **E**).

- 13 Inform the patient that you are about to administer the local anaesthetic and that this will cause a stinging sensation.

To prepare the patient. The first injection can be painful and causes a stinging sensation (BNF 2014, **C**, **P**).

- 14 With a 25 G needle, administer the first millilitre of local anaesthetic intradermally directly over the cuff site, causing a raised bleb.

To commence the numbing of the area to be incised. To provide a raised area for the next injection and identification of the site (Macklin and Chernecky 2004, **E**).

- 15 Give a further 1–2 mL of local anaesthetic subcutaneously, using the bleb as the area for insertion of the needle but directing the needle out and around the area of the cuff site.

To reduce pain for the patient with repeated injections. To ensure all the incision area is numb (Dougherty 2011, **E**).

- 16 Attach the 21 G needle and with the last remaining 4 mL of local anaesthetic, give two deeper injections to either side of the cuff area.

To ensure anaesthesia at a deeper level during the blunt dissection around the cuff (Macklin and Chernecky 2004, **E**).

- 17 Test the area above the cuff for numbness and then make the incision over the cuff site (but slightly to the side of the cuff site in very thin patients). The incision should be longitudinal and about 2 cm in length. Ensure that the incision is through the epidermis and dermis.

To ensure that the patient will not experience any pain. To facilitate identification and removal of the cuff. To allow access to the cuff which is situated below the dermis. To reduce the risk of cutting through the cuff before the cuff has been identified (Dougherty 2006, **E**; Drewett 2009, **E**).

- 18 With one pair of the small artery forceps, commence blunt dissection of tissue from around the cuff. At intervals, place your finger into the site and feel the cuff.

To free the cuff from the surrounding fibrous tissue. To assess the mobility of the cuff. To reduce the risk of bleeding and damage of catheter (Dougherty 2006, **E**; Drewett 2009, **E**).

- 19 Continue with blunt dissection around and under the cuff until it feels mobile.

To facilitate the loosening of the cuff (Dougherty 2006, **E**).

- 20 With one pair of artery forceps or the dissecting hook, loop under the cuff and lift it up out of the incision.

To identify the catheter to allow removal (Dougherty 2006, **E**).

- 21 Once the cuff is free, still maintaining a grip on the cuff, gently and carefully peel away the thin straw-coloured tissue from the catheter with the blade, ensuring the blade is pulled away from the catheter.

To free the catheter from the anchoring fibrous bands to enable removal. To reduce the risk of accidental incision of the catheter (Dougherty 2006, **E**).

- 22 As the last strands of fibre are separated, you should feel the catheter becoming free and you should be able to see the white material of the catheter.

To ensure that you have completely freed the catheter for removal (Dougherty 2006, **E**).

(continued)

Procedure guideline 14.10 Central venous catheter (skin-tunnelled): surgical removal (continued)

Action	Rationale
23 Ask the patient to perform the Valsalva as the proximal portion of the catheter is withdrawn from the vein and apply gentle pressure at the vein exit site.	To remove the catheter and prevent bleeding or air entry (Drewett 2009, E).
24 Remove the distal portion and cut through the catheter using a blade or scissors and remove via the skin exit site.	To remove the distal half of the catheter below the cuff (Dougherty 2006, E).
25 If the catheter is removed because of infection, carefully cut off the tip (approximately 5 cm) of the catheter using sterile scissors and place it in a sterile container for microbiological investigation.	To detect any infection related to the catheter and thus provide necessary treatment (DH 2010, C).
26 Close the incision with three sutures. Commence the first suture in the middle of the incision, with the remaining sutures evenly on either side.	To close the incision efficiently. To ensure that the skin edges and insert are brought together in alignment (Dougherty 2006, E).
27 If there continues to be any bleeding, Steri-Strips can be applied across the incision over the sutures.	To minimize blood loss (Dougherty 2006, E).
28 It is not usually necessary to suture the exit site.	To leave the exit site to granulate without a suture (Drewett 2009, E).
Post-procedure	
29 Apply a small pressure dressing and cover with an airtight dressing.	To absorb any slight bleed and to maintain a clean site (Scales 2008, E).
30 Advise patient that there might be some oozing and to reapply a dry dressing after 24 hours and thereafter once a day until the sutures are removed. Advise the patient that the sutures should be removed in 7 days.	To ensure that the incision has fully closed and healed (Dougherty 2006, E ; Drewett 2009, E).
31 Dispose of the equipment in the appropriate containers.	To reduce the risk of environmental contamination (DH 2010, C).
32 Ask the patient to rest on the bed for the next 30–60 minutes, or longer if required, especially patients who are prone to bleeding.	To reduce the risk of bleeding and air embolism as the patient sits or gets up (Dougherty 2006, E).
33 Liaise with the nursing team and document the date, time and reason for removal and any problems in the nursing and medical notes.	To ensure there is good communication between all teams and a written record of the procedure (NMC 2010, C).

Problem-solving table 14.5 Prevention and resolution (Procedure guideline 14.10)

Problem	Cause	Prevention	Action
Unable to locate cuff.	Cuff too deep. Lack of knowledge of cuff location.	Knowledge of all types of catheters and where cuff located as measurement differs between manufacturers.	Contact the catheter manufacturer for cuff details.
Bleeding at site.	Low platelets or raised INR. Small vessels cut.	Not undertaking procedure unless levels are corrected.	Apply pressure to site until bleeding stops. May need vessel to be tied off.
Cut through catheter/ catheter breaks.	Removing catheter by traction. Incision made too deeply directly over cuff.	Only remove catheter by using surgical technique. Make incision to side of cuff.	Attempt to clamp any remaining catheter with artery forceps. Contact surgical team for assistance.

Post-procedural considerations**Immediate care****Following insertion**

The dressing should be left intact and changed 24 hours after insertion.

Following removal

Since the vein closes following removal of the catheter, there is usually no bleeding. However, there may be slight bleeding at the exit site immediately after removal because of the passage of the cuff.

Following either removal method, pressure should be applied to the site until the bleeding stops, and a dressing may be required for up to 24 hours. The patient should be encouraged to rest flat for 30–60 minutes to allow the tissue tract time to seal (Galloway and Bodenham 2004).

Ongoing care**Following insertion**

Healing of the skin tunnel takes approximately 7 days, so at this time the sutures at the entry site may be removed (Dougherty 2006). The exit site sutures should be retained until the fibroblastic response to the Dacron cuff is adequate to secure the catheter,

usually in 2–3 weeks (Perucca 2010, Stacey et al. 1991, Weinstein and Plumer 2007). A transparent dressing should cover the site and be changed weekly until removal of sutures. Thereafter, a dressing is not usually required unless the patient requests one (Dougherty 2006).

Following removal

Sutures at the incision site should be removed after 7 days (Dougherty 2006).

Education of patient and relevant others

See 'Discharging patients home with a VAD *in situ*'.

Complications

Infection and thrombosis are the main complications – see 'PICC, Complications'.

Implanted ports

Definition

An implanted port is a totally implanted VAD made of two components: a reservoir with a self-sealing septum which is attached to a silicone catheter (Figure 14.33). The port is usually placed subcutaneously on either the chest or the arm but it can be placed on the lower chest wall/abdomen or thigh, depending on patient needs (Busch et al. 2012, Wilkes 2011). It is accessed percutaneously using a special non-coring (Huber) needle (Dougherty 2006, Weinstein and Plumer 2007, Wilkes 2011).

Evidence-based approaches

Rationale

Ports are implanted subcutaneously to provide repeated long-term access (Weinstein and Plumer 2007) to the vascular system (other ports include arterial, epidural and peritoneal). Implanted ports require little care of the site because of the intact skin layer over the port, except when accessed. When not in use, the only

care required is a monthly flush (Weinstein and Plumer 2007). Other benefits include a reduced risk of infection (Bow et al. 1999, Mirro et al. 1989, Moureau et al. 1999), less interference with daily activities such as bathing or swimming (Wilkes 2011), and body image is less threatened than by the presence of an external catheter (Biffi et al. 2011, Bow et al. 1999, Mirro et al. 1989). Patients with ports are often very satisfied with their access devices (Chernecky 2001, Johansson et al. 2009).

Disadvantages of the port include discomfort when accessing is performed (particularly if placed deeply or in a difficult area to access). This can be overcome with the use of topical local anaesthetic. However, the tissue over the septum becomes calloused or scarred and over time there is loss of sensitivity (Fougo 2012a, Hadaway 2010). Needle dislodgement with resulting extravasation and needlestick injury are well-documented problems associated with ports (Dougherty 2012, Nesti and Kovac 2000, Schulmeister and Camp-Sorrell 2000, Viale 2003). There are also issues related to occlusion and 'sludge' build-up although other designs are attempting to reduce this (Stevens et al. 2000). Finally there are often problems with obtaining blood return (Moureau et al. 1999).

Indications

An implanted port can be used for long-term venous access for all types of therapies, both continuous and intermittent, and if patients have problematic venous access (Bassi et al. 2012, Dougherty 2006, Heibl et al. 2010).

Contraindications

Contraindications would be related to location of port, for example not on the chest if there has been bilateral mastectomy or radiation burns, or inability to undergo a general anaesthetic for insertion if required.

Methods of insertion

Implantation is a surgical procedure carried out under general anaesthetic or sedation and local anaesthetic (Goossens et al. 2011). Some catheters are pre-attached to the reservoir whilst others require attachment on insertion (Dougherty 2006, Wilkes 2011). The most common veins used are the subclavian, internal jugular and femoral or the veins of the upper arm (Hadaway 2010, Pittiruti et al. 2012, Weinstein and Plumer 2007). Ports must be implanted over a bony prominence and most commonly over the bony area below the clavicle, less commonly on the ribs or the forearm (Biffi 2012b, Wilkes 2011).

The catheter is introduced into the SVC via the subclavian or jugular vein and fluoroscopy verifies the placement of the tip. The catheter is then tunneled to the pocket (Dougherty 2006). The pocket is made just under the skin, usually on a bony prominence for stabilization (Wilkes 2011). The port is then sutured into place to the underlying fascia. The suture line can be lateral, medial, superior or inferior to the port septum to remove it from the area where the port will be accessed because repeated access could cause stress to the suture line (Dougherty 2006, Weinstein and Plumer 2007). The area is tender and oedematous for up to a week following implantation and any manipulation/accessing may be painful. When immediate use is indicated, the port should be accessed and dressed immediately following insertion (Wilkes 2011).

They are associated with a low rate of complications, particularly infection (Barbetakis et al. 2011, Beckers et al. 2010, Dal Molin et al. 2011).

Legal and professional issues

Although some nurses insert ports (Hadaway 2010, Pittiruti et al. 2012), many are responsible for accessing and deaccessing the ports. It is vital that the needle is placed in the port because if it is not, there is a risk of the medications extravasating or infiltrating. Therefore any nurse who wishes to access ports must undergo

Figure 14.33 Implantable port cross-section, accessed with non-coring needle.

Figure 14.34 Implanted ports.

Figure 14.35 Non-coring needles have the penetration of a knife so when the needle is removed, the septum closes behind it.

specific training to gain the necessary knowledge and skills to select the correct type and length of needle and access the port successfully with little patient discomfort.

Pre-procedural considerations

Equipment

A variety of ports are available and choice is dependent on a number of factors; for example, whether the patient is a child or an adult, the amount of access required and where it is located (Fougo 2012a). Ports are usually single lumen, although double-lumen ports are available (Dougherty 2006). However, double-lumen ports have two septums and therefore require needle access into each septum (Wilkes 2011). Port reservoirs (Figure 14.34) are about 2.5 cm in height and 0.625 cm in diameter and can weigh from 21 to 28 g; low-profile ports are smaller and often placed in the arm (Ives 2009). Entry can be gained via the side or top but most are accessed by top entry (Weinstein and Plumer 2007). There are now also CT-rated ports that allow CT contrast to be administered through the port without causing damage. Catheters are made of silicone and may be valved or non-valved (Biffi et al. 2011). The port body may be made of stainless steel, plastic or titanium, although stainless steel is rarely used now as it interferes with electromagnetic imaging procedures and is quite heavy in comparison with other materials (Dougherty 2006). The self-sealing silicone septum can be accessed approximately 2000 times (regular size; small ports

may take only 750), often dependent upon the size of the needle used (Hadaway 2010, Wilkes 2011).

Non-coring needles have the penetration of a knife so when the needle is removed, the septum closes behind it (Fougo 2012b, Hadaway 2010) (Figure 14.35). The bevel opens on the side of the needle instead of the end (Gabriel 2008, Weinstein and Plumer 2007). Needles are available in straight or 90° angle configuration with or without extension sets (Wilkes 2011) and with a metal or plastic hub in gauges 19–24 and lengths from 0.65 to 2.5 cm. Needle gauge is selected dependent on type and rate of infusate as well as the location of the port (Dougherty 2006, Fougo 2012b). Safety needles are also now available and activate on withdrawal from the port and are recommended for use (HSE 2013).

Pharmacological support

Prior to accessing a port, topical local anaesthetic may be used over the site (Gorski et al. 2010). Whilst the port is accessed, it is usual to flush it with 0.9% sodium chloride and heparinized saline 50 international units in 5 mL but, once the needle is due to be removed, a higher strength of heparin is recommended – 100 international units heparin per mL to a total of 5 mL (500 international units) (Blackburn and van Bortel 2012, Wilkes 2011). There is now evidence to suggest that ports can be flushed with 0.9% sodium chloride (Bertoglio et al. 2012) and less frequently than monthly is both safe and beneficial (Ignatov et al. 2010, Kefeli et al. 2009, Kuo et al. 2005).

Procedure guideline 14.11 Implanted ports: insertion and removal of non-coring needles

Essential equipment

- Plastic apron
- Sterile dressing pack (containing sterile gloves)
- 10 mL syringes containing 0.9% sodium chloride × 2
- Non-coring (Huber point) needle with extension set
- Plaster

Optional equipment

- Transparent dressing if needle remaining *in situ*

Medicinal products

- Heparinized saline in 10 mL syringe
- 2% chlorhexidine in 70% alcohol

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.

Rationale

To ensure the patient understands the procedure and gives their valid consent (NMC 2013, C).

- | | |
|--|--|
| 2 If required, apply topical local anaesthetic cream for 30–60 minutes. | To reduce the feeling of pain on insertion of the needle. E |
| 3 Place the patient in a comfortable position. | To aid patient comfort and to gain access to port. E |
| 4 Locate the port and identify the septum; assess the depth of the port and thickness of the skin. | In order to select correct length of needle (Dougherty 2006, E). |
| 5 Check length and type of therapy. | In order to select correct gauge and configuration of needle (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |

Procedure

- | | |
|---|---|
| 6 Wash hands using a bactericidal hand soap. Open pack and empty equipment out onto sterile field. | To minimize the risk of contamination (DH 2010, C). |
| 7 Put on sterile gloves. | To minimize the risk of contamination (DH 2010, C). |
| 8 Flush port needle and extension set with 0.9% sodium chloride. | To check patency of needle and set (Dougherty 2006, E). |
| 9 Clean the skin over the port with 2% chlorhexidine in 70% alcohol using back-and-forth strokes. Allow to dry. | To minimize the risk of contamination and destroy skin flora (DH 2010, C). To ensure disinfection (DH 2010, C). |
| 10 Holding the needle in the dominant hand, stabilize the port between the forefinger and index finger of the non-dominant hand (Action figure 10). | To ensure the port is stabilized and will not move on insertion of the needle (Dougherty 2006, E). |
| 11 Inform the patient you are about to insert the needle. | To prepare the patient for a pushing sensation. P, E |
| 12 Using a perpendicular angle, push the needle through the skin until it hits the back plate. | To ensure the needle is well inserted into the portal septum. E |
| 13 Draw back on the syringe and check for blood return. | To check the needle is correctly placed and the port is patent (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 14 Flush with 0.9% sodium chloride and observe the site for any swelling or pain. | To check for patency and correct positioning (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 15 Administer the drug as required. | To carry out instructions as per prescription. E |
| 16 Flush with 10 mL 0.9% sodium chloride. | To ensure all of the drug is administered (RCN 2010, C). |
| 17 If the needle is to remain <i>in situ</i> , attach a needlefree injection cap and flush with heparinized saline using a pulsatile flush and ending with positive pressure. | To maintain patency (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 18 Secure the needle by placing gauze under the needle (if necessary) and cover with transparent dressing. | To ensure the needle is well supported and will not become dislodged (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 19 If the needle is to be removed, then heparinize using 500 IU heparin in 5 mL 0.9% sodium chloride. | To maintain patency over a longer period of time, for example 1 month (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 20 Maintain pressure on the plunger as syringe is disconnected from injection cap. | To prevent backflow of blood and possible clot formation (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 21 Press down on either side of the portal of the implanted port with two fingers. | To support the port while removing the needle (Camp-Sorrell et al. 2004, C ; Dougherty 2006, E). |
| 22 Withdraw the needle using steady traction and activate safety device where appropriate. Discard needle in appropriate sharps container. | To prevent trauma to the skin and the risk of needlestick injury (HSE 2013, C). |

Post-procedure

- | | |
|---|--|
| 23 No dressing is usually required, but a small plaster may be applied. | To prevent oozing at the site. E |
| 24 Remove gloves and dispose of waste in the appropriate containers. | To reduce the risk of environmental contamination (DH 2010, C). |
| 25 Document date of access, size and length of needle and number of attempts in patient's notes or care plan. | To ensure adequate records and to enable continued care of device and patient (NMC 2010, C). |

(continued)

Procedure guideline 14.11 Implanted ports: insertion and removal of non-coring needles (continued)

Action Figure 10 Flushing a port.

Problem-solving table 14.6 Prevention and resolution (Procedure guideline 14.11)

Problem	Cause	Prevention	Action
Unable to access port.	Incorrect length of needle selected. Port too deep or mobile. Unable to locate port.	Choice of correct length needle. Skilled practitioners should access difficult ports.	Ask for assistance from a colleague to locate port and help to stabilize it.
Unable to withdraw blood.	Needle not in port. Fibrin sheath.		Realign needle or remove and ask colleague to access port. Instil urokinase to remove fibrin.

Post-procedural considerations

Immediate care

Once accessed

The needle should be supported with gauze (if necessary) and covered with a transparent dressing to minimize the risk of needle dislodgement.

Ongoing care

Regular assessment of the port when accessed is essential to check for signs of erythema, swelling or discomfort, which could indicate infection, infiltration or extravasation (INS 2011). Most manufacturers recommend that only syringes 10 mL or larger should be used for drug administration or when flushing, to prevent excessive pressure which could result in separation of the catheter from the reservoir or rupture if the catheter is occluded (Conn 1993). When the port is accessed, the needle can remain *in situ* for 7 days (Dougherty 2006, Gorski et al. 2010) although Karamanoglu et al. (2003) found that leaving the needle in place for up to 28 days showed no increase of infection or irritation. When not in use, the port only requires flushing once a month with a concentrated solution of heparin (100 international units in 1 mL), usually a total of 5–6 mL (Blackburn and van Bortel 2012, Gorski et al. 2010, Weinstein and Plumer 2007).

Removal

Implanted ports must be removed using surgical technique and after removal the site must be assessed for any signs of inflammation (Galloway and Bodenham 2004, Labella and Tang 2012).

Education of patient and relevant others

Patients can be taught to access their own ports. See ‘Discharging patients home with a VAD *in situ*’.

Complications

As for all other CVADS.

‘Twiddler’s syndrome’

This term is used to describe patients who nervously touch and potentially dislodge their ports by turning them over so the septum cannot be accessed (Gorski et al. 2010). If this occurs then it may need to be turned back surgically. Explain to patients who ‘twiddle’ their ports why it can result in problems.

Arterial cannulas

Definition

An arterial cannula is a plastic tube inserted and secured in a peripheral or central artery. They are most commonly used in intensive

care units and during surgery to provide the means for continuous intra-arterial pressure monitoring and facilitate frequent blood sampling for blood gas and laboratory analysis (Koh et al. 2008).

Anatomy and physiology

Arteries are elastic, muscular blood vessels which carry oxygenated blood from the left side of the heart. The large pressure generated by the heart and resistance in the arteries ensure that organs and tissues receive highly oxygenated blood (Scales 2008). The safest and most common peripheral sites for arterial cannulation are the radial artery or dorsalis pedis. If peripheral arterial cannulation is not possible then femoral cannulation is the central site of choice.

Arterial pressure waveforms

The arterial waveform has three separate components that reflect the cardiac cycle (Figure 14.36).

- 1 The upstroke: the positive deflection occurs at the peak of systole.
- 2 The dicrotic notch occurs with aortic valve closure and reflects the beginning of diastole.
- 3 The lowest point of the waveform is end-diastole.

Peripheral artery waveforms differ from central arterial waveforms; their traces have a higher peak systolic pressure, a wider pulse pressure and a more prominent dicrotic notch, described as distal pulse amplification (Dorman et al. 1998). This is because peripheral arteries are smaller and less compliant than central arteries. Despite ongoing debate about whether central arterial cannulation (e.g. femoral) is superior to peripheral arterial cannulation when monitoring mean arterial blood pressure (MAP), it appears there is no statistically significant evidence to corroborate this (Mignini et al. 2006).

In addition to the continuous arterial pressure readings, the shape of the arterial waveform can be very informative when assessing the haemodynamic status of a patient. The slope of the arterial upstroke gives an indication of myocardial contractility. Also, an exaggerated swing in systolic pressure is seen on the monitor in pulsus paradoxus, a term used when the difference in peak systolic pressure between inspiration and expiration is greater than 10 mmHg. This is caused by:

- pericardial disease, for example cardiac tamponade causing impeded ventricular filling
- exaggerated inspiration by the patient
- changes in intrathoracic pressure, caused by lung pathology, such as asthma
- hypovolaemia, particularly when the patient has concurrent high airway pressures.

Evidence-based approaches

Rationale

It is worth noting that morbidity associated with arterial cannulation is less than that associated with five or more arterial punctures (Bersten et al. 2009). An arterial puncture is a one-off insertion of a needle attached to an appropriately heparinized syringe enabling the aspiration of blood from the artery for analysis. Arterial punctures are important and useful in the initial and short-term assessment of acid/base balance and respiratory function. However, multiple puncture attempts will increase the risk of injury, not only due to the direct trauma but also associated with vasospasm (Lipsitz 2004). If repetitive blood sampling is necessary, it may be more appropriate to admit the patient into a more clinically suitable area where arterial cannulation is possible. This not only minimizes both the distress to the patient and time taken by skilled personnel in obtaining each sample, but reduces the risks associated with multiple punctures.

An arterial cannula provides an invaluable tool in providing continuous monitoring of systemic blood pressure and facilitates frequent arterial blood gas (ABG) and laboratory sampling. Arterial cannulation is most commonly achieved and maintained in the critical care and theatre setting (Daud et al. 2013, Mignini et al. 2006). Ideally, prior to obtaining any arterial blood gas sample, the patient should be in a respiratory steady state for 15–20 minutes. The oxygen should not be titrated, and if ventilated, suction should not be attempted and ventilation parameters not adjusted (Weinstein and Plumer 2007).

The arterial device is attached to a transducer that enables the mechanical energy of the arterial pressure to be transformed into an electrical signal. This is displayed as a waveform by a haemodynamic monitoring system. An amplifier enhances the signal, which is converted into a digital display and oscilloscope trace (Hazinski 1992). Arterial device tubing should be stiff with low compliance as this prevents the loss of pressure signals through tube expansion, and it must not exceed 120 cm in length because this may alter pressure readings (Daily and Schroeder 1994).

Indications

- During and following major anaesthesia.
- Monitoring of acid/base balance and respiratory status in (Adam and Osborne 2005):
 - acute respiratory failure
 - mechanical ventilation, especially in response to alteration of support and oxygenation
 - the period during and after cardiorespiratory arrest
 - severe sepsis
 - shock conditions
 - major trauma
 - acute poisoning
 - acute renal failure
 - severe diabetic ketoacidosis
 - critically ill patients.

Contraindications

- Previous upper extremity surgery (harvested for pedicled/free flaps).
- Previous axillary clearance.
- Peripheral vascular disease.
- Raynaud's disease.
- Diabetes.
- Collagen vascular disease.
- Active upper or lower limb infection.

Principles of care

In critical care, continuous arterial monitoring is invaluable in optimizing and evaluating treatments, particularly in patients receiving intravenous nitrates and inotropes where their effects on

mean blood pressure (MBP) can be instantaneous, necessitating appropriate titration (Mignini et al. 2006). Arterial devices must be cared for, managed and interpreted by skilled personnel who are able to regularly assess areas distal to the cannula, identify accurate waveforms, distinguish artefact, troubleshoot complications and maintain safe practice. The hazard of disconnection, the necessary monitoring systems, the potential consequence of severe haemorrhage and risks associated with accidental intra-arterial drug administration limit their use outside specialized areas.

Routes of cannulation

Radial arterial cannulation

The radial artery originates from the brachial artery at the neck of the radius and passes along the lateral aspect of the forearm (Drake et al. 2005). The radial artery gives off multiple fasciocutaneous perforators until it reaches the wrist, where it forms the deep palmar arch. It contributes to the main artery of the thumb and index finger (Wallach 2004). The radial pulse can be felt by gently palpating the radial artery against the underlying muscle and bone (Drake et al. 2005). Cannulation of the radial artery is the most common placement of arterial cannulas (Brezezinski et al. 2009, Mignini et al. 2006) and is performed in most acute care settings. The hand has a good collateral blood supply, as the radial artery is near the skin surface, it is readily accessible, easily secured, and the patient is disturbed less (Adam and Osborne 2005, Brezezinski et al. 2009, Wallach 2004). Ideally, the cannula should not be positioned close to any intravenous cannula as this may compromise blood flow around the adjoining structures.

Dorsalis pedis cannulation

The dorsalis pedis originates from the anterior tibial artery and arises at the anterior aspect of the ankle joint (Irwin and Rippe 2008). The dorsalis pedis route for arterial cannulation is equally as risky as radial cannulation, and more technically difficult, but provides a safe and easily available alternative when radial arteries are not accessible (Durbin 1995).

Blood pressure measured from the dorsalis pedis and radial artery typically have a higher systolic and lower diastolic than centrally measured blood pressure (distal amplification), although the mean blood pressure is identical and clinically interchangeable (Mignini et al. 2006). Antiembolic stockings need to be adapted to avoid any pressure on the device itself which may dampen the waveform trace or cause a pressure sore, and also to leave the insertion site visible.

Femoral artery cannulation

The femoral artery may be cannulated if it is not possible to cannulate a peripheral artery. This is particularly useful if the patient is haemodynamically compromised as it can be palpated with relative ease even when there is only a weak pulse (Adam and Osborne 2005). Lower extremity insertion sites such as the femoral artery were thought to be difficult to maintain asepsis and increase the risk of infection but this has not been corroborated (Sheer et al. 2002). Femoral catheters should be positioned at a 45° angle, as there is an increased risk of catheter fracture (Ho et al. 2003). This is particularly serious as there is no collateral blood supply to the leg and lower limb, and as such arterial fracture may have serious long-term consequences for the patient.

Brachial artery cannulation

The brachial artery is the major artery of the arm and divides into the radial and ulnar branches (Irwin and Rippe 2008). A cannula inserted at the antecubital fossa into the brachial artery may risk cannula fracture in the conscious patient due to arm flexion. Its placement may also be uncomfortable and cause inconvenience as the patient will be asked to reduce their arm flexion.

Ulnar artery cannulation

The ulnar artery, along with the radial artery, forms the blood supply to the forearm and hand (Irwin and Rippe 2008). It is often

Box 14.9 Action required by the National Patient Safety Agency when using arterial catheters

- Sampling from arterial devices is risky and should only be undertaken by competent trained staff. Trusts should raise awareness of the risks and review local guidelines. These should include criteria for requests for blood gas analysis, sampling technique, monitoring and interpretation of results (including unexpected findings).
- Arterial infusion sets must be identified clearly. This means labelling or use of safety solutions such as marked sets adopted by some trusts.
- Any infusion (or additive) attached to the arterial catheter must be prescribed before administration. Further checks should be made at regular intervals and key points (such as shift handover).
- Staff should only use sodium chloride 0.9% to keep catheters open.
- Labels should clearly identify the contents of the infusion bags, even when pressure bags are used. Over time, the manufacturers should develop a universal system to address this problem.

Source: National Patient Safety Agency (www.npsa.nhs.uk). © Crown copyright. Reproduced under the Open Government Licence v2.0. For updates see www.england.nhs.uk/.

avoided as it is usually the dominant artery of the hand, providing the most collateral circulation. Cannulation of the ulnar artery is also technically challenging because of its deeper and more painful course; its size also associates it with more risk of bleeding on removal than the radial artery (Brezezinski et al. 2009). For these reasons the ulnar artery is an unfavourable peripheral site and generally avoided.

Legal and professional issues

In 2008 the National Patient Safety Agency (NPSA) published a rapid response report which highlighted the many potential errors associated with the use of arterial cannulas. Various recommendations were given and immediate actions had to be in place by January 2009 (www.npsa.nhs.uk/patientsafety/alerts-and-directives/rapidrr/) (Box 14.9).

In order to minimize risks associated with arterial cannulation, sampling should only be done by competent trained staff (NPSA 2008b).

Pre-procedural considerations

Assessment

It is important prior to any cannulation that the circulation of the hand is assessed: temperature, capillary refill and the colour of the hand (RCN 2010). More than 97% of patients have adequate flow through collateral supply, which prevents ischaemia should either the radial or ulnar artery be interrupted (Durbin 2001). Although not fully reliable, the Allen test should be completed prior to radial arterial cannulation in order to establish whether there is adequate blood supply to the hand (Figure 14.37). The Allen test consists of simultaneously compressing both the radial and ulnar arteries for approximately 1 minute (Tegtmeyer et al. 2006). During this time, the conscious patient rapidly opens and closes the hand to promote local exsanguination. Approximately 5 seconds after release of one of the arteries (usually the ulnar), the extended hand should blush owing to capillary refilling. If blanching occurs, palmar arch circulation is inadequate and a radial cannula could lead to ischaemia of the hand (Pierce 1995).

Evaluation by a Doppler probe may be carried out as a more reliable alternative (Adam and Osborne 2005, Brezezinski et al. 2009). Shiloh et al. (2010) suggest that using ultrasound guidance may improve arterial cannulation.

Figure 14.37 The Allen test.

Procedure guideline 14.12 Arterial cannula insertion: preparation and setting up of monitoring set

Essential equipment

- 500 mL pressure infuser cuff
- Pressure monitoring system equipment
- Designated arterial cannula
- Sterile intravenous pack
- Non-sterile gloves
- Transparent dressing
- Syringes: various sizes
- A label to identify arterial device

- 2% chlorhexidine in alcohol swab
- Transpore tape
- Bactericidal hand cleanser

Medicinal products

- 500 mL bag of 0.9% sodium chloride
- 1% lidocaine injection

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Wash hands using a bactericidal handrub.
- 3 Prepare infusion and transducer sets using aseptic technique.
- 4 Check that all Luer-Lok connections are secure.

Rationale

- To ensure the patient understands the procedure and gives valid consent wherever appropriate (NMC 2013, **C**).
- Note:* many patients are anaesthetized when arterial devices are inserted.
- To minimize the risk of infection (Fraise and Bradley 2009, **E**; Loveday et al. 2014, **C**).
- To minimize the risk of infection (Fraise and Bradley 2009, **E**; Loveday et al. 2014, **C**).
- To prevent disconnection, as equipment is often loose when taken straight from package. **E**

Procedure

- 5 Connect transducer to bag of 500 mL 0.9% sodium chloride, which must be prescribed.

To prepare infusion, saline is more effective than heparinized flush (Gamby and Bennett 1995, **R3**; Kulkarni et al. 1994, **R3**; O'Grady et al. 2002, **C**). Only sodium chloride 0.9% must be used as flush (NPSA 2008b, **C**).

To prime the administration set and three-way tap ports. **E**
- 6 Open roller clamp fully, squeeze the flush device-actuator (see instructions with set).

To reduce the risk of air embolus, although retrograde air embolus is a rare event after routine radial artery cannula flushing. **E**
- 7 Check thoroughly for air bubbles in the circuit.

To reduce the risk of inaccurate pressure readings caused by bubbles in the set (Daily and Schroeder 1994, **R4**).
- 8 Insert bag into pressure infuser, inflate the pressure bag to 300 mmHg.

To prevent backpressure of blood into the transducer set by ensuring pressure is higher than arterial blood pressure (Morton and Fontaine 2009, **R5**). An automatic flush mode is activated within the system which delivers 3 mL per hour, which maintains patency of cannula.

(continued)

Procedure guideline 14.12 Arterial cannula insertion: preparation and setting up of monitoring set (continued)

Action	Rationale
Procedure	
9 Wash hands with bactericidal soap and water or bactericidal handrub.	To reduce the risk of cross-infection (DH 2010, C ; Fraise and Bradley 2009, E).
10 Prepare trolley near the patient.	To reduce the risk of cross-infection (DH 2010, C ; Fraise and Bradley 2009, E).
11 Complete the Allen test if radial artery is to be used.	To assess whether palmar arch circulation is adequate, although this assessment is not entirely reliable (Wallach 2004, R4).
12 Prepare the insertion site with 2% chlorhexidine swab and place a sterile towel under the appropriate area.	To maintain asepsis. To provide a clean working area (DH 2010, C).
13 Administer adequate local anaesthetic.	To minimize pain during the procedure; this may reduce the sudden movement which could result in through puncture (Lipsitz 2004, R5). Local vasodilation effects of the local anaesthetic may reduce vasospasm, making a successful cannulation more likely (Lipsitz 2004, R5).
14 Put on gloves.	To prevent contamination of hands if blood spillage occurs (Loveday et al. 2014, C).
15 Another nurse may act as an assistant and hold the patient's foot or arm. If the radial artery is cannulated, the wrist must be hyperextended.	To prevent movement and to flex the hand/foot slightly to facilitate insertion. E Prolonged hyperextension may be associated with changes in median nerve conduction, so promptly return the wrist to the neutral position following cannulation (Chowet et al. 2004, R4).
16 Insert the cannula and observe for blood flashback.	To ascertain that the cannula is in the artery. E
17 Attach transducer set and fully open roller clamp.	To commence flush infusion system, and prevent backflow of blood. E
18 Apply transparent dressing over the cannula and tape tubing securely.	To leave the site visible and secure and to allow the observer to recognize immediately any dislodgement, inflammation or disconnection. E
19 Clearly label the device as arterial, on the dressing as well as on the tubing.	To ensure the device is not mistaken for a venous cannula, preventing accidental intra-arterial injection of drugs (E), particularly if the tubing is disconnected and cannula capped off, in the event of a transfer (NPSA 2008b, C), although this practice should be discouraged.
20 Loop the tubing around the thumb, ensuring this is not too tight (Action figure 20).	To minimize movement of cannula and damage to the vessel, to prevent ulcer formation. E
21 Connect transducer to monitoring equipment.	Allows checking of arterial waveform and obtaining continuous blood pressure measurements. E
22 Calibrate the arterial device.	The transducer will read an arterial pressure calibrated to atmospheric air which offsets the extraneous atmospheric and hydrostatic pressures. E

Post-procedure

23 Remove gloves and dispose of equipment and clinical waste appropriately.	To prevent sharps injury (NHS Employees 2007, C).
24 Document clearly date and placement of arterial cannula inserted.	To maintain accurate records and provide appropriate reference (NMC 2010, C).

**Action Figure 20** Positioning, securing and labelling of cannula.

Post-procedural considerations

Ongoing care

Arterial cannulas are not replaced routinely so frequent and accurate assessment is essential in order to minimize complications. In the event of a spike in temperature and raised inflammatory markers, removal may be considered.

The arterial cannula site must be assessed at regular intervals to check for appropriate labelling of the device, correct flush fluid, any pain or erythema at the site. The arterial site should (where appropriate) be left exposed to minimize any delay in detecting dislodged devices or exsanguination from the artery. There should always be vigilance if the sample taken from the arterial cannula is not within the expected range and staff must be trained in considering and eliminating any risk of contamination which may affect blood results which could in turn determine changes in consequent therapies. The NPSA (2008b) described a number of serious incidents associated with changes in treatment directly associated with arterial blood sampling results. This was because of inappropriate flush agents, predominantly dextrose;

for example, patients had insulin sliding scale infusions titrated in response to contaminated samples where blood glucose was abnormally high and not reflective of the patient's actual serum glucose.

The following volumes of blood should be withdrawn and discarded in order to clear 0.9% sodium chloride, old blood and small emboli from the dead space, the cannula and the three-way tap.

- Generally, when using a peripheral artery cannula, 3–5 mL must be taken and discarded.
- A femoral artery cannula is longer and commonly 5 mL should be taken and discarded, but always check manufacturer's instructions.

On each shift it is advisable that the site of the cannulated artery is checked and documented, that an appropriate flush agent is prescribed, that labelling is appropriate and there is absence of pain and colour changes distal to the cannula. Arterial administration sets should be replaced every 24–72 hours, depending on local policy (Daud et al. 2013).

Removal of arterial cannula

923

Procedure guideline 14.13 Arterial cannula: removal

Essential equipment

- Sterile dressing pack
- Non-sterile gloves
- Hypoallergenic tape
- 2% chlorhexidine in 70% alcohol

Pre-procedure

Action

Rationale

- | | |
|---|--|
| 1 Explain and discuss the procedure with the patient. | To ensure the patient understands the procedure and gives their valid consent (NMC 2013, C). |
| 2 Check platelet and coagulation screen. | To prevent delay in removal whilst coagulation is corrected. E |
| 3 Prepare trolley. | To reduce the risk of cross-infection (DH 2010, C ; Fraise and Bradley 2009, E). |
| 4 Wash hands with bactericidal soap and water or bactericidal alcohol handrub before leaving the clinical room. | To reduce the risk of cross-infection (DH 2010, C ; Fraise and Bradley 2009, E). |

Procedure

- | | |
|---|---|
| 5 Turn three-way tap diagonally or turn off flow switch, depending on arterial product. | To prevent backflow of blood into cannula. E |
| 6 Turn off flush set. | To prevent spillage when removing cannula. E |
| 7 Deflate pressure cuff. | Pressure is no longer required. E |
| 8 Loosen transparent dressing and tape from the cannula site. | To facilitate removal of cannula. E |
| 9 Clean hands with bactericidal skin-cleaning solution. | To minimize the risk of infection (DH 2010, C ; Fraise and Bradley 2009, E). |
| 10 Apply gloves. | To prevent contamination of hands with blood (Loveday et al. 2014, C). |
| 11 Remove dressing and tape. Clean cannula site area with 2% chlorhexidine swab. | To reduce the risk of infection (DH 2010, C ; Fraise and Bradley 2009, E). |
| 12 Place sterile gauze over area and gently remove cannula. | To minimize bleeding and blood spillage (Loveday et al. 2014, C). |
| 13 Apply pressure for a minimum of 5 minutes. | To prevent haematoma and blood loss (RCN 2010, C). |
| 14 Apply a clean, sterile, low-linting gauze dressing. | To maintain asepsis and minimize blood loss. E |
| 15 Secure with tape. Do not create a tourniquet type dressing. | To ensure pressure and prevent haematoma or blood loss. E |

(continued)

Procedure guideline 14.13 Arterial cannula: removal (continued)

Action	Rationale
Post-procedure	
16 Remove gloves and dispose of equipment appropriately.	To prevent sharps injury (NHS Employers 2007, C).
17 Document the date and time of removal in the patient's notes.	To ensure adequate records and enable continued care of device and patient (NMC 2010, C).

Problem-solving table 14.7 Prevention and resolution (Procedure guideline 14.13)

Problem	Cause	Prevention	Action
Backflow of blood into the cannula.	The pressure infusor cuff may not be inflated to the optimum.	Ensure that the pressure infusor cuff is inflated to 300 mmHg.	Check that the pressure infusor cuff is inflated to 300 mmHg and, if not, inflate to correct level.
Arterial spasm.	Forceful flushing or forceful aspiration when withdrawing blood.	When the flushing pressure is higher than arterial blood pressure an automatic flush mode is activated in the system which delivers 3 mL per hour. This maintains patency of circuit, cannula and artery (Allan 1984).	Check that the pressure infusor cuff is inflated to 300 mmHg and, if not, inflate to correct level.
Cerebral embolism.	Prolonged, high-pressure flushing can drive a clot or gas bubbles retrograde to produce cerebral embolism.	Avoid forceful flushing or aspiration and maintain a slow even pressure when withdrawing blood.	Check that the pressure infusor cuff is inflated to 300 mmHg and, if not, inflate to correct level.

Post-procedural considerations**Immediate care**

Following the procedure, check the patient's hand, assessing and documenting the temperature, colour, swelling and any signs of bleeding. Avoid blood pressure measurement being taken manually on the arm where the arterial cannula was removed for 12–24 hours to minimize bleeding or haematoma formation. Medical staff must be informed immediately if the hand or forearm becomes discoloured or swollen, or if the patient complains of pain in the limb. In the event of any complication, careful documentation is essential; consider a request for medical photography to photograph the affected area.

Education

Ask the patient to apply pressure if they notice any oozing from the dressing and immediately inform a member of staff.

Complications

There are a number of complications that can occur as a result of arterial cannulation: see Box 14.10.

Box 14.10 Complications of arterial cannulation

- Vascular thrombosis
- Distal embolization (see Box 14.11)
- Proximal embolization: digital ischaemia
- Local/systemic infection
- Vascular spasm
- Skin necrosis of catheter site due to accidental intra-arterial injection
- Hypovolaemia secondary to accidental disconnection
- Cannula fracture/breakage
- Pseudo-aneurysm formation
- Median nerve palsy (Bersten et al. 2009)
- Damage to nearby structures

Box 14.11 Treatment of distal embolism

- Remove the cannula.
- Arrange for Doppler imaging.
- After consultation with consultant, heparinize (if no contra-indications).
- Consider a peripheral vasodilator.

Infections

If the arterial device is inserted under emergency conditions and asepsis has been compromised, the Communicable Diseases Centre (O'Grady et al. 2011) recommends that the cannula should be replaced within 24 hours. Colonization and infection of arterial devices are rare (Minnaganti and Cunha 2000) and are usually related to duration of cannulation.

Historically, arterial cannulas were associated with a significantly lower risk of local cannula-related infection when compared to short-term peripheral venous cannulas which have been left *in situ* for the equivalent length of time. Despite a common risk of catheter colonization, serious soft tissue infections are very rare, which may be related to exposure to high vascular pressures and subsequent local turbulence experienced in arterial cannulas (Koh et al. 2008, O'Grady et al. 2011, RCN 2010). However, more recent studies have begun to challenge this theory and suggest that infection risks are actually comparable to those of central venous catheters (Gowardman et al. 2010). Additionally, if the puncture site is well stabilized and treated with asepsis and all samples are obtained using aseptic technique, this will further minimize the risk of soft tissue infection (Marini and Wheeler 2010). There is little evidence suggesting any difference in infection rates between femoral or peripheral arterial cannulation (O'Grady et al. 2011). However, regular observation of the arterial cannula insertion site is imperative for signs of inflammation which may predispose patients to cannula-related infection. Cannulation for more than 4 days also increases this risk (O'Grady et al. 2011).

There is potential for the administration sets attached to the arterial device to provide a pathway for micro-organisms into the bloodstream, exposing the patient to catheter-related bloodstream infections (CRBSIs). Current practices related to changing administration sets of arterial devices are based on the Saving Lives guidelines for infections in central venous devices (DH 2010); they advocate changing sets every 72 hours. There are no specific recommendations set out by any British governing body for when to change administration sets in peripheral artery devices. In a recent systematic review (mainly Canadian and American studies) it was clear that practices for routinely changing arterial administration sets ranged from 24 to 96 hours. There is some evidence to suggest that changing the administration set between 24 and 72 hours is associated with less risk of infection among critically ill patients but there is not enough evidence to suggest a definitive life time of the sets (Daud et al. 2013).

Hypovolaemia

Hypovolaemia can occur as a result of severe haemorrhage, which can be caused by (a) accidental disconnection of tubing from the cannula or from one of the connections within the system or (b) dislodgement of the cannula.

The flow from an 18 G cannula can result in blood loss of 250 mL per minute (Bersten et al. 2009). Unconscious or delirious patients and children are at particular risk. The risk can be minimized by clear labelling of the arterial cannula (Zideman and Morgan 1981), arterial tubing and sets should be predominantly red in colour, and alarm settings on the monitor must be turned on and audible (Adam and Osborne 2005). The use of Luer-Lok connections, ensuring visibility of the cannula, appropriate nurse/patient ratios, adequate training and competency of nurses caring for patients with arterial cannulas will also help reduce this complication.

The cannula may become dislodged, particularly if the patient is diaphoretic and dressings tend to lift. Securing the cannula using an appropriate cannula-securing device may be useful. Inform the patient about the danger of dislodging the cannula and the amount of movement that is preferred. Staff must also take care when moving the patient, and avoid putting stress on the arm and connections. Ideally, non-invasive blood pressure should not be measured on the same arm as the arterial cannula. Marini and Wheeler (2010) recommend attempting a minimum of once-daily sphygmomanometry in order to confirm cannula pressure, especially in patients whose vasopressors are titrated to these pressures, and particularly in those patients who are elderly, are hypertensive or those with underlying vascular disease.

Accidental intra-arterial injection of drugs

Accidental intra-arterial injection of drugs intended for administration through a central or peripheral venous device may cause distal ischaemia and necrosis, sometimes resulting in permanent functional damage (Marieb and Hoehn 2010, Teplitz 1990, Tinker and Zapol 1992). Drugs such as calcium channel blockers and vasopressors are particularly harmful if injected intra-arterially (Marini and Wheeler 2010). Careful and appropriate labelling and appropriate staff training can minimize this risk. In the event of accidental injection of any drug, stop administering the drug and report immediately to medical staff and the senior nurse. The nurse should then attempt to withdraw blood from the three-way tap in order to aspirate any of the drug. Then assess the limb pulse, colour and temperature hourly, or more frequently if required, and complete an accident form and/or other relevant documentation.

Ischaemia

Radial artery catheterization is considered a relatively safe procedure with an incidence of permanent ischaemic complications of only 0.09% (Sheer et al. 2002). However, it is believed that many cases of hand ischaemia go unreported and hence it remains difficult to estimate its true incidence (Brezekinski et al. 2009). Local damage to the artery is the most common complication of arterial cannulation (Marieb and Hoehn 2010). Cannulation

for as little as 6 hours has been associated with arterial wall scarring (Brezekinski et al. 2009). Regular close inspection and assessment of the limb and areas distal to the cannula must be carried out as there is a risk of thrombosis and embolism. Arterial catheter-related ischaemia can present as:

- absent pulse
- dampened waveform
- mottled/blanched skin
- delayed capillary refill
- painful/cold hand
- motor weakness.

To minimize such risks, cannulation of the non-dominant hand should be attempted whenever possible (Wallach 2004).

The medical team should be informed if any of the above are discovered (Adam and Osborne 2005). If a distal embolism is suspected, the cannula may have to be removed and limb warming attempted in order to avoid permanent damage (Box 14.11). The risk of ischaemia distal to the cannula is increased when associated with low cardiac output, shock, sepsis and prolonged cannulation (Bersten et al. 2009, Gamby and Bennett 1995).

Chapter 15

Wound management

Procedure guidelines

15.1 Dressing a wound 945

15.2 Suturing a simple wound 956

15.3 Suture removal 960

15.4 Clip removal 961

15.5 Negative pressure wound therapy 964

Overview

The aim of this chapter is to provide an overview of wound care principles and current practice.

Wounds

Definition

A wound can be defined as an injury to living tissue, breaking its continuity (Martin 2010). Wounds can be divided into six basic categories:

- 1 contusion (bruise)
- 2 abrasion (graze)
- 3 laceration (tear)
- 4 incision (cut)
- 5 puncture (stab)
- 6 burn.

Both external and internal factors can contribute to the formation of a wound and a holistic approach is essential for accurate assessment and planning care (Eagle 2009).

936

- *External:* mechanical (friction, surgery), chemical, electrical, temperature extremes, radiation, micro-organisms, environment.
- *Internal:* circulatory system failure (venous, arterial, lymphatic), endocrine (diabetes), neuropathy, haematological (porphyria cutanea tarda, mycosis fungoides), nutritional status (smoking and alcohol history), malignancy, infection and age (Eagle 2009).

Anatomy and physiology

The skin is the largest organ in the body and makes up about 10% of the adult total bodyweight (Hess 2005). The skin is important as it functions as an outer boundary for the body and helps preserve the balance within (Tortora and Derrickson 2011). The skin needs to remain intact to perform vital functions (Timmons 2006) and without it humans would not survive insults from bacterial invasion or heat and water loss (Marieb and Hoehn 2010).

The skin varies in thickness from 1.5 to 4 mm depending upon which part of the body it is covering (Marieb and Hoehn 2010). The skin is made up of two main layers, the dermis and epidermis, which have six main functions: protection, sensation, thermoregulation, metabolism, excretion and non-verbal communication (Hess 2005, Timmons 2006).

The *epidermis* is the outermost layer and is avascular and thin. It regenerates every 4–6 weeks and functions as a protective barrier, preventing environmental damage and micro-organism invasion (Hess 2005). The thickness of the epidermis varies and it is thicker over the palms of the hands and soles of the feet (Marieb and Hoehn 2010).

The *dermis* provides support and transports nutrients to the epidermis. It contains blood and lymphatic vessels, sweat and oil glands and hair follicles. The dermis is made up of collagen and fibroblasts, elastins and other extracellular proteins which bind it together and keep it strong (Hess 2005). Its extracellular matrix (ECM) contains fibroblasts, macrophages and some mast cells and white blood cells (Marieb and Hoehn 2010). The connective tissue within the dermis is highly elastic and provides strength to maintain the skin's integrity and combat everyday stretching and wear and tear (Tortora and Derrickson 2011).

The subcutaneous layer just below the dermis is the deepest extension and binds the skin to underlying tissues (Tortora and Derrickson 2011). This layer is known as the *hypodermis* or superficial fascia and stores fat. It also assists the body as a protective layer and allows movement (Marieb and Hoehn 2010).

Related theory

Classification of wounds

An acute wound is traumatic or surgical and moves through the stages of the healing process in a predictable time frame. A chronic wound does not progress through the stages of healing and is not resolved over an expected period of time regardless of the cause (Broderick 2009).

Evidence-based approaches

Methods of wound healing

Wound healing is the process by which damaged tissue is restored to normal function. Healing may occur by primary, second or tertiary intention.

Healing by *primary intention* involves the union of the edges of a wound under aseptic conditions, for example, a laceration or incision that is closed with sutures or skin adhesive (Dealey 2005).

Healing by *secondary intention* occurs when the wound's edges cannot be brought together. The wound is left open and allowed to heal by contraction and epithelialization. Epithelialization encourages restoration of the skin's integrity (Giele and Cassell 2008). Wounds that heal by secondary intention include surgical or traumatic wounds where a large amount of tissue has been lost, heavily infected wounds, chronic wounds or, in some cases, where a better cosmetic or functional result will be achieved (Benbow 2005, Dealey 2005).

Healing by *tertiary intention*, or delayed primary closure, occurs when a wound has been left open and is then closed primarily after a few days' delay, usually once swelling, infection or bleeding has decreased (Giele and Cassell 2008).

Phases of wound healing

Wound healing is a cellular and biochemical process which relies essentially on an inflammatory process (Hampton and Collins 2004). These processes are dynamic, depend upon each other and overlap (Dealey 2005, Timmons 2006). It is important to support a wound-healing environment that encourages progression from one phase to the next without bacterial contamination, as this increases slough and necrosis (Hampton and Collins 2004).

The generally accepted phases of healing are:

- 1 haemostasis
- 2 inflammatory phase
- 3 proliferation or reconstructive phase
- 4 maturation or remodelling phase (Dealey 2005).

Haemostasis (minutes)

Vasoconstriction occurs within a few seconds of tissue injury and damaged blood vessels constrict to stem the blood flow. When platelets come into contact with exposed collagen from damaged blood vessels, they release chemical messengers that stimulate a 'clotting cascade' (Hampton and Collins 2004, Timmons 2006). Platelets adhere to vessel walls and are stabilized by fibrin networks to form a clot. Bleeding ceases when the blood vessels thrombose, usually within 5–10 minutes of injury (Hampton and Collins 2004) (Figure 15.1).

Inflammatory phase (1–5 days)

With the activation of clotting factors comes the release of histamine and vasodilation begins (Dowsett 2002). The liberation of histamine also increases the permeability of the capillary walls and plasma proteins, leucocytes, antibodies and electrolytes exude into the surrounding tissues. The wound becomes red, swollen and hot. These signs are accompanied by pain and tenderness at the wound site, last for 1–3 days and can be mistaken for wound infection (Hampton 2013) (Figure 15.2).

Polymorphonuclear leucocytes and macrophages migrate to the wound within hours and these phagocytose debris and bacteria and begin the process of repair (Hart 2002). If the number and

function of macrophages are reduced, as may occur in disease, for example diabetes (Springett 2002), healing processes are affected. Nutrients and oxygen are required to produce the cellular activity and therefore malnourished patients and hypoxic wounds are more susceptible to infection (Dealey 2005, Timmons 2006). The breakdown of debris causes an increased osmolarity within the area, resulting in further swelling. A chronic wound can get stuck in this phase of wound healing (Dealey 2005, Hampton and Collins 2004) with prolonged healing, tendency to infection and high levels of exudate (Timmons 2006). The phases that follow start the process of repair (Tortora and Derrickson 2011).

Proliferative phase (3–24 days)

Acute wounds will start to granulate within 3 days, but the inflammatory and proliferative phases can overlap, with both granulation and sloughy tissue present (Timmons 2006) (Figure 15.3).

The fibroblasts are activated to divide and produce collagen by processes initiated by the macrophages (Timmons 2006). Newly synthesized collagen creates a 'healing ridge' below an intact suture line, thus giving an indication of how primary wound healing is progressing. This mechanism is dependent on the presence of iron, vitamin C and oxygen. Vitamin C (ascorbic acid) and lactate are stimulants for fibroblast activity (Hampton and Collins 2004). Fibroblasts are also dependent on the local oxygen supply

(Dealey 2005). The wound surface and the oxygen tension within encourage the macrophages to instigate the process of angiogenesis, forming new blood cell vessels. These vessels branch and join other vessels, forming loops. The fragile capillary loops are held within a framework of collagen. This complex is known as granulation tissue (Gray et al. 2010).

Endothelial buds grow and the fibroblasts continue the process of repair by laying down fibrous tissue (Hampton and Collins 2004). Epithelial cells will burrow under contaminated debris and unwanted material while also secreting an enzyme that separates the scab from underlying tissue. Through a mechanism called contact inhibition, epithelial cells will cease migrating when they come into contact with other epithelial cells (Tortora and Derrickson 2011).

Epithelialization (migration, mitosis and differentiation) occurs at an increased rate in a moist wound environment, as do the synthesis of collagen and formation of new capillaries. Wound contraction is a function of myofibroblasts, which are prominent in granulating tissue. The extent of wound contraction is dependent on the number of myofibroblasts present and it is maintained by collagen deposition and cross-linking (Giele and Cassell 2008).

Maturation phase (21 days onward)

Maturation or remodelling of the healed wound begins at around 21 days following the initial injury and may last for more than a year (Figure 15.4). Re-epithelialization occurs at this stage and covers the wound (Benbow 2005). Collagen is reorganized, the fibres becoming enlarged and orientated along the lines of tension in the wound (at right angles to the wound margin) (Silver 1994). This occurs via a process of lysis and resynthesis. Inter-molecular cross-linking aids the tensile strength of the wound. During this reorganization, fibroblasts may constrict the neighbouring collagen fibres surrounding them, causing contraction of the tissue and reduction of blood vessels within the scar (Cho and Hunt 2001). At the end of the maturation phase, the delicate granulation tissue of the wound will have been replaced by stronger avascular scar tissue. Rationalization of the blood vessels also results in thinning and fading of the scar, although it is not fully known why this varies amongst people (Dealey 2005).

Methods of wound assessment

In order to provide a method of wound assessment and a simple way of selecting appropriate dressings, an international group of wound care experts developed a concept using 'TIME' (tissue, infection/inflammation, moisture balance and edge advancement) as an acronym to identify the key barriers to healing (Dowsett and Ayello 2004, Werdin et al. 2008) (Table 15.1).

Wound bed preparation

Wound bed preparation (WBP) focuses on controlling and optimizing the wound environment for healing chronic wounds (Falanga 2004). It provides a means of bringing together a cohesive plan of both patient and wound care and is a holistic dynamic process (Moffatt 2004).

Tissue factors affecting wound healing

The rate of wound healing varies depending on the general health, age and mobility of the individual, the location of the wound, the degree of damage and the treatment applied. It is necessary when treating a wound to appraise all potential detrimental factors and minimize them, where possible, in order to provide the optimum systemic, local and external conditions for healing.

Factors that may delay healing include disease, poor nutritional state and infection. Other influences involve the local microenvironment of the wound, including temperature, pH, humidity, air gas composition, oxygen tension, blood supply and inflammation (Storch and Rice 2005). Whether this influence is positive or negative may depend on the stage of wound healing that has been reached. Other important considerations are external variables such as continuing trauma or the presence of foreign bodies (Table 15.2).

Achieving a well-vascularized wound bed

Improving the blood flow to the wound bed will increase the availability of nutrients, oxygen, active cells and growth factors within the wound environment (Collier 2002). This may be achieved through the use of compression therapy, topical negative pressure therapy or wound management products that exert an osmotic pull on the wound bed, increasing capillary growth (Collier 2002).

Debridement of devitalized tissue

Surgical debridement is the most effective method of removing necrotic tissue (Woolcott et al. 2009). It is performed by a surgeon and usually involves excision of extensive or deep areas of necrosis, usually to the point of bleeding viable tissue to ‘kick-start’ healing (Hampton and Collins 2004). While this option is very effective, it carries the risks associated with general anaesthesia. An alternative method of rapid debridement is ‘sharp’

Table 15.1 TIME principles for wound bed preparation

Clinical observations		Proposed pathophysiology	Wound bed preparation Clinical actions	Effect on wound bed preparation actions	Clinical outcomes
Tissue non-viable or deficient	T	Defective matrix and cell debris impair healing	Debridement (episodic or continuous) <ul style="list-style-type: none">• Autolytic, sharp debridement, mechanical or biological (tissue viability nurse only)• Biological agents	Restoration of wound base and functional extracellular matrix proteins	Viable wound base
Infection or inflammation	I	High bacterial counts or prolonged inflammation ↑ Inflammatory cytokines ↑ Protease activity ↓ Growth factor activity	Remove infected foci Topical/systemic <ul style="list-style-type: none">• Antimicrobials• Anti-inflammatories• Protease inhibition	Low bacterial counts or controlled inflammation ↓ Inflammatory cytokines ↓ Protease activity ↑ Growth factor activity	Bacterial balance and reduced inflammation
Moisture imbalance	M	Desiccation slows epithelial cell migration Excessive fluid causes maceration of wound margin	Apply moisture-balancing dressings Compression, negative pressure or other methods of removing fluids (tissue viability nurse only)	Restored epithelial cell migration Desiccation avoided Oedema, excessive fluid controlled Maceration avoided	Moisture balance
Edge of wound non-advancing or undermined	E	Non-migrating keratinocytes Non-responsive wound cells and abnormalities in extracellular matrix or abnormal protease activity	Reassess cause or consider corrective therapies <ul style="list-style-type: none">• Debridement• Skin grafts• Biological agents• Adjunctive therapies	Migrating keratocytes and responsive wound cells Restoration of appropriate protease profile	Advancing edge of wound

Table 15.2 Factors that may delay wound healing

Extrinsic factor	Action	Intrinsic factor	Action
Cold	Any drop in temperature delays healing by up to 4 hours	Age	The elderly have a thinning of the dermis and underlying structural support for the wound (i.e. less moisture and subcutaneous fat). The metabolic process and circulation also slow with age
Excessive heat	Temperature over 30°C reduces tensile strength and causes vasoconstriction	Medical and general health conditions	Diabetes, cardiopulmonary disease, hypovolaemic shock, rheumatoid arthritis, anaemia, obesity
Chronic excessive exudate	Wounds should not be too wet or too dry (see moisture balance section in Table 15.1)	Malnutrition or protein–energy malnutrition	Poor healing, decreased tensile strength and higher risk of wound dehiscence and infection. Low serum albumin causes oedema
Poor dressing application and techniques	Gaping of dressing material or multiple layers, tape/adhesive not fastened securely and allowing slipping of wound exudates/dressing materials and/or bandaging too tight/loose	Psychosocial factors	Alcohol and smoking (carbon monoxide affects the blood vessels and circulation of oxygen), poor mobility, stress, isolation, anxiety and altered body image
Poor surgical technique	Prolonged operating time, inappropriate use of diathermy and drains can lead to haematomas and infection	Drugs	Steroids and non-steroidal anti-inflammatories, anti-inflammatories, immunosuppressives, cytotoxic chemotherapy

939

debridement, which may be utilized for the removal of loose, devitalized, superficial tissue only. Sharp debridement can be performed at the patient's bedside by an experienced healthcare professional with relevant training (Stephen-Hayes 2007). However, this can be a dangerous practice in inexperienced hands and is controversial (Fairbairn et al. 2002). Potentially, ligaments may be severed as they can have the appearance of sloughy tissue or vascular damage could occur (Hampton and Collins 2004). It is also acknowledged that informed patient consent is required

as this is an invasive procedure with potential risks and complications (Fairbairn et al. 2002).

Autolytic debridement is recommended as a less invasive technique which utilizes the body's natural debriding mechanism. This effect is enhanced in a moist wound environment, which can be achieved through the use of hydrogel dressings or semi-occlusive dressings that maintain moisture at the wound surface. Many dressings are designed for this purpose and break down necrotic tissue naturally (Hampton and Collins 2004, Hess 2005) (Table 15.3).

Table 15.3 Dressing groups. Please refer to manufacturer's recommendations with regard to individual products

Dressings	Description	Advantages	Disadvantages
Activated charcoal	Contains a layer of activated charcoal that traps and reduces odour-causing molecules	Easy to apply as either primary or secondary dressing; can be combined with another dressing with absorbency	Need to obtain a good seal to prevent leakage of odour; some dressings lose effectiveness when wet*
Adhesive island	Consists of a low adherent absorbent pad located centrally on an adhesive backing	Quick and easy to apply; protects the suture line from contamination and absorbs exudate/blood	Only suitable for light exudate; some can cause skin damage (excoriation, blistering) if applied incorrectly
Alginates	A textile fibre dressing made from seaweed; the soft woven fibres gel as they absorb exudate and promote autolytic debridement. Available as a sheet, ribbon or packing	Are suitable for moderate to heavy exudate; can be used on infected wounds; useful for sinus and fistula drainage; have haemostatic properties; can be irrigated out of wound with warm saline	Cannot be used on dry wounds or wound with hard necrotic tissue (eschar); sometimes a mild burning or 'drawing' sensation is reported on application*
Antimicrobials	These topical dressings can be used as primary or secondary dressings and are available as a primary layer and impregnated in other dressings or as a cream	Suitable for chronic wounds with heavy exudate that need protection from bacterial contamination by providing a broad range of antimicrobial activity; can reduce or prevent infection	Sometimes sensitivity occurs with the use of silver and some skin staining can occur; instructions vary with products and dressings are expensive. Evidence base for use is controversial and needs monitoring*

(continued)

Table 15.3 Dressing groups. Please refer to manufacturer's recommendations with regard to individual products (*continued*)

Dressings	Description	Advantages	Disadvantages
Capillary wound dressings	Composed of 100% polyester filament outer layers and a 65% polyester and 35% cotton woven inner layer; outer layer draws exudate, interstitial fluid and necrotic tissue into the inner layer via a capillary action	Suitable for light to heavy exudate; debride necrotic tissue; protect and insulate the wound; maintain a moist environment and prevent maceration; encourage development of granulation tissue; can be cut to any shape and are available in large rolls; can be used as a wick to drain sinus and cavity wounds	Can be hard to cut and are quite stiff to fit into wounds; cannot be used where there is the risk of bleeding due to the 'drawing' action and resultant increase in blood flow to the wound bed Expensive and should be used on a named patient basis
Collagen	This protein is fibrous and insoluble and produced by fibroblasts. Collagen encourages collagen fibres into the granulation tissue. It is available in sheets/gels	Conforms well to wound surface, maintains a moist environment, suitable for most wounds to accelerate healing. Supports ECM	Not recommended for necrotic wounds*
Foams	Produced in a variety of forms, most being constructed of polyurethane foam, and may have one or more layers; foam cavity dressings are also available	Suitable for use with open, exuding wounds; highly absorbent, non-adherent and maintain a moist wound bed Available for low-high exudates and/or bordered to simplify dressing choice	May be difficult to use in wounds with deep tracts and need a combined approach with an alginate
Honey – most widely used is Manuka honey	Available as tubes of liquid honey or impregnated dressings	Suitable for acute and chronic infected, necrotic or sloughy wounds; provides a moist wound environment; non-adherent; antibacterial; assists with wound debridement; eliminates wound malodour; has an anti-inflammatory effect	Can be messy to use and causes leakage if excess exudate is present* May have a burning/drawing effect when first applied
Hydrocolloid	Usually consists of a base material containing gelatin, pectin and carboxymethylcellulose combined with adhesives and polymers; base material may be bonded to either a semi-permeable film or a film plus polyurethane foam; some have a border	Suitable for acute and chronic wounds with low to no exudate; provides a moist wound environment; promotes wound debridement; provides thermal insulation; waterproof and barrier to micro-organisms; easy to use	May release degradation products into the wound; strong odour produced as dressing interacts with exudate; some hydrocolloids cannot be used on infected wounds
Hydrofibre	Same consistency as hydrocolloid but in a soft woven sheet (also available with silver)	Forms a soft, hydrophilic, gas-permeable gel on contact with the wound and manages exudate whilst preventing maceration of wound edge. Easy to remove without trauma to wound bed	Does not have haemostatic property of alginates*
Hydrogels	Contain 17.5–90% water depending on the product, plus various other components to form a gel or solid sheet	Suitable for light exudate wounds; absorb small amounts of exudate; donate fluid to dry necrotic tissue; reduce pain and are cooling; low trauma at dressing changes; can be used as carrier for drugs	Cool the wound surface; use with caution in infected wounds; can cause skin maceration due to leakage if too much gel is applied or the wound has moderate to heavy exudate* Moderate care of sheets so they do not dry out
Semi-permeable films	Polyurethane film with a hypoallergenic acrylic adhesive; have a variety of application methods often consisting of a plastic or cardboard carrier	Only suitable for shallow superficial wounds; prophylactic use against friction damage; useful as retention dressing; allow passage of water vapour; allow monitoring of the wound	Possibility of adhesive trauma if removed incorrectly; do not contain exudate and can macerate, slip or leak
Skin barrier film	Alcohol-free liquid polymer that forms a protective film on the skin	Non-cytotoxic; does not sting if applied to raw areas of skin; high wash-off resistance; protects the skin from body fluids, friction and shear and the effects of adhesive products	Requires good manual dexterity to apply; may cause skin warming on application

*Requires a secondary dressing.

Source: Adapted from Dealey (2005), Hess (2005).

Inflammation and infection (or bacterial burden)

It is generally agreed that all chronic wounds harbour a variety of bacteria to some degree and this can range from contamination through colonization to infection. There is also a stage between colonization and infection called 'critical colonization' where the bacterial load has reached a level just below clinical infection (Collier 2002). The virulence of the infection involves a complex interaction between the individual and condition of the wound (Butcher 2012). When a wound becomes infected, it will display the characteristic signs of heat, redness, swelling, pain, heavy exudate and malodour. The patient may also develop generalized pyrexia. An essential role within wound management is therefore reducing bacterial burden and many dressings are impregnated with antimicrobial compounds, e.g. silver, iodine, honey (Butcher 2012). There is supporting evidence for the use of silver and other antimicrobials in reducing colonization and increasing healing rates (Leaper 2011).

However, immunosuppressed patients, diabetic patients or those on systemic steroid therapy may not present with the classic signs of infection. Instead, they may experience delayed healing, breakdown of the wound, presence of friable granulation tissue that bleeds easily, formation of an epithelial tissue bridge over the wound, increased production of exudate and malodour and increased pain.

Defining wound infection in all wounds is still debatable (Cutting 2011). The clinical presentation of a wound should lead to the diagnosis of an infection. A wound swab should only be taken if the clinical picture advocates it as the swab will only identify the type of bacteria present. The technique for swabbing a wound should be specified in local protocols and should include the cleaning of a wound prior to swabbing to remove surface contaminants and dressing residue (Young 2012). For further advice see Chapter 10: Interpreting diagnostic tests. Topical antibiotics are contraindicated as they may increase bacterial resistance and the use of antimicrobials prophylactically is controversial (Butcher 2012, Cutting 2011).

Moisture balance

Wound exudate usually performs a useful function by aiding autolytic debridement and providing nutrients to the healing wound bed. It is required in the process of epithelialization, to allow the movement of cells across the surface of the wound (Jones 2013). However, in the presence of excess exudate, the process of wound healing can be adversely affected. This is especially so in chronic wounds where there is an increased proteolytic activity, leading to damage in the wound bed. Matrix metalloproteases (MMPs) are found in exudate, and when present in chronic exudate, their beneficial properties, such as the provision of essential nutrients for cell metabolism, are hindered. This can be a significant factor in delayed healing (Hampton 2013).

The control of oedema or elevating the affected limb, e.g. in a lower leg wound, will undoubtedly help in the reduction of wound exudate. However, if the methods for achieving these goals are unsuccessful or contraindicated then exudate must be managed through the use of wound management products. These include such products as absorbent wound dressings (e.g. alginates, hydrofibre, foams), non-adherent wound contact layers with a secondary absorbent pad, wound manager bags and negative pressure wound therapy (NPWT). NPWT is highly effective in controlling excessive exudate (Probst and Huljev 2013). It is also vital to protect the skin surrounding the wound from maceration by excess exudate and excoriation from corrosive exudate. Useful products for skin protection include ointments/pastes, alcohol-free skin barrier films and thin hydrocolloid sheets used to 'frame' the wound (Flett et al. 2002).

Edge non-advancement

The clearest sign that the wound is failing to heal is when the epidermal edge is not advancing over time (Dowsett and Ayello

2004). In this case a thorough assessment should commence using the TIME principles and interventions.

Principles of wound cleansing

The aim of wound cleansing is to help create the optimum local conditions for wound healing.

If the wound is clean with little exudate and particularly with granulation tissue present, repeated cleaning may be detrimental to the healing process, damaging new tissue and decreasing the temperature of the wound unnecessarily (Watret and Armitage 2002). A fall in the temperature of the wound of 12°C is possible if the procedure is prolonged or the lotions are cold. It can take 3 hours or longer for the wound to return to normal temperature, during which time the cellular activity is reduced and therefore the healing process slowed (McKirdy 2001).

Sodium chloride (0.9%) is a physiologically balanced solution that has a similar osmotic pressure to that already present in living cells and is therefore compatible with human tissue. Although sodium chloride has no antiseptic properties, it dilutes bacteria and is non-toxic to tissue (Thomas 2009). There is an increasing use of tap water for irrigating chronic wounds; no significant difference has been shown in the healing and infection rates in wounds irrigated with tap water or 0.9% sodium chloride (Hall 2007). Evidence shows that although swabbing wounds may be effective in removing foreign bodies from the surface of a wound, irrigation is far less harmful to wound tissue (Hall 2007).

Principles of dressing a wound

With the exception of wounds where the main aim is to ameliorate symptoms such as malignant wounds, an ideal wound dressing must be capable of fulfilling the following functions.

- Allows gaseous exchange.
- Maintains optimum temperature and pH in the wound.
- Forms an effective barrier to bacteria (contains cellular debris or exudate to prevent the transmission of micro-organisms into and out of the wound).
- Allows removal of the dressing without pain or skin stripping.
- Is acceptable to the patient.
- Is highly absorbent (for heavily exuding wounds).
- Is cost-effective.
- Requires minimal replacement or disturbance.
- Appropriate to the wound; debridement activity, haemostatic properties, odour absorbing (Thomas 2009).

Pre-procedural considerations

Equipment

Dressings are named and categorized to make choices more clear (see Table 15.3 for details of groups of dressings). The dressing that is applied directly over the wound bed is the *primary* dressing. Dry dressings (such as gauze) do not fulfil most of the criteria for an ideal dressing and should not be used as a primary contact layer as they are likely to adhere and disturb healing (Dealey 2005). Silicone can be beneficial in protecting delicate wound beds and the peri-wound area due to its protective and atraumatic properties (Yarwood-Ross 2013). However, this also depends on the definition of 'dry' dressing as some dressings appear dry but 'gel' on contact with the wound, which maintains a moist environment, and are non-adhesive, thus becoming 'wet' (examples include hydrofibres, alginates and hydrocolloids). The wound itself has the ability to produce moisture. Wet dressings, such as hydrogels, can make a wound too wet and be responsible for maceration if used inappropriately (Hampton and Collins 2004).

Occlusive dressings achieve many of the criteria for an ideal dressing. They affect the wound and healing in several ways. They have the ability to maintain hydration and prevent the formation

Date: _____		Date: _____	
Notes on use Use one chart per wound. Complete a wound assessment at least once a week. Measure the wound at its widest points using a clean ruler, use a sterile wound swab or blunt probe to measure wound depth. For the 'skin around wound' assessment more than one box may be ticked. Odour and pain should be assessed using the scales at the top of page 2. Following the assessment a wound management care plan should be written and updated if necessary after each reassessment.			

Figure 15.5 Continued

of an eschar. As they are designed for moderate exudates, chronic wounds and pressure sores are often dressed with occlusive dressings that are bordered with adhesive. They have a combined primary and secondary layer. If patients have sensitive skin and adhesive borders are traumatic, dressings should be held in place with netting (Netelast) or bandages (see Table 15.3). NB: A dressing used to hold another in place in this way would be a *secondary dressing*.

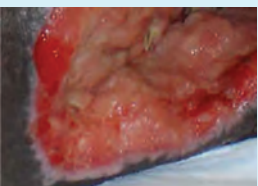

Dressings should be changed when leakage occurs or the dressing no longer absorbs exudates, around every 2–7 days or as instructed (Hess 2005).

Assessment and recording tools

The wound should be evaluated each time a dressing is applied or if it gives cause for concern. The aim of evaluating the wound is to assess healing and to establish which treatment will best provide the ideal environment for healing. The surface area or volume of the wound should be measured and recorded. Photography also provides a useful record in wound assessment, but patient consent should always be gained (Bianco and Williams 2002).

Figure 15.5 is an example of a wound assessment chart and Table 15.4 illustrates the types of wound and guidance on choice of dressing following assessment. The underlying cause of the

wound should also be assessed, with the primary focus on details such as size and depth as well as the stage of healing (Teare and Barrett 2002). Links can then be made between the wound dressing and the optimal healing environment. The use of this type of documentation to assist in the assessment process is recommended to:

- facilitate continuity of care by providing a central reference point for wound progression
- facilitate appropriate evaluation of all relevant parameters
- fulfil legal and professional requirements (Teare and Barrett 2002).

Procedure guideline 15.1 Dressing a wound

Essential equipment

- Sterile dressing pack containing gallipots or an indented plastic tray, low-linting swabs, disposable forceps, gloves, sterile field, disposable bag and disposable plastic apron
- Fluids for cleaning and/or irrigation
- Hypoallergenic tape
- Appropriate dressing
- Appropriate hand hygiene preparation
- Any other material will be determined by the nature of the dressing; special features of a dressing should be referred to in the patient's nursing care plan
- Detergent wipe
- Total traceability system for surgical instruments and patient record form

Optional equipment

- Sterile scissors

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient and check analgesia requirements.	To ensure that the patient understands the procedure and gives his or her valid consent, and to reduce anxiety (NMC 2013, E).
2 Wash hands with soap and water, put on a disposable plastic apron.	Hands must be cleaned before and after every patient contact and before commencing the preparations for aseptic technique, to prevent cross-infection (Fraise and Bradley 2009, E).
3 Clean trolley with detergent wipe.	To provide a clean working surface (Fraise and Bradley 2009, E).
4 Place all the equipment required for the procedure on the bottom shelf of the clean dressing trolley. Check integrity and use-by dates of all equipment (i.e. packs are undamaged, intact and dry).	To maintain the top shelf as a clean working surface. To ensure sterility of equipment prior to use. E
5 Screen the bed area and provide privacy. Position the patient comfortably so that the area to be dealt with is easily accessible without exposing the patient unduly.	To allow any airborne organisms to settle before the sterile field (and in the case of a dressing, the wound) is exposed (Fraise and Bradley 2009, E). Maintain the patient's dignity and comfort. E
6 Take the trolley to the treatment room or patient's bedside, disturbing the screens as little as possible.	To minimize airborne contamination (Fraise and Bradley 2009, E).

Procedure

7 Clean hands with a bactericidal alcohol handrub.	To reduce the risk of wound infection and cross-contamination (Fraise and Bradley 2009, E).
8 Open the outer cover of the sterile dressing pack and slide the contents onto the top shelf of the trolley.	To ensure that only sterile products are used (Fraise and Bradley 2009, E).
9 Open the sterile field using only the corners of the paper.	So that areas of potential contamination are kept to a minimum. E
10 Loosen the dressing tape (if necessary). If contamination on outer dressings, gloves should be worn.	To make it easier to remove the dressing. E For personal protection (Kingsley 2008, E).
11 Clean hands with a bactericidal alcohol handrub.	Hands may become contaminated by handling outer packets, dressing, and so on (Fraise and Bradley 2009, E).
12 Using the plastic bag in the pack, arrange the sterile field. Pour cleaning solution into gallipots or an indented plastic tray.	The time the wound is exposed should be kept to a minimum to reduce the risk of contamination. To prevent contamination of the environment. To minimize risk of contamination of cleaning solution. E
13 Remove dressing by placing a hand in the plastic bag, lifting the dressing off and inverting the plastic bag so that the dressing is now inside the bag. Thereafter use this as the 'dirty' bag. Use gloves if there is difficulty removing dressing.	To reduce the risk of cross-infection. To prevent contamination of the environment (Fraise and Bradley 2009, E).
14 Attach the bag with the dressing to the side of the trolley below the top shelf on the side next to the patient.	To avoid taking soiled dressings across the sterile area. Contaminated material should be disposed of below the level of the sterile field. E
15 Assess wound healing with reference to Table 15.1.	To evaluate wound care (Dealey 2005, E ; Hampton and Collins 2004, E ; Hess 2005, E).

(continued)

Procedure guideline 15.1 Dressing a wound (continued)

Action	Rationale
16 Clean hands and put on sterile gloves.	To reduce the risk of infection to the wound and contamination of the nurse. Gloves provide greater sensitivity than forceps and are less likely to traumatize the wound or the patient's skin. E
17 If necessary, gently irrigate the wound with 0.9% sodium chloride, unless another solution is indicated.	To reduce the possibility of physical and chemical trauma to granulation and epithelial tissue (Hess 2005, E).
18 Apply the dressing that is most suitable for the wound using the criteria for dressings (see Table 15.2).	To promote healing and/or reduce symptoms. E
19 Make sure the patient is comfortable and the dressing is secure.	A dressing may slip or feel uncomfortable as the patient changes position. E
Post-procedure	
20 Dispose of waste in orange plastic clinical waste bags and sharps into a sharps bin. Remove gloves and wash hands.	To prevent environmental contamination and sharps injury. Orange is the recognized colour for clinical waste (DH 2005, C).
21 Ensure the patient is comfortable and draw back the curtains.	To promote well-being and maintain dignity and comfort. E
22 Clean hands with bactericidal alcohol rub. Wipe trolley with detergent wipe and return to storage.	To prevent the risk of cross-contamination from previous episode of care (Fraise and Bradley 2009, E).
23 Record assessment in relevant documentation at the end of the procedure.	To maintain an accurate record of wound-healing progress (NMC 2010, C).

946

Post-procedural considerations**Ongoing care**

Dressings need to be changed when 'strike-through' occurs; that is, the dressing becomes soiled and damp at the surface or edge or leakage of wound exudate occurs (see individual dressing packs for instructions to guide practice). The medical team may take the dressing down to view the wound and the nurse should be present to monitor this and reapply an appropriate dressing. Record any changes and/or instructions in the patient's notes or wound care plan (NMC 2010). Included in the notes should be the amount of exudate, any signs of inflammation or odour and appearance of the tissue (Lippincott Williams & Wilkins 2008).

Pressure ulcers**Definition**

Pressure ulcers are areas of localized tissue damage caused by excess pressure, shearing or friction forces (NPUAP/EPUAP/PPPIA 2014). The extent of this damage can range from persistent erythema to necrotic ulceration involving muscle, tendon and bone (RCN 2005).

Anatomy and physiology

A pressure ulcer usually results from compromised circulation secondary to pressure over time and is a local site of cell death (Hess 2005). Pressure ulcers are classified in four stages, according to depth. The first is superficial damage which is characterized by local inflammation and may present as a persistent area of redness with no breach of the epidermis. The second stage is partial loss of the epidermis or dermis, often with a blistering or abrasion. The third stage involves damage to the dermis and subcutaneous layers of tissue and clinically appears as an ulcer but does not involve

the underlying fascia. The fourth stage involves tissue necrosis and full-thickness skin loss, often with tunnelling sinus tracts (Hess 2005, NPUAP/EPUAP/PPPIA 2014) as illustrated in Figure 15.6.

Evidence-based approaches

Pressure ulcers are a major healthcare issue and are associated with pain, infection, prolonged hospital stay, and in extreme cases can be a causative factor in a patient's death (Bennett et al. 2004, RCN 2005). It is important to use a structured approach that involves skin assessment and identification of risks (NPUAP/EPUAP/PPPIA 2014). The risk assessment should be carried out by a Registered Nurse or healthcare professional who has undergone appropriate training to recognize the risk factors that contribute to the development of pressure ulcers and how to initiate and maintain correct and suitable prevention measures (Waterlow 2007) (Figures 15.7, 15.8, 15.9). The use of assessment tools should be undertaken in conjunction with clinical judgement (RCN 2005, Waterlow 2007).

The three major extrinsic factors that are identified as being significant contributory factors in the development of pressure ulcers are pressure, shearing and friction. These factors should be removed or diminished to reduce injury (RCN 2005).

An individual's potential for developing pressure ulcers may be influenced by the following intrinsic factors.

- Reduced mobility or immobility
- Acute illness
- Level of consciousness
- Extremes of age
- Vascular disease
- Severe, chronic or terminal illness
- Previous history of pressure damage
- Malnutrition and dehydration
- Neurologically compromised
- Obesity
- Poor posture

Pressure Ulcer Category System and Decision Making Tool

Category 1: Intact skin with non blanching*¹ Redness

The area may be: painful, firm or soft, warmer or cooler than adjacent tissue. It may be difficult to detect in people with darker skin tones.

- Pressure area care*²
- Film spray
- Hydrocolloid dressing
- Skin barrier product

Category 2: Partial thickness

Loss of dermis presenting as a shallow ulcer with a pink wound bed without slough. May present as a shiny ulcer without slough or bruising.

- Pressure area care*²
- Hydrocolloid dressing
- Skin barrier product
- Non-adhesive dressing
- Rapid capillary dressing
- Foam dressing

NHS

Figure 15.6 Pressure ulcer category system and decision making tool. *Source:* The Royal Marsden NHS Foundation Trust (2013).

Category 3: Full thickness tissue loss.

Subcutaneous fat may be visible, slough and undermining*³ may be present.

- Pressure area care*²
- Skin barrier product
- Rapid capillary dressing
- Negative pressure dressing
- Non-adhesive dressing
- Honey based dressing
- Alginate dressing
- Foam absorbent dressing

Category 4: Full thickness tissue loss with exposed bone, muscle and/or tendon.

Often includes wound undermining. This must be reported as a Serious Incident (SI). Slough may be obvious in the wound.

- Pressure area care*²
- Skin barrier product
- Negative pressure dressing
- Alginate dressing
- Rapid capillary dressing

*¹ Non-blanching, means that the area does not turn white when pressed.

*² Pressure area care includes assessing patient's skin regularly, moisturising the skin regularly with a suitable emollient, and turning the patient as condition allows, following hospital guideline. See pressure ulcer prevention protocol.

*³ Undermining may present as tissue destruction in the periwound area under the intact skin.

Figure 15.9 Managing risk factors. *Source:* The Royal Marsden NHS Foundation Trust (2013).

- Use of equipment such as seating or beds which do not provide appropriate pressure relief (NPUAP/EPUAP/PPPIA 2014, RCN 2005, Royal Marsden NHS Foundation Trust 2013)

The potential of an individual to develop pressure ulcers may be exacerbated by the following factors, which therefore should be considered when performing a risk assessment.

- Sedatives and hypnotics may make the patient excessively sleepy and thus reduce mobility.
- Analgesics may reduce normal stimulus to relieve pressure.
- Inotropes cause peripheral vasoconstriction and tissue hypoxia.
- Non-steroidal anti-inflammatory drugs (NSAIDs) impair inflammatory responses to pressure injury.
- Cytotoxics and high-dose steroids may induce immunosuppression which impairs inflammatory responses to pressure injury and may lead to an increased risk of wound infection.
- Moisture to the skin (e.g. from incontinence, perspiration or wound exudate) (NPUAP/EPUAP/PPPIA 2014).

Skin inspection

Systematic skin inspection should occur regularly, with the frequency determined in response to changes in the individual's condition in relation to either deterioration or recovery. Individuals at risk should have their skin inspected at least once a day if an inpatient or at every visit in the community setting.

Skin inspection should be based on an assessment of the most vulnerable areas of risk for each patient, inclusive of daily removal of antiembolic stockings. Areas for observation include heels, sacrum, ischial tuberosities, elbows, temporal region of skull, shoulders, back of head and toes, femoral trochanters, parts of the body where pressure, friction and shear are exerted in the course of daily living activities, parts of the body where external forces are exerted by equipment and clothing. Other areas should be inspected as necessitated by the patient's condition.

Individuals who are willing and able should be encouraged, following education, to inspect their own skin. Individuals who are wheelchair users should use a mirror to inspect the areas that they cannot see easily or get others to inspect them.

Healthcare professionals should be aware of the following signs that may indicate incipient pressure ulcer development: persistent erythema, non-blanching hyperaemia (previously identified as non-blanching erythema), blisters, discoloration, localized heat, localized oedema and localized induration. In those with darkly pigmented skin, the signs are purplish/bluish localized areas of skin, localized heat which, if tissue becomes damaged, is replaced by coolness, localized oedema and localized induration.

Skin changes should be documented/recorded immediately using the European Pressure Ulcer Advisory Panel Pressure Ulcer Grading (NPUAP/EPUAP/PPPIA 2014) to classify the ulcer stage and extent of tissue damage.

Maintaining skin integrity

Avoid excessive rubbing over bony prominences, as this does not prevent pressure damage and may actually cause additional damage.

Find the source of excess moisture due to incontinence, perspiration or wound drainage and eliminate this, where possible. When moisture cannot be controlled, interventions that can assist in preventing skin damage should be used.

Skin injury due to friction and shear forces should be minimized through correct positioning, transferring and repositioning techniques (see 'Positioning').

As the patient's condition improves, the potential for improving mobility and activity status exists. Rehabilitation efforts may be instituted if consistent with the overall goals of therapy and

referral to a physiotherapist should be considered. Maintaining activity level, mobility and range of movement is an appropriate goal for most individuals.

All interventions and outcomes should be monitored and documented/recorded.

Equipment

The data currently available to evaluate the clinical effectiveness of pressure-relieving devices are variable (RCN 2005). A systematic review of support surfaces for the prevention of pressure ulcers reported that alternative foam mattresses show improvement over standard foam whilst the benefits of alternating pressure (AP) and continuous low pressure (CLP) mattresses are unclear (McInnes et al. 2011). The AP mattresses mould themselves around the person's shape, thereby redistributing the pressure, whilst CLP mattresses alter the pressure surface (RCN 2005). The cost of these systems is also a consideration in planning prevention (McInnes et al. 2011).

The following recommendations are supported.

- Patients with pressure ulcers should have access to pressure-relieving support surfaces and strategies, for example mattresses and cushions, 24 hours a day and this applies to all support surfaces.
- All individuals assessed as having a grade 1–2 pressure ulcer should, as a minimum provision, be placed on a high-specification foam mattress or cushion with pressure-reducing properties. Observation of skin changes, documentation of positioning and repositioning scheme must be combined in the patient's care.
- If there is any potential or actual deterioration of affected areas or further pressure ulcer development, an AP (replacement or overlay) or sophisticated CLP system (e.g. low air loss, air fluidized, air flotation, viscous fluid) should be used.
- Depending on the location of ulcer, individuals assessed as having grade 3–4 pressure ulcers (including intact eschar where depth, and therefore grade, cannot be assessed) should be, as a minimum provision, placed on an AP mattress or sophisticated CLP system.
- If AP equipment is required, the first choice should be an overlay system. However, circumstances such as patient weight or patient safety may indicate the need for a replacement system (RCN 2005).

Positioning

- Individuals who are 'at risk' of pressure ulcer development should be repositioned and the frequency of repositioning determined by the results of skin inspection and individual needs, not by a ritualistic schedule.
- Repositioning should take into consideration other relevant matters, including the patient's medical condition, their comfort, the overall plan of care and the support surface.
- A patient positioning chart should be used to document the patient's position each hour. In the community this should be at each nursing visit. This will give clear documented evidence of repositioning and injury resultant from prolonged periods in a certain position (Figure 15.10).
- Individuals who are considered to be acutely at risk of developing pressure ulcers should restrict chair sitting to less than 2 hours at a time until their general condition improves. Caution should also be exercised once their condition has improved.
- Positioning of patients should ensure that prolonged pressure on bony prominences is minimized, that bony prominences are kept from direct contact with one another, and friction and shear damage are prevented.
- A repositioning schedule, agreed with the individual, should be recorded and established for each person 'at risk'.

- Correct positioning of devices such as pillows or foam wedges should be used to keep bony prominences (for example, knees, heels or ankles) from direct contact with one another in accordance with a written plan. Care should be taken to ensure that these do not interfere with the action of any other pressure-relieving support surfaces in use.
- Individuals who are willing and able should be taught how to redistribute weight every 15 minutes. Carers should be taught how to assist in patient weight distribution.
- Manual handling devices should be used correctly in order to minimize shear and friction damage. After manoeuvring, slings, sleeves or other parts of the handling equipment should be removed from underneath individuals.
- In the community setting, patients and carers (both formal and informal) should be informed of the importance of repositioning (Royal Marsden NHS Foundation Trust 2013).

Pre-procedural considerations

Nurses must consistently question whether they are employing measures for preventing pressure ulcers and whether the patient and caregivers are following the care plan. Nutritional status and the patient's ability to self-care and mobilize should also be evaluated and documented (NPUAP/EPUAP/PPPIA 2014).

954

Patients who are able and willing should be informed and educated about risk assessment and resulting prevention strategies. This strategy should, where appropriate, include carers.

Patient/carer education leaflets are available and should include information on the following.

- The risk factors associated with them developing pressure ulcers.
- The sites that are at the greatest risk of pressure damage.
- How to inspect skin and recognize skin changes.
- How to care for skin; methods for pressure relief/reduction.
- Where they can seek further advice and assistance should they need it.
- Emphasize the need for immediate visits to a healthcare professional should signs of damage be noticed (Royal Marsden NHS Foundation Trust 2013).

Administration of analgesia as prescribed and the setting of a time frame with the patient's agreement are recommended to improve the experience for the patient (NPUAP/EPUAP/PPPIA 2014). If the patient refuses care, this should be documented, and/or evaluation of whether the patient improves or deteriorates should be recorded to keep the care plan up to date (Royal Marsden NHS Foundation Trust 2013). Nurses should consult additional guidance if unfamiliar with the patient or regimen (NPUAP/EPUAP/PPPIA 2014, NMC 2015).

Assessment

The use of a pressure ulcer classification system to estimate tissue loss and assess skin by colour, temperature and consistency (i.e. firm/turgid or soft/boggy) is recommended (NPUAP/EPUAP/PPPIA 2014).

- *Stages 1–2 with light exudates:* for reddened areas, barrier cream and relief of pressure are recommended, whilst superficial ulcers require dressing with transparent films as they effectively retain moisture and prevent friction (Bluestein and Javaheri 2008).
- *Stage 3 ulcers* should be dressed with synthetic dressings rather than gauze as these cause less pain and require less frequent changes (Bluestein and Javaheri 2008, NPUAP/EPUAP/PPPIA 2014). These dressings include alginates, hydrocolloids and foams and are often available in site-specific shapes to ease application and removal and minimize

leakage. See previous guidance on 'Wound bed preparation' (see Table 15.1).

Surgical wounds

Evidence-based approaches

Methods of wound closure

There are four main methods of wound closure:

- sutures
- adhesive skin closure strips
- tissue adhesive
- clips.

See Table 15.5 for advantages and disadvantages of each method.

Wounds may vary and therefore careful assessment is required before the method of closure is selected. The following guiding principles can assist with decision making (Richardson 2007).

- *What is the aim of the wound closure?* For example, eliminating dead space where a haematoma can develop, realigning tissue correctly or holding aligned tissues until healing has occurred.
- *What is the history of the wound?* This informs the practitioner about the depth of the wound and likelihood of infection.
- *What is the wound site pattern?* This and biomechanical properties may rule out some methods of closure.

Suturing

Evidence-based approaches

Rationale

Suturing as a method of wound closure is appropriate in managing deep, large wounds. As there is a direct relationship between the time of wound closure and infection risk, suturing is usually best suited for primary closure in recently acquired, non-infected wounds (Jain 2013).

Indications

This method is used to promote primary healing, realign tissue layers and hold the skin edges together until enough healing occurs to withstand stress without mechanical support (Wicker and O'Neill 2010). There are a number of common suturing errors as listed in Table 15.6.

Contraindications

Experts are usually required to manage wounds of a certain depth or in complex areas such as the face or hand. This is to minimize scarring and not restrict movement by poor technique. Therefore local policy will probably prevent nurses from suturing these wounds (Reynolds and Cole 2006).

Legal and professional issues

Competencies

Nurses should decline to carry out procedures that they have not been prepared for (NMC 2015). Suturing wounds requires skill and should be performed by practitioners who have undergone appropriate training.

Pre-procedural considerations

The environment should be warm, quiet, relaxed and private prior to suturing in order to promote patient comfort and maintain dignity (Hughes and Mardell 2009). It is advisable to lie the patient down to relieve anxiety and prevent further injury that could occur if the patient faints (Reynolds and Cole 2006).

Table 15.5 Advantages and disadvantages of methods of wound closure

Method	Advantages	Disadvantages
Suturing	Provides secure closure. Allows accurate approximation of tissue layers. Necessity of local anaesthesia use provides good conditions for thorough wound cleansing	Suturing must be performed by an experienced practitioner. Incorrect technique can lead to delayed healing, tissue necrosis and/or dehiscence. More time consuming than other methods. Requires local anaesthetic. Suture material is a foreign body and thus increases infection risk
<i>Interrupted</i> sutures are separate sutures each with its own knot	This is the simplest suture to appose two wound edges. Wound support is not reliant on any individual suture, therefore if there is a weakness or breakage in one, the others should continue to provide support.	Relatively time consuming to perform as each suture requires its own knot. Time consuming to remove if non-absorbable material used
<i>Continuous</i> sutures consist of a continuous over-and-over suture that forms a spiral within the tissues	Quick to perform with knots placed only at the beginning and end of the suture line. Easy to remove	The whole suture line may unravel if there is weakness or breakage anywhere along it. Difficult to drain localized subcutaneous collections by opening part of a wound, therefore interrupted sutures are preferable for wounds particularly at risk of infection
<i>Subcuticular</i> sutures are continuous or interrupted sutures placed in the dermis, with each bite placed horizontally in the dermal layer	This technique avoids suture marks on the skin so can be very neat and thus is popular in skin closure. Easy to remove	If continuous, the same disadvantages apply as above. If the sutures are not placed at the correct depth on each side of the wound, a 'step' can occur, resulting in poor cosmesis and delayed healing
Adhesive skin closure strips	No local anaesthetic required and tissue damage is minimal Strips are cheap and simple to apply and remove	Only suitable for clean wounds as lack of local anaesthesia may reduce ability to thoroughly cleanse wound and remove all foreign bodies Shear forces may cause blistering of the skin Oedema at the site may cause taped wound edges to invert, causing delayed healing
Tissue adhesive	No local anaesthetic required and tissue damage is minimal Rapidly produces a strong flexible bond Sloughs off as skin re-epithelializes, producing good cosmetic results Less painful than suturing No statistically significant difference from suturing for infection and patient satisfaction (Coulthard et al. 2004)	Only suitable for clean wounds as lack of local anaesthesia may reduce ability to thoroughly cleanse wound and remove all foreign bodies Requires a second person to assist in getting skin edges accurately aligned Not suitable over joints, areas of excessive tension or wounds on the eyes, mouth or scalp Care must be taken to avoid any contact with the open wound as adhesive in the wound will create a barrier to healing Sutured wounds were less likely to dehisce (Coulthard et al. 2004)
Skin clips	Can be used on many types of surgical incisions Reduce operating time and tissue trauma Produce excellent cosmetic results when correctly applied Produce uniform tension along the suture line and less distortion from the stress of individual suture points	Clips are more expensive than sutures Must be inserted by an experienced practitioner Failure to align tissue edges may cause scar deformity An extractor is required for clip removal

Source: Adapted from Kirk (2010), Tulloh and Lee (2007).

Table 15.6 Common suturing errors

Error	Resulting problems
Sutures too loose	Fails to bring wound edges together, leading to gaping, poor healing and poor cosmetic outcomes Sutures may fall out
Sutures too tight	Tissues tend to swell with oedema fluid in the first few hours after suturing. Does not allow for normal wound swelling. This may cause the tissues bound up within the suture line to strangulate and necrose with subsequent wound breakdown. Care must be taken to allow for this by gently apposing the tissues, ensuring sutures are neither too loose nor too tight May induce vascular compromise of the wound edges leading to necrosis. May lead to the stitch breaking, delayed healing, poor cosmetic results
Uneven tension on interrupted sutures	The tightest suture is exposed to excess tension and may give way
Sutures spaced too widely apart	Gaping between adjacent sutures leading to poor healing
Wound edge overlapping	The resultant 'step' caused by the overlap is likely to delay healing and produce a more obvious scar
Sutures too near the wound edge	These are likely to pull out
Traumatic tissue handling	Tissue handling (e.g. with forceps) should be gentle to preserve tissue integrity and blood supply, thereby promoting healing

Source: Adapted from Kirk (2010), Tulloh and Lee (2007).

956

Before closing the wound by any method, the wound must be thoroughly cleansed to minimize the risk of wound infection and ensure that any dirt or foreign bodies are removed (Reynolds and Cole 2006). Dirty wounds should be thoroughly cleansed with irrigation of sterile 0.9% sodium chloride using a large syringe until cleared of visible debris (Giddings 2013).

The wound area needs to be prepared by administering local anaesthetic and as a result suturing is more painful and takes longer than other methods of wound closure (Reynolds and Cole 2006). Prophylactic antibiotics are not indicated after a simple laceration repair but should be given in cases of probable contamination, i.e. dirty wounds (Jain 2013).

Procedure guideline 15.2 Suturing a simple wound

Essential equipment

- Plastic apron
- Sterile gloves
- Electric clippers with disposable head
- Suture pack (containing needle holder, tissue forceps, dressing forceps, scissors, low-linting swabs, solution pot)
- Traceability form

- Sutures in varying gauges and materials
- 10 mL syringe and needles (21 and 25 G)
- Dressing

Medicinal products

- Local anaesthetic (1% lidocaine hydrochloride)
- Sterile 0.9% sodium chloride solution

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Follow the procedure for aseptic technique, i.e. use of a trolley, clean hands, apply apron and gloves.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To reduce the risk of contamination (Fraise and Bradley 2009, **E**).

Procedure

- 3 Using a bright light, assess the wound, clean if necessary and decide the type of material and gauge of needle to use.
- 4 The skin surrounding the wound may require clipping to remove hair. This should be performed using electric clippers with disposable head immediately prior to the procedure.
- 5 Draw up the local anaesthetic and first administer an intracutaneous bleb, using a fine needle. Wait for this to take effect then inject the remainder through the anaesthetized area, infiltrating deeper using a longer, larger needle. Keep the point moving as you inject to ensure the needle is not in a vessel.
- 6 Wait a minimum of 4–5 minutes and test the area gently with a needle tip or instrument prior to beginning. Do not begin the procedure until the anaesthetic has had time to act.

- To ensure that the wound is closed using most appropriate material to promote healing (Reynolds and Cole 2006, **E**).
- To prevent hairs from becoming trapped in the closed wound. Clipping has been demonstrated to cause significantly fewer surgical site infections than shaving and is the only method of perioperative hair removal recommended (Tanner et al. 2006, **E**).
- To reduce pain during the procedure **E**.
- Inadvertent injection of local anaesthetic into a blood vessel can result in local anaesthetic toxicity. Signs and symptoms are dose related and can include metallic taste, tinnitus and circumoral numbness, progressing to seizures and cardiac arrest (Rothrock 2011, **E**).
- Beginning the procedure before the wound is fully anaesthetized will cause pain and undermine the confidence and trust of the patient (Kirk 2010, **E**).

7 Select appropriate tissue forceps, needle and needle holder.	In readiness to perform the procedure. E
8 The needle should be grasped in the needle holder on its flattened area about a third of the way along from the suture material (Action figure 8).	To prepare the suture material for use. Holding it where the needle is flat in cross-section will prevent it from rotating in the jaws of the needle holder and enable good control (Tulloh and Lee 2007, E).
9 The needle holder should be held in the dominant hand and support the wound edge with the closed tips of tissue forceps.	To facilitate control of the equipment and to promote accurate tissue apposition. Tissue approximation should err on the side of slight eversion (an outward turning) and avoid inversion (an inward turning) or overlapping (Tulloh and Lee 2007, E).
10 If a linear wound, suturing should begin at the centre.	To evenly distribute the tissue and promote accurate apposition (Kirk 2010, E).
11 The needle should be inserted at a 90° angle to the skin and traverse the full thickness of the wound. The distance of the needle puncture from the edge of the wound should be equal to the depth of the layer of tissue being sutured (Action figure 11).	To create secure tension-free apposition of the wound edges (Giddings 2013, E ; Jain 2013, E). To ensure that the correct tension of the sutures as this can affect healing and cosmetic appearance (Hampton and Collins 2004, E) with inflammation occurring when they are too tight (leading to devitalized tissue (Reynolds and Cole 2006, E). If too loose, the scar will not align and hold the wound edges in apposition (Clark 2004, E ; Reynolds and Cole 2006, E). See Table 15.6 for common suturing errors.
NB: This does not apply to deep wounds where layered closure is required.	
12 Bring the needle up in between the wound edges (Action figure 12).	To allow visualization of the depth of bite and enable matching of this on each side of the wound (Tulloh and Lee 2007, E).
13 Pull the suture through the tissue until a short tail of approximately 2 cm remains at the initial skin entry site.	To ensure there is enough suture to use for knot tying (Giddings 2013, E).
14 Reinsert the needle at a 90° angle from the base of the wound on the other side and push the suture through the tissue, following the curve of the needle, so as to emerge perpendicular to the skin (Action figure 14).	To bring the wound edges together and promote accurate apposition. If the tissues are not pierced perpendicular to the upper and lower surfaces of the wound, an inverted or everted effect will result (Kirk 2010, E).
15 Hold the needle parallel to the skin and, grasping the needle end of the suture, make two clockwise loops around the needle holder to produce a surgeon's knot (Action figure 15).	To begin to create a knot (Giddings 2013, E).
16 Grasp the tail of the suture with the needle holder. The wrapped suture will slide off the holder to encircle the tail (Action figure 16).	To 'set a throw' (Giddings 2013, E).
17 Pull the tail end of the suture toward you and the long suture strand away from you, making sure the suture lies flat.	To 'tighten the throw' (Giddings 2013, E).
18 Follow this by a single anticlockwise loop around the needle holder and move the needle to the opposite side of the wound (Action figure 18).	To square the knot (Giddings 2013, E).
19 Then create a third throw of one loop. Do not tie it too tightly, just sufficient to secure the knot, thus approximating wound edges without constriction (Action figure 19).	Sutures tied too tightly may cause tissue necrosis, delayed healing and increased scarring (Jain 2013, E).
20 The suture can then be cut free from the knot, leaving tails of about 5 mm (Action figure 20).	If the tails are left too long they may entangle with the next suture. If they are too short there is a risk of knot slippage and they will also be difficult to remove (Jain 2013, E).
21 Insert each suture in the same way until the wound is entirely closed. The distance between adjacent sutures should be about the same as the depth and width of each one.	To close the wound securely with even spacing and no gaping between adjacent sutures (Tulloh and Lee 2007, E).
22 Once completed, discard needle in sharps bin.	To prevent potential sharps injury (Hughes and Mardell 2009). E
Post-procedure	
23 Clean any blood from the surrounding area using aseptic technique and sterile saline solution of 0.9% sodium chloride.	To prevent any possible wound infection (Fraise and Bradley 2009, E).
24 Apply a suitable dressing.	To protect the wound from further trauma or contamination and ensure optimum healing (Fraise and Bradley 2009, E).
25 Record the date, time and name of the practitioner, amount of local anaesthetic used and size and type of suture material and number of sutures on the appropriate charts.	To maintain accurate records and provide a point of reference in the event of any queries (NMC 2010, C ; Reynolds and Cole 2006, E).

(continued)

Procedure guideline 15.2 Suturing a simple wound (continued)

Action	Rationale
26 Provide the patient with written and verbal advice regarding wound care and when the sutures should be removed.	To ensure optimum care for the wound and correct removal time. Premature suture removal may lead to wound dehiscence and sutures kept in too long cause excessive scarring (Weinzweig 2010, E).

Action Figure 8 Grasp the needle.

Action Figure 11 Insert the needle at a 90° angle.

Action Figure 12 Bring the needle up between the wound edges.

Action Figure 14 Reinsert the needle on the other side.

Action Figure 15 Make two clockwise loops.

Action Figure 16 Grasp the tail of the suture with the needle holder.

Action Figure 18 (a) Loop the suture around the needle holder. (b) Move the needle to the opposite side of the wound.

Action Figure 19 (a) Tying the knot to approximate the edges of the wound. (b) Tying the knot to approximate the edges of the wound.

Action Figure 20 The suture can be freed from the knot.

Post-procedural considerations

On completion of suturing, a dressing should be applied. The nurse should then document the following: how many sutures were inserted, type of material, and when they should be removed (NMC 2010).

Removal of sutures or clips

Evidence-based approaches

Rationale

Removal of sutures is usually performed between 7 and 10 days post insertion, but this is dependent on where the wound is

and whether it has healed. Routinely, every other suture or clip is removed first, with the rest removed if the incision remains securely closed. If any sign of suture line separation is evident during the removal process, the remaining sutures should be left in place and reported to the medical team (Pudner 2005).

Pre-procedural considerations

Assess the wound, as the time period for removal of sutures depends upon the patient's underlying pathology, condition of their skin and the wound position (Pudner 2005). Surgical notes and instructions should also be taken into account along with the skills of the practitioner (NMC 2010). Analgesia may be offered depending on the patient and wound site.

Procedure guideline 15.3 Suture removal

Essential equipment

- Sterile dressing pack containing gallipots or an indented plastic tray, low-linting swabs and/or medical foam, disposable forceps, gloves, sterile field, disposable bag
- Apron
- Fluids for cleaning and/or irrigation
- Hypoallergenic tape
- Appropriate dressing
- Appropriate hand hygiene preparation
- Any other material will be determined by the nature of the dressing; special features of a dressing should be referred to in the patient's nursing care plan
- Detergent wipe for cleaning trolley
- Total traceability system for surgical instruments and patient record form

Optional equipment

- Any extra equipment that may be needed during procedure, for example sterile scissors, stitch cutter, staple remover, sterile adhesive sutures

Pre-procedure

Action

- 1 Explain and discuss the procedure with the patient.
- 2 Perform procedure using aseptic technique, i.e. use of a trolley, clean hands, apply apron and gloves.

Rationale

- To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, **C**).
- To prevent infection (Fraise and Bradley 2009, **E**).

Procedure

- 3 Clean the wound with an appropriate sterile solution such as 0.9% sodium chloride.
- 4 Lift knot of suture with metal forceps.
- 5 Using stitch cutter or scissors, snip stitch close to the skin. Pull suture out gently towards the side that has been cut. For intermittent sutures, alternate sutures should be removed first before remaining sutures are removed.
- 6 Use tips of scissors slightly open or the side of the stitch cutter to gently press the skin when the suture is being drawn out. Continue until all the sutures are removed as required.
- 7 Apply a suitable dressing.

- To prevent infection (Fraise and Bradley 2009, **E**).
- Plastic forceps tend to slip against nylon sutures. **E**
- To prevent infection by drawing exposed suture through the tissue (Pudner 2005, **E**).
- To ensure wound closure and predict dehiscence (Pudner 2005, **E**).

- To minimize pain by counteracting the adhesion between the suture and surrounding tissue. **E**

- To protect the wound from further trauma or contamination and ensure optimum healing (Fraise and Bradley 2009, **E**).

Post-procedure

- 8 Dispose of waste in orange plastic clinical waste bags and sharps into a sharps bin. Remove gloves and wash hands.
- 9 Record condition of suture line and surrounding skin (amount of exudate, pus, inflammation, pain, and so on).

- To prevent environmental contamination and sharps injury. Orange is the recognized colour for clinical waste (DH 2005, **C**).
- To document care and enable evaluation of the wound (Bale and Jones 2006, **E**; Dealey 2005, **E**; NMC 2010, **C**).

Procedure guideline 15.4 Clip removal

Essential equipment

- Sterile dressing pack containing gallipots or an indented plastic tray, low-linting swabs and/or medical foam, disposable forceps, gloves, sterile field, disposable bag
- Fluids for cleaning and/or irrigation
- Hypoallergenic tape
- Appropriate dressing
- Appropriate hand hygiene preparation
- Any other material will be determined by the nature of the dressing; special features of a dressing should be referred to in the patient's nursing care plan
- Detergent wipe for cleaning trolley
- Total traceability system for surgical instruments and patient record form

Optional equipment

- Any extra equipment that may be needed during procedure, for example sterile scissors, stitch cutter, clip remover, sterile adhesive sutures

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient and gain their consent.	To ensure that the patient understands the procedure and gives their valid consent (NMC 2013, C).
2 Perform procedure using aseptic technique, i.e. use of a trolley, clean hands, apply apron and gloves	To prevent infection (Fraise and Bradley 2009, E).

Procedure

3 Clean the wound with an appropriate sterile solution such as 0.9% sodium chloride.	To prevent infection (Fraise and Bradley 2009, E).
4 If the suture line is under tension, use free hand to gently guide the skin either side of the surgical incision line.	To reduce tension of skin around suture line and lessen pain on removal of clip. E
5 Slide the lower bar of the clip remover with the V-shaped groove under the clip at an angle of 90°. Squeeze the handles of the clip removers together to open the clip.	To release the clip atraumatically from the wound. If the angle of the clip remover is not correct, the clip will not come out freely (Pudner 2005, E).
6 Continue till all clips are removed.	Clips should all be removed at the earliest possible point to avoid marks from the clips along the suture line (Widgerow 2013, E).
7 Apply a suitable dressing.	To protect the wound from further trauma or contamination and ensure optimum healing (Fraise and Bradley 2009, E).

Post-procedure

8 Dispose of waste in orange plastic clinical waste bags and sharps into a sharps bin. Remove gloves and wash hands.	To prevent environmental contamination and sharps injury. Orange is the recognized colour for clinical waste (DH 2005, C).
9 Record condition of suture line and surrounding skin (amount of exudate, pus, inflammation, pain, etc.).	To document care and enable evaluation of the wound (Bale and Jones 2006, E ; Dealey 2005, E ; NMC 2010, C).

Plastic surgery

Definition

Plastic surgery is the process of reconstructing or repairing parts of the body by the transfer of tissue, to restore normal functional ability and aesthetic form. This may be following trauma, disease or congenital malformations (Storch and Rice 2005). This is achieved by using flaps and skin grafts for reconstruction purposes, in addition to using the natural elasticity and mobility of the skin. Surgical reconstruction is often required following extensive surgery for cancer, trauma or congenital abnormalities.

There are several reconstructive options available, ranging in complexity from split-skin graft, full-thickness skin graft, local tissue transfer, distant tissue transfer to free flap-based reconstruction. This initial philosophy of reconstruction was of a

'reconstructive ladder' whereby the simplest procedure was performed first, and where this was not possible, to proceed up the ladder in a step-wise approach to the next most complex. This philosophy has now given way to a reconstructive menu or toolbox approach where the optimal procedure for the individual patient is selected, and a more complex procedure may be the first choice if this is likely to produce a better overall outcome (Giele and Cassell 2008).

Related theory

A surgical flap is a strip of tissue, usually consisting of skin, underlying fat, fascia, muscle and/or bone, which is transferred from one part of the body (known as the donor site) to another (known as the recipient site) (Storch and Rice 2005).

A skin graft is living but devascularized (separated from its blood supply) tissue consisting of all or some of the layers of the

skin which is removed from one area of the body and applied to a wound on another area of the body. The common methods of skin grafting are full-thickness skin grafts (FTSG), in which the entire epidermis and dermis is removed, and split-thickness or split-skin graft (SSG), which consists of the epidermis and the upper part of the dermis only (Giele and Cassell 2008).

Evidence-based approaches

Principles of care

Each patient will require individually planned, and therefore unique, surgery. Reconstructive surgery of this type often results in altered anatomy, in both appearance and function, which may affect the psychological and physical well-being of the patient. Pre-operative patient assessment must be as detailed as possible; this should include information on past and present medical conditions that may delay wound healing.

The complexity of the surgery will often require intensive nursing care. Post-operative observation of the wound sites, flap, dressings and drains is crucial as deterioration of a wound can occur suddenly, necessitating the need for prompt nursing action and/or surgical intervention. The main aim following flap reconstruction is to ensure easy access for observation so that monitoring can be carried out effectively and efficiently during the crucial first 72 hours. Figure 15.11 shows a flap observation chart. These should adhere to medical notes and instructions as per patient. The principles are clarified in the procedure guidelines (e.g. change of wound dressing, removal of drains).

Negative pressure wound therapy

Definition

Negative pressure wound therapy (NPWT), previously known as topical negative pressure (TNP), is the application of a controlled negative pressure across the wound bed to promote healing (Ubbink et al. 2008). The benefits of NPWT include the management of exudate, reduction of wound odour and an increase in local blood flow in the periwound area, a reduction in the number of dressing changes required and an improvement in quality of life (Milne 2013, Ubbink et al. 2008).

Evidence-based approaches

Rationale

Negative pressure wound therapy optimizes wound healing by stimulating granulation in an enhanced well-vascularized wound bed. It creates a moist wound environment and removes exudate from the wound (KCI 2007) whilst protecting from outside contaminants and potentially reducing wound bioburden (Smith and Nephew 2011). The interstitial fluid that mechanically compromises healing is gently removed whilst the capillary circulation is increased (Ubbink et al. 2008). Pressures are set dependent on the wound aetiology and patient tolerance (Henderson et al. 2010). The suction can be set on continuous or intermittent according to the therapy required (Benbow 2005). Continuous therapy can be used for high-volume wounds, and

Name: Hospital No: Ward:.....														 THE ROYAL MARSDEN	
Flap Observation Chart															
Instructions				Criteria for Assessment									Normal	Arterial Insufficiency	Venous Congestion
1. Confirm with the surgeon the frequency of flap observations (see medical notes / nursing care plan) Suggested immediate post-op assessment frequency: <ul style="list-style-type: none"> every 15 minutes for first 4 hours, every 30 minutes for the next 4 hours, hourly for 24–36 hours, then 2–4 hourly thereafter 2. If signs of venous or arterial occlusion seek immediate help 3. At each handover, confirm flap status/observations at the bedside				Colour <ul style="list-style-type: none"> If it is an external flap then check with the donor site for original colour If it is an internal flap then monitor for extremes of colour 									Usual skin tone	Paler than usual skin tone	Blue / Purple / Mottled
				Temperature <ul style="list-style-type: none"> An external or internal flap should always feel warm to touch If the flap feels cool or has increased warmth, seek medical assessment immediately A warmer flap may be due to an abnormal inflammatory response, e.g. infection 									Warm	Cold	Increased warmth
				Turgidity (Texture) <ul style="list-style-type: none"> The flap should usually feel soft (spongy), not hard or flaccid Hard or swollen flap indicates possible oedema or haematoma 									Soft	Flaccid	Turgid (hard)
				Capillary Refill (Blanching) <ul style="list-style-type: none"> If possible this should be timed (in seconds) If timing not possible and an alteration in perfusion is suspected, seek medical assessment immediately 									2–3 seconds	Absent / Sluggish > 6 seconds	Brisk < 3 seconds
				Specific Monitoring Instructions (e.g. Monitor the tension on the flap and check for kinking)											
Type & Location of Flap: Donor Area (if appropriate):															
Timing		Colour (tick one)			Temperature (tick one)			Turgidity (Texture) (tick one)			Capillary Refill (Blanching) (tick one)			Specific Instructions (specify):	Signature and Print Name
Date	Time	Usual skin tone	Paler than usual skin tone	Blue / purple / mottled	Warm	Cold	Increased warmth	Soft	Flaccid	Turgid (hard)	2–3 seconds	Absent / sluggish > 6 seconds	Brisk < 3 seconds		

Figure 15.11 Flap observation chart.

is recommended for use over unstable structures to minimize movement and help to stabilize the wound bed, when used on flaps and grafts and for patients with a high risk of bleeding (Smith and Nephew 2011). Intermittent therapy stimulates more granulation tissue and improves the rate of healing, and can be used on any wounds other than those with high exudate (Milne 2013). It has proven to be cost-efficient, safe and effective as a treatment modality for wound care (KCI 2007).

The benefits to chronic wound healing of using NPWT versus other treatments have been shown in a number of clinical trials, but further research is needed with fewer methodological flaws and clearer reporting of infection rates and length of hospital stay (NICE 2009, Ubbink et al. 2008).

Indications

Negative pressure wound therapy is indicated for:

- chronic wounds, e.g. venous insufficiency and pressure ulcers
- diabetic and neuropathic ulcers
- post-operative and dehisced surgical wounds
- partial-thickness burns
- skin flaps and grafts
- traumatic wounds
- explored fistulae (Milne 2013, Smith and Nephew 2011).

Contraindications

Negative pressure wound therapy is contraindicated in:

- grossly contaminated wounds
- malignant wounds due to the potential to stimulate proliferation of malignant cells (with the exception of palliative care to improve quality of life)
- untreated osteomyelitis
- non-enteric and unexplored fistulae (KCI 2007)
- the force of the negative pressure can damage or rupture vessels if used over anastomotic sites or organs, exposed vasculature or nerves (Benbow 2005, Henderson et al. 2010)
- wounds with necrotic tissue with eschar present or thick slough will require debridement prior to the application of NPWT (Henderson et al. 2010). (See individual company precautions for use of NPWT systems.)

Precautions should be exercised when there is active bleeding in the wound, difficult haemostasis or when the patient is taking anticoagulants (Benbow 2005), on spinal cord injury, vascular anastomoses and wounds with sharp edges such as bone fragments (Henderson et al. 2010). The wound site must be carefully assessed to ensure that NPWT is indeed the appropriate treatment modality. If signs of infection or complications develop, the therapy should be discontinued (KCI 2007). There is currently not enough evidence to recommend NPWT for open abdominal wounds (NICE 2009). See Figure 15.12 and Figure 15.13 for examples of NPWT.

Pre-procedural considerations

Consulting the appropriate company representative for training is essential as application and approaches are individually determined and companies have their own comprehensive clinical guidelines. There are specific types of foams and gauze dressings which should be used in undermined wounds, tunnels or sinus tracts. See the list of websites at the end of the chapter for contact details. If the patient is discharged into the community with NPWT, consideration should be given to the management of the dressings, the patient's mobility, risk of falls and psychological capability to cope with the therapy (Milne 2013).

Equipment

All equipment used should be the manufacturer's recommended materials for the relevant system (KCI 2007).

Figure 15.12 Negative pressure wound therapy: dressing.

Figure 15.13 Negative pressure wound therapy: pump.

Procedure guideline 15.5 Negative pressure wound therapy

Essential equipment

- NPWT unit
- NPWT dressing pack; foam or gauze
- NPWT canister and tubing
- Forceps
- Sterile scissors
- Sterile gloves
- Apron
- Dressing procedure pack
- Sterile 0.9% sodium chloride for irrigation (warmed to approx. 37°C in a jug of warm water)

Optional equipment

- Extra semi-permeable film dressings to seal any leaks
- Non-adherent wound contact layer to prevent foam adhering to wound bed
- Alcohol-free skin barrier film to protect any fragile or macerated skin around the wound or thin hydrocolloid to protect peri-wound area

Pre-procedure

Action	Rationale
1 Explain and discuss the procedure with the patient and gain their consent.	To ensure the patient understands the procedure and other options available and gives their valid consent (NMC 2013, C).
2 Provide routine analgesia prior to dressing procedure.	To prevent unnecessary procedural pain. E
3 Ensure there is adequate lighting and the patient is comfortable and in a position where the wound can be accessed and viewed easily. Assemble all necessary equipment.	To allow access to area for dressing change. Dressing application can be complicated and prolonged so the patient should be in a comfortable position for the procedure. E

Procedure

4 Use aseptic technique and sterile equipment (as listed above). See Figure 15.12 and Figure 15.13.	To prevent infection (Fraise and Bradley 2009, E ; Pudner 2005, E).
5 To remove the NPWT dressing, put on a pair of non-sterile gloves.	To reduce the risk of cross-infection (Pudner 2005, E).
6 Clamp the dressing tubing and disconnect it from the canister tubing. Allow any fluid in the canister tubing to be sucked into the canister. Switch off the pump and clamp the canister tubing.	To prevent spillage of body fluid waste from the tubing or canister. E
7 Remove and discard the canister (if full or at least weekly).	To prevent pump alarming and for infection control. E
8 Carefully remove the occlusive film drape by gently lifting one edge and then stretching the drape horizontally and slowly remove from the skin.	To prevent damage to the periwound skin. E
9 Carefully remove the wound filler.	To prevent damage to newly formed tissue within the wound bed and prevent pain. E
10 Irrigate with sterile 0.9% sodium chloride if indicated.	To prevent infection and remove surface debris/necrotic tissue (Dealey 2005, E).
11 Debride the wound if applicable.	To remove loose necrotic tissue that may be a focus for infection (Vowden and Vowden 2002, E).
12 To apply the dressing, cut the NPWT foam to fit the size and shape of the wound. Appropriate foam or gauze should be used if tunnelling and undermined areas are present.	The foam should fit the wound exactly to ensure full benefit of the negative pressure therapy. E
13 Avoid cutting the foam over the wound bed.	To prevent loose particles of foam falling into the wound. E
14 Place the foam into the wound cavity.	The whole wound bed must be covered with foam. If the foam is touching, it will transfer the negative pressure to the next piece. E
15 If the wound bed is friable/granulating and likely to bleed, a non-adherent contact layer may be used under the foam to protect the extracellular matrix (ECM).	The ECM requires a trauma-free dressing removal and, once the exudate subsides, the wound bed may become less moist (Flett et al. 2002, E).
16 Cut the occlusive film drape to size and apply over the top of the foam. The film should extend 5 cm from the wound margin and not be stretched or applied under pressure. (NB: Do not compress the foam into the wound.)	To obtain a good seal around the wound edges. E

17 Choose a location on the sealed occlusive film drape to apply the tubing where the tubing will not rub or cause pressure. Cut a hole through the film (size dependent on system being used), leaving the foam intact.	To reduce the risk of pressure injury to skin. E
18 Align the opening of the port over the hole in the film. Apply gentle pressure to anchor the port to the film.	To ensure correct position and seal of the pad (Smith and Nephew 2011, C).
19 To commence the NPWT, insert the canister into the pump until it clicks into place. (Do not clamp any part of the canister tubing.)	Indicates the canister is positioned correctly and is secure. E The pump will alarm if the tubing is clamped or not connected. E
20 Connect the dressing tubing to the canister tubing.	To complete the circuit set-up. E
21 Press POWER button and follow the on-screen instructions to set the level and type of pressure required according to instructions from the patient's medical/surgical team.	To ensure the therapy is set to the individual requirements of the patient. E
22 When therapy is commenced the foam should collapse into the wound, be firm to touch and have a wrinkled appearance (Smith and Nephew 2011).	Any small air leak will prevent the foam dressing from contracting and reassessment is required. E
Post-procedure	
23 Document the dressings and settings, frequency of changes, wound description and exudate in the patient's notes.	To provide a record of care in the patient's care plan (NMC 2010, C).

Post-procedural considerations

Ongoing care

Careful monitoring of the periwound area for signs of infection, skin breakdown or oedema and checking the equipment whilst *in situ* are imperative to ensure patient safety. The dressings should be changed every 48–72 hours. The NPWT unit should not be switched off for more than 2 hours without the dressing being replaced (KCI 2007).
